CABLE STATIONS.

The announcement a few days ago that the West Coast of Africa is now in direct telegraphic communication with London was perhaps chiefly interesting because of the grateful and loyal address which accompanied it from the inhabitants of that geographical area of which SIERRA LEONE is regarded as the capital. To them the laying of the submarine cable, so long desired, but so little expected, is a fresh proof of "Her Majesty's interest" in the welfare of her settlements, and a new ground for hoping that the "benign influence" of the British Government will be more largely exerted for their development in the future. To us the event is merely an evidence of the growing commercial importance of localities now for the first time connected by telegraph to the Mother Country, and perhaps also of the political interests which have sprung into prominence in those regions during the last two or three years. It is a good stride towards realising that girdle round the Dark Continent which the growth of our African possessions and responsibilities will one day demand. Besides the political objects which this and similar cables in that part of the world are intended to serve, there is little doubt that the expectations of the settlers will not be disappointed in the development of the vast resources of the interior by expediting the means of communication with the manufacturing and commercial centre of the British Empire.

Some particulars with reference to the route and position of the DIRECT AFRICAN CABLE will be found in a letter from an esteemed correspondent which we publish elsewhere, as well as of the WEST AFRICAN—which he calls the pioneer—Company's cables. According to our informant, the first-named Company, which has laid the sections between St. Vincent (Cape de Verd) and St. Thiago, and their branches to Dakar, Conakry, and Bulawa, extend their operations to Bathurst, and will eventually connect the whole of the English ports on what is technically designated the West Coast. The pioneer company is of longer standing, but has hitherto confined its operations to the foreign settlements, though the undertaking is—as usual—an English one, and worked by English operators. Our correspondent, who is not connected in any way with the telegraph service, though he has seen a great deal of it in former years, paid a visit to at least one typical "station" of the WEST AFRICAN Company, and has given us a graphic, if not picturesque, account of what he saw there. Being untrammeled by official responsibility, he speaks his mind freely, and is liberal with suggestions which only an outsider would venture to offer. But we have no reason to doubt the substantial accuracy of his account; on the contrary, we know that it could be matched by descriptions from other parts of the cable-world besides West Africa, though the dangers and hardships may be of a different kind; and as our correspondent has been "roughing it" the best part of his lifetime, he is not the man to have formed a fastidious ideal of the essentials for life and health in foreign climes.

The picture he has drawn of the actual condition of the Bulawa station is instructive from at least two points of view. First, as concerns the servants of the Cable Companies; next, as touching the companies and the public who patronise them. To the general public, a submarine telegraph company is merely an ordinary commercial concern, whose expenditure can be estimated by the common rule of business establishments, and whose charges ought to be regulated on similar principles. Now, setting aside all the risks peculiar to submerged cables, but with which we are not concerned at present, there are the less known, but hardly less serious, risks attending their staffs of operators and superintendents at foreign stations. The hardships they undergo, and the casualties to which they are liable are, judged by ordinary standards, altogether disproportionate to the services they perform, which are neither military in obligation nor governmental in point of honour. Men who voluntarily run such risks without hope of reward or distinction have to be paid handsomely; and unless they are to be speedily swept away by epidemic or something worse, which of itself would be a new charge upon their employers who must train and transport fresh men to fill the vacant places, these valuable lives must be cared for, must be shifted about periodically, and must have long leave of absence at not infrequent intervals. In short, the expense of maintaining a thoroughly efficient staff abroad, especially at isolated stations, and affording the necessary relief and relaxation, is far greater than the public suppose, and must always be taken into account when criticising the income and charges of Submarine Cable Companies.

In the long run it will pay the companies to remunerate their servants liberally. Even at Bulawa there are no complaints on that score. But something more than pay is needed, something without which high wages are simply thrown away. From the early days of deep sea cable enterprise this fact has been recognised by shipping out to the expatriated and disconsolate bands of telegraphists such luxuries as billiard tables, cricket utensils, and a good stock of books, with most excellent results. Rates were not then what they are now, and the best we can say to those who possess such treasures is "take great care of them." We have hinted at something worse than epidemic; and there are, indeed, ailments bred of solitariness and *ennui* such as overtake the Queensland shepherd, to escape from which the deadly grip of a Gold Coast fever would be a merciful visitation. Next to recreation and social companionship, locality is of most importance. It has always been a

Digitized by Google

difficulty to hit upon a spot for the "station" which shall be at once healthy and handy. Handiness has in reality been the first consideration, though with a few such experiences like that described by our correspondent in the mangrove swamps off Cape Coast it ought soon to be quite secondary. Not where men can survive for a time, but where they can live in moderate comfort and maintain enough vitality to be relied upon for a considerable portion of the year, is the truly economic as well as the most humane thing to be discovered. In its way Bulawa is a sample of "stations" both East and West which are by no means exceptional. There is not much to choose between the fogs of Newfoundland, the simoons of Arabia, and the miasma of Sierra Leone.

We cannot leave this subject without a tribute of admiration to the brave men whom the Cable companies are proud to claim as their servants all over the world. Bulawa furnishes us with a type of *employé* more common, it is to be hoped, than the station at which a patient, dutiful and almost solitary life is being spent without complaint and with no thought of desertion. Englishmen have peopled and almost subdued the world by their physical capacity for adapting themselves to every climate; but none the less are those heroic qualities deserving of the highest praise which keep men at their posts under such trying circumstances as almost everywhere prevail where cables are landed on distant and foreign shores. It is greatly to be hoped that neither the pressure of competition nor the clamour of an unthinking public at home will so far impoverish the cable companies as to tempt them to overlook the well-being of their devoted servants abroad.

HEATING FOOT-WARMERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue attention is called to "an improvement in the plan for heating foot-warmers for railway carriages," stated to have been introduced by Mr. Tomasi, by causing a current of electricity to produce an increase of temperature in a solution of acetate of soda.

The heating of trains by electricity has, without doubt, a great future, and the various modes of carrying it out are of general interest. You may therefore consider it right to call attention to the fact that the mode alluded to *as novel* was fully described by me in 1883 in my patent (also published in France) for apparatus for electrical heating, No. 4,961, fol. 3, lines 44-46:—"Apparatus constructed as described may be employed for heating purposes generally; for example, it may be used to heat reservoirs or holders of water or of chemical salts—such, for example, as may be used for foot-warmers for railways." Acetate of soda was at that time well known as a suitable chemical salt for retaining heat for foot-warmers.—Yours, &c., JOHN S. SELLON.

The Hall, Sydenham, July 28, 1866.

AN EXPLANATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We note that in your issue of the 23rd inst. you mentioned that we are supplying two 80v. 500 amp. machines for the Prudential Assurance Company. Although we believe these machines are for the company above mentioned, yet we are supplying them to the Electrical Power Storage Company, who are the contractors for carrying out the installation. We shall be obliged if you will kindly insert this correction in your next week's issue.—Yours, &c., R. E. CROMPTON & Co.

London, E.C., 27th July, 1886.

INFORMATION WANTED.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There is an important error in my letter under the above heading, as printed in last week's issue. The third line should read "Optician to *His* Majesty," as I have reason to believe the machine is quite 100 years old, if not more.—Yours, &c., T. H.

July 24, 1886.

MAGNETIC RESEARCHES.

BY PROF. G. WIEDEMANN.

(*Concluded from page 219.*)

From the preceding we may assume that in the action of any torsional forces (which may also be zero), the molecules are displaced and rotated in accordance with the deformation produced by these forces, and afterwards, upon the action of other forces, pass from their first positions of equilibrium into others, which, however, are conditioned by the first. If, then, the molecules are greatly displaced and rotated by a more powerful torsion, they still partially retain this displacement and rotation upon the action of a feebler force; whilst, conversely, upon changing from a feebler to a stronger torsional force, the latter is unable to produce so great a displacement and rotation of the molecules which lie nearer their neutral position.

A similar behaviour in the case of wires is shown by an experiment of H. Tomlinson's*, in which, however, only small differences were observed between loading and unloading.

VI. The behaviour of iron bars in temporary magnetisation, by increasing and decreasing forces, is exactly similar to the mechanical behaviour here described. Messrs. Righi, Fromme, and Warburg have shown that if an iron bar is successively magnetised by forces a, b, c, b, a, of which $a<b<c$, the temporary moment M'_b, corresponding to the force b with decreasing magnetisation, is greater than the temporary moment M_b, corresponding to the same force with increasing magnetisation. Warburg has ingeniously deduced from this the behaviour of a magnetic needle vibrating above an iron plate.

In order to investigate whether this phenomenon occurs only with the first increasing and decreasing magnetisations of the bars, or whether it occurs also after they have attained a permanent condition after repeated action of the magnetising forces, the following experiments were made, in which freshly heated iron bars were magnetised by currents passed round them in such a way that their intensity could be gradually increased up to a certain magnitude and then gradually reduced to zero, so avoiding the influence of all disturbing induction-currents.

For this purpose a special regulating Bunsen's element was employed (Fig. 11). It consisted of a porcelain cylinder

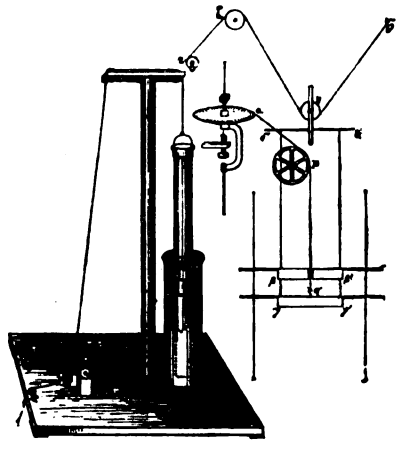

FIG. 11.

36 centim. high and 10 centim. wide, on the bottom of which was cemented a second concentric porcelain cylinder closed at the top, 25 centim. high and 5 centim. wide. This supported

* *Phil. Trans.* Roy. Soc. Lond., 1883, Part I. p. 10 (Exp. V.). Tomlinson, in his experiments, put on the weights by hand without observing irregularities; it seems to me that in the method now described, which was used by me in 1858, better security against accidents is obtained.

Digitized by Google

a porous cell 10 centim. high and 5 centim. wide, in which was contained a Bunsen carbon-cylinder provided with a connecting wire, and was filled with nitric acid. It was surrounded by a cylinder of amalgamated zinc 10 centim. high and 9 centim. wide, which was suspended by means of strips of zinc soldered to it from the edges of the outer porcelain cylinder, which contained dilute sulphuric acid. A glass tube 40 centim. long closely surrounded the porous cell and its support, and could be raised or lowered by means of a cord attached to it, which passed over a pulley to a roller and handle. A brass band stretched by a weight pressed against the roller and held it firmly in any position. By this arrangement the current could be increased from nearly zero up to a considerable strength. Of course the same arrangement might be employed as a Daniell cell*.

The current from this cell was passed through a copper-wire spiral 25 centim. long, 2·7 centim. internal diameter, and 7 centim. external diameter, lying horizontally magnetic east and west, 50 centim. distant from the steel mirror of the reflecting galvanometer. The deviation thus produced was compensated by means of the vertical copper ring placed in front of the mirror. A freshly heated bar of soft cast steel, 24 centim. long and 1 centim. thick, was fixed in the spiral, and its momentum determined from the deflection of the mirror. The corresponding intensity of the current was determined as before, by turning down the ring. In order, further, to be able to adjust the current during the temporary magnetisation of the bar to any desired strength, the ends of the spiral were connected, in particular cases, with the quadrants of a Mascart electrometer, the needle of which was charged from a battery of 100 copper-water-zinc elements. Its deflection was read by means of a telescope and scale distant one metre from the mirror attached to the needle.

In the following Tables E denotes the deflection of the needle of the electrometer, M the temporary moment of the magnet, I the intensity of the current measured by lowering the ring.

In the first series of experiments the iron bar was repeatedly magnetised by currents which in each case rose to a definite maximum intensity determined by the electrometer, and were then reduced to zero. The permanent moment was determined in each case after complete cessation of the current (E = 0). The results obtained were as follows :—

(1) E	5	13	13	17	23	17	12·8	9·5	6	0
M	55·5	—	61	157	379	323	278	231	177	99
(2) E	5·5	9	13·2	18	23·5	17·7	12·7	9	5·8	0
M	146	184·6	230·2	291·3	381	323	269	228	184	109·5
(3) E	5·8	9	13	18	23·2	16·7	13	9	5·8	0
M	155	190·6	234·5	301·2	381	309	270·5	228·2	185	113
(4) E	5·8	8·9	13	18	25	17 5	13	9	5·8	0
M	159 2	190	236	296	394·2	322·2	272	229·8	187·5	116·2

and after *ten* similar magnetisations,

(15) E	5·8	9	13	17	23	16·5	13	9	5·8	0
M	173	206	249·3	303	380·5	319	281·5	237·6	194·2	126·2

In another series of experiments a fresh iron bar was repeatedly magnetised to the same temporary maximum moment M_l; then the intensity of the current was decreased to zero, and the permanent moment M read off after complete cessation of the current.

Thus :—

	1.	2.	3.	4.	5.	10.
M_l	320	320	320	320	320	320
m	90	94	96	97	97·5	98·5

and the temporary moment M after the eleventh magnetisation :—

I.....	14	20·7	27	34	42·5	52·2	62	71
M....	137	157 5	176	200	226	258	294	317
I.....	60·8	45·5	36·7	27	21·3	15·8	14	—
M....	292·2	254·5	225·6	199	176	155·2	150	—

It follows from these observations that even after an iron bar, by repeated temporary magnetisation, either to the same maximum of temporary magnetism, or by currents which always attain the same maximum of intensity, has attained a permanent condition, the temporary moment corresponding to a given magnetising force is always greater with decreasing forces than with increasing forces.

Here, also, there prevails then a complete analogy to the mechanical behaviour under torsion produced by increasing and decreasing torsional forces.

VII. The gradual accommodation of the molecules upon repeated torsion within certain limits, described in the foregoing pages, as recognised by magnetic behaviour, in which the deflections with the same torsion increase at first, agrees with the result of my former experiments, that the permanent torsions of a wire, upon repeated temporary twistings of the same up to a certain limit, and also in the same way upon repeated action of the same torsional force, increases gradually up to a maximum. This behaviour shows clearly that the molecules in the deformed wire are only carried gradually from the position of equilibrium corresponding to the zero into that which corresponds to the deformation. The same holds good of the action of magnetic forces tending to rotate the molecules. Here, also, as the second Table, Section 6, shows, the permanent moment increases gradually up to a certain maximum, upon repeated temporary magnetisation up to a certain limit.

In the same way, as the above experiments show, an iron bar only attains, after the repeated action of a given magnetising force, the maximum magnetic moment corresponding thereto.

This last-mentioned behaviour has already been observed by Quetelet in repeatedly rubbing steel needles with a magnet, and by Hermann and Scholz upon repeated contact with the pole of a steel magnet, and similarly by Bouty and Fromme upon the repeated introduction of iron bars into magnetising spirals traversed by a constant current.* In this last method, the separate portions of the bars are successively exposed to the magnetising forces of different intensity at the different points of the spiral, and thus the position of the molecules of the bars already taken up at one point may assist the adjustment of the molecules at other points in the subsequent introduction into the spiral, or rubbing, and thus explain the increase of the permanent moments. That this is also the case with an unchanged distribution of the magnetising forces is seen from the above experiments.

VIII. In close connection with these phenomena is the thermo-electric behaviour of stretched wires towards the same unstretched, studied by Cohn,† which is certainly one of the most sensitive modes of detecting changes in structure. Here, also, the thermoelectric forces which correspond to equal tensional forces are different with increasing and with decreasing tension. There could be no doubt that the investigation of the thermoelectric behaviour of wires twisted to and fro would give similar results, and this is confirmed by experiment; as also in the investigation of the same behaviour with iron and steel bars, which are magnetised by increasing and decreasing magnetising force. In so far as the torsion or detorsion affects the electric conductivity of the wires, it must show analogy to the magnetic behaviour. This much may, however, safely be concluded from these investigations, that if the molecules of the bodies are displaced or rotated from their former positions of equilibrium, before as well as after the molecules have accommodated themselves by the repeated action of the force, they will always, to some extent, also retain this displacement or rotation upon gradual alteration of the force.

This is seen in various ways. Thus, for example, if the force influencing the body is reduced to zero, a permanent displacement and rotation remains; again, in order to reduce a permanent torsion or magnetisation to zero, a smaller force is necessary than is required for the production of the same. Further, a body which has accommodated itself by the repeated action of increasing and decreasing forces, and is then again repeatedly exposed to the action of the same forces, shows each time, more or less, the position of the molecules

* Meanwhile a similar arrangement has been described by Stebbins, *Centralbz. f. Opt. u. Mech.* IV. p. 119 (1885); *Beibl.* VII. p. 474 (1883).

* I have formerly obtained a series of results on the magnetisation and demagnetisation of iron and steel bars by the same method. Experiments by the method now employed with constant distribution of the magnetising forces give (qualitatively) the same results.

† Wied. *Ann.* VI. p. 385 (1879).

Digitized by Google

corresponding to the greater or smaller force preceding that allowed to act last.

Since it is not possible, in the present condition of our knowledge, to express these phenomena of elasticity in the widest sense of the word by mathematical laws under appropriate theories, further experimental researches on this subject are required, in which the time during which the forces act, and the time which elapses after they cease to act, must be taken into account. A thorough study of the magnetic properties of bodies, from which we can infer, up to a certain point, the rotations of the molecules, seems to be especially suited to this purpose.

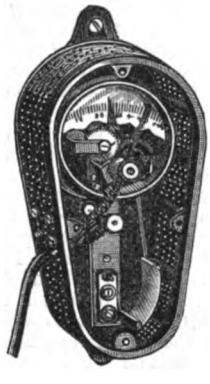
IX. The behaviour of bodies under changes of temperature is quite different from their magnetic and mechanical behaviour.

If a body, whether deformed or magnetised, has been accommodated by repeated heating and cooling, so that the molecules have assumed their final mean position of equilibrium for each single temperature degree, the same mechanical or magnetic condition corresponds to the same temperature, whether with rising or falling temperature. Thus a thermometer, after repeated changes of temperature, gives the same indications at the same temperature, whether with rising or falling temperature, when once the extreme indications have become constant. So also a thermo-element (say of copper and german silver) shows, after accommodation, always the same electromotive force, and a magnet always the same permanent moment at a given temperature, as is shown by direct experiment. The difference is just this, that in mechanical deformation and magnetisation the molecules have been carried over into new more or less stable positions of mechanical equilibrium, by means of mechanical displacements and rotations, out of which they may be directly displaced by fresh mechanical influences; whereas by heating we change only the amplitude of the vibrations of the molecules in all directions above the same position of equilibrium.

A THERMOMETER WITH ELECTRIC ALARM.

The thermometer, figured herewith, is designed for giving indications as to the temperature of silos, grain depositories, piles of coal, or certain fabrics that are apt to burst into flame spontaneously and set fire to factories or ships.

The thermometer used is a metal one, of the Bourdon type, enclosed in a strong cast iron box, provided with a cover of the same nature. This latter is omitted in the figure, so that the



Gerboz's Alarm Thermometer.

internal arrangement may be seen. This box is everywhere perforated, so that the thermometer may be in contact with the surrounding air. The apertures, however, are small enough to prevent the entrance of particles of coal or fragments of seeds, &c.

The apparatus, when placed in a coal bunker or a silo, is connected with the exterior by means of conductors that traverse the surrounding substance, and that serve to indicate, at every moment, that the temperature has or has not reached a dangerous height. As soon as the needle of the thermometer strikes an index, placed at the degree of temperature that it is important to know (50°, for example, showing that there is danger of fire), a bell rings.

We shall now give a few details of construction. As the rotary axis of the needle and that of the index are on the same line, contact between these two pieces takes place at the same point, whatever be the respective angular position of these two parts. Instead of being a simple rod, making one piece with the manœuvering button, the index is composed of a barrel that forms one piece with the button, and upon which is mounted (1) the index needle properly so called, (2) a spring for holding the index in a constant position with respect to the barrel, and (3) a toothed pinion. This latter gears with a cog-wheel upon the same axis with the polarised armature of an electro-magnet. This armature moves in a plane at right angles with the axis of the bobbins of the electro, and as near as possible to the extremity of the core.

The electric communications are established, and the two proposed controls are made as follows:—The cable consists of three conductors. One of these runs from the negative pole of the battery to the thermometer needle and one of the wires of the electro. Another runs from the index to the alarm bell, and from thence to the positive pole of the pile. The third runs from the positive pole of the pile to a galvanometer, then to a button or interrupter, and from thence to the second wire of the electro.

When a contact has been established by the button, the current, on traversing the galvanometer and causing it to deflect, indicates that the two wires and the electro-magnet are in proper order. When the current traverses the electro it polarises the cores, and causes the armature, and consequently the movable index, to revolve around the barrel and under the action of the armature; the index thus tends to move from the maximum point towards the needle, and with it to establish a contact that rings the alarm bell.

When the current is broken by the button or interrupter, the armature, as the current no longer traverses the electro, returns along with the maximum needle to its position of rest under the action of the spring mounted upon the axis of the index.

Were the maximum index made to bear against a metallic rack, forming an electric interrupter in a special circuit comprising an electric counter, we might count the number of contacts between the maximum point and the needle, and thereby ascertain the latter's position.

It will be seen from what precedes that the apparatus may be submitted to a permanent control that permits of making sure that it is ready to operate regularly. Such control is of prime importance, since this thermometer is designed to be used in accessible places (coal bunkers, silos, and so forth), the dampness of which might interfere with the contacts being kept in a proper condition. Besides, the motions of a ship on the sea might cause a breakage of the cable, notwithstanding that it is covered with steel. These two things cannot occur without attracting attention.—*La Nature.*

LEGAL INTELLIGENCE.

Libel on Mr. Cyrus W. Field.

On Monday an action brought by Mr. Cyrus W. Field against Mr. James Gordon Bennett, of the *New York Herald*, in which judgment had been allowed to go by default, came before the Middlesex Sheriff's Court, in Red Lion-square, in order that damages might be assessed for two libels on the plaintiff published in the defendant's newspaper. The case was heard before Mr. Under Sheriff Burchell and a special jury. There was no appearance on behalf of the defendant.

Mr. POLLARD, counsel for the plaintiff, said his client's name was well known on both sides of the Atlantic as the pioneer of Atlantic telegraphy. To his enterprise the public owed the construction of a cable which was carried out at a vast expenditure of his own money and that of his friends. The speculation ultimately resulted in the formation of the Anglo-American Cable Company, of which Mr. Cyrus Field had all along been a director, and had represented its interests solely and successfully in New York. Mr. Field was proprietor of the *New York Mail* and *Express*, and was one of the members of the American Associated Press, which was a body consisting of the seven leading newspaper proprietors in the United States. The defendant was also a member of that association, but later on he was instrumental in bringing about the laying of the Mackay-Bennett cable in opposition to those already existing. This latter company had offices in Cornhill for the collection and transmission of news, and on the 4th of February, 1885, the first libel complained of was sent through that medium as follows:—"London, February 4th, 1885.—Mr. William Abbott, broker and operator, Token-house-yard, supported by many stockholders of the Anglo-American Cable Company, announces that at the Friday meeting of the directors of the company he will introduce a resolution to expel Mr. Cyrus W. Field from the directorship, on the ground that he is unworthy of any position of confidence and trust." This telegram appeared in the *New York Herald* of the 5th of February. There never was such a resolution proposed and there never was any intention to do so. It was, therefore, not only libellous, but utterly untrue in fact. There was a second libel sent on the 12th of the same month, and consisted of an extract from *Truth*, aggravated by a leading article calling attention to it. The telegram was in these terms:—"At a meeting of the company (meaning the Anglo-American Cable Company) held last week, Mr. William Abbott moved that Mr. Cyrus W. Field should not be re-elected. This worthy philan-

Digitized by Google

thropist, it would appear, was concerned with Jay Gould in the issue of Wabash preference stock, on which sham dividends were paid until the British public had been induced to buy it, when it fell from 92, the issue price, to about 12. According to American newspapers, Mr. Cyrus Field made by this operation about one million sterling. In these circumstances Mr. Abbott was right in opposing the re-election of this gentleman." For these libels the plaintiff now claimed £10,000 damages. Subsequently Mr. Abbott apologised handsomely and *Truth* also. The *Financial News*, which had copied the telegram, likewise apologised, and the fact of these copies having appeared was telegraphed by the American Associated Press and was inserted in other American papers, but not in the *New York Herald*, showing that the defendant, relying on his own wealth, was regardless of the injury he had done to a fellow journalist. This was clearly a case in which nothing except exemplary damages would bring Mr. Bennett to a sense of his wrong-doing, or compensate Mr. Field for the injury he had sustained.

Mr. Cyrus W. Field, the plaintiff, was called and bore out the opening statement of his counsel. He stated that he was a special partner in the firm of Field, Lindley, and Co., the largest shippers of grain from America to Europe, and having agencies in London, Liverpool, Glasgow, Bristol, and other British and Continental ports. He was besides director of ten large corporations, seven of which were in America and three in London. For some years past he had spent more than half his time in England, where he had a great many friends. There was not a shadow of foundation for either of the libels, and they were calculated to do him immense injury.

A juror: Have you taken any action in America?

Mr. Field: Not yet; I am going to take other action by-and-bye. The libel was originated here.

Mr. POLLARD: The point is that the defendant sent over false intelligence by his own cable, which he neglected to contradict, and for that we seek redress.

Mr. James Maclean, London agent of the American Associated Press, produced the flimsies of three messages transmitted by him contradicting the libellous publications in the *New York Herald*.

After deliberating for an hour and a quarter, the jury returned into court and inquired whether they were to take into account the loss the plaintiff might have sustained in America.

The UNDER SHERIFF: To that I must reply, No.

Mr. POLLARD: I think the jury have a perfect right to take it into consideration, because the libel could not have been published in America if it had not been sent over from the defendant's offices in Cornhill, where it was actually conceived.

The jury again retired, and after an absence of 15 minutes, found a verdict for the plaintiff—damages, £5,000.

COMPANIES' MEETINGS & REPORTS.

The Globe Telegraph and Trust Company (Limited).

The thirteenth ordinary general meeting of the Globe Telegraph and Trust Company (Limited) was held on the 29th inst., at Winchester House, 50, Old Broad-street, E.C., under the presidency of John Pender, Esq.

The SECRETARY (Mr. William Payton) read the notice convening the meeting and the minutes of the last meeting.

The CHAIRMAN: Gentlemen, the resolution I have to move is as follows:—"That the report and accounts for the year ended the 18th July, 1886, submitted to this meeting, be and they are hereby received and adopted, and that dividends be now declared, payable on and after this day, as follows, viz., 3s. per share on the preference shares, making, with previous quarterly payments, a total dividend for the year of 6 per cent. on the preference shares, less income-tax, and of 2s. 9d. per share net on the ordinary shares, making with the previous distributions a total payment for the same period of £3. 12s. 6d. per cent. per annum on the ordinary shares."

Sir DANIEL GOOCH, Bart., seconded the motion.

The CHAIRMAN: Before asking you to approve of that resolution I will make a few remarks on the report, and also give you some information as to the cause of the slightly reduced dividend to-day, and our prospects for the future. Since 1874, when we paid a dividend of 5½ per cent. on the ordinary shares, up to 1885, when we paid 4½ per cent., our dividend has never fallen below 4 per cent., except in the year 1877, when we paid a similar dividend to that which we recommend to-day, viz., £3. 12s. 6d. per cent. per annum on the ordinary shares. The cause of this diminution of dividend is the same to-day as it was then in 1877. It has resulted from the reduction of the tariff for messages across the Atlantic. The rate then was 1s. per word, and to-day it is at 6d. for the associated Atlantic companies. Our average dividend for the thirteen years of our existence has been £4. 8s. 8d. per cent. Of course, our six per cent. preference dividend has been constantly paid, and if we take the two dividends in combination—that is, the six per cent. and the average of £4. 8s. 8d. per cent.—we shall find that we have paid on the combined shares during the past thirteen years a dividend of £5. 4s. 4d., or about 5¼ per cent. Unfortunately for us the dividend from the Atlantic traffic has been a descending one. In 1883 the Anglo and Direct Companies paid us £46,300, in 1884 they paid us £44,800, and in 1885 they paid us £38,500. This year we have only received from the Anglo-American Company £14 000, and from the Direct Company £6,000, say together £20,000, which shows a loss of income, as compared with last year, of £18,500, and this is equal to about 1 per cent. on our ordinary shares. We have therefore only to look at the decrease in the revenue which we receive from our Atlantic holding to find that the results of the competition have been to diminish our dividend on our ordinary shares. Gentleman, that is the dark side of the question at the present moment, the low rates ruling in the Atlantic; but even that dark side has also a bright one. We find that there has been a very large increase in the traffic at these low rates. I might mention that in three months there has been an increase of something like 110 to 118 per cent. We believe that the low rate will develop traffic to such an extent that it may probably 12 months hence enable us to receive, if not the full amount, probably nearly what we have been receiving at the higher rate. I do not mean to say that the sixpenny rate is to be the permanent rate, but this I do say—that the associated companies have resolved to give that rate such a trial as will enable them to judge whether it is to be a paying rate or not. That rests with the telegraphing public. They have now got a rate which cannot be lowered, and if the telegraphing public respond, as we hope they will, I believe that in future the rate for Atlantic telegraphing will be lower than has hitherto prevailed—probably something like the rate which exists to-day. With respect to the other companies, which, as you are aware, form a large part of the capital of the Globe Company, I will first allude to the Eastern and the Eastern Extension Companies. We are also trying in those companies what reduced rates will do as regards increasing the traffic. We have just made a new departure, arising from the Berlin Conference. We have made a new departure from the 1st of July. We have reduced the rates. It takes some time before reduced rates begin to tell, but we hope before long that we may find in the increased traffic some compensation for the reductions which we have made. Altogether, the Eastern and the Eastern Extension system is as hopeful as at any time since the formation of these companies. The German Union Company is suffering to a small extent from the reduced Atlantic rate, and the German-Norwegian Company also. These companies, however, are giving us fair dividends. The Indo-European Company is giving us a very satisfactory dividend. In short, the dividends from the other companies named compensate to some extent for the reduction on the Atlantic companies. That is the great advantage of the Globe Company—that it enables you to get a dividend. Probably had you been in the Anglo-American Company you would be getting no dividend at all at the present time. The future of telegraphy I need not dwell upon, as I have done so so frequently. This, however, I may say—that whether it is in mercantile life or in political life, those who begin to use telegraphy cannot give it up. It has a natural growth. If the country prospers telegraphy must prosper, and therefore, looking at the future, it has all these elements of progress and prosperity in it. I think I have now said all that I have to say at the present time. I would repeat that the Atlantic companies are going to give a fair chance to the low rates now ruling, and that the Eastern and Eastern Extension Companies have laid the foundation of increased traffic by lowering the rates. I hope the result will be that we shall have such an increase of traffic as will enable us, at a very early period, to return to the dividends which we have been paying in the Globe Company heretofore. I now move this resolution, which has been seconded by Sir Daniel Gooch. If any gentleman desires to make any remarks or to ask any question, I shall be very pleased to answer him.

Mr. JOHN NEWTON said he was sorry that he could not allow the accounts to pass without making his usual objection as regarded the deduction of income-tax. A very important principle was involved in that reduction. He did not know how it might affect him in the future, but it concerned him at present so little as regarded this Company that he contented himself with recording his objection. He contended that they had no right to take from him a sum of money as income-tax, and pay the tax to any one else, except to the Government. They did not pay the income-tax at all, and could not deduct it from their shareholders. He would like to ask whether the auditors had seen a voucher for the payment of income-tax to the Government. He knew that they had counsel's opinion on the subject, but he could also produce counsel's opinion to show that they were acting illegally in making a deduction for income-tax. The calling of the meeting on the same day as that fixed for the meeting of the Anglo-American Company was an inconvenience to the shareholders, and he considered that the Directors ought to have sacrificed their own convenience in this matter. They had arrived now at a juncture in telegraphy when Directors must listen to what shareholders had to say. The first declaration in the Articles of Association was as follows:—"That which is at present contemplated as the principal object for which the Company is formed is the acquisition and amalgamation in one company of the principal lines of submarine telegraph and the land lines used to connect therewith. It is proposed in the first instance to acquire these shares and other securities of the companies owning them, issuing the shares of this Company in exchange for them, or to raise funds for the purpose of paying for them, and, as opportunity offers, acquiring and absorbing the businesses and property of the companies themselves." He had the authority of two gentlemen sitting behind the table, in a printed paper issued by them some time since, for saying that it was for shareholders to tell the Directors they wished that principle carried out. If they had carried out that principle they would not have had the trouble in the Atlantic at the present moment, nor would the Atlantic telegraph shareholders be now without a dividend, nor would they have seen the competing lines that had been started—lines started for no other purpose than for five or six gentlemen engaged in commerce to oppose them and take splendid positions as Directors.

The CHAIRMAN: That is a very pretty idea of Mr. Newton's. I always listen with a great deal of attention and respect to anything he says. But would he just show us how we could have prevented the Commercial Company from coming into the field—business men, men of great experience, who, had they looked into the affairs of the existing companies, would

Digitized by Google

have been prevented, I think, from putting such an enormous sum of money as they have put into the bottom of the sea. There were strong representations made to them, but they treated those representations as coming from interested parties trying to dissuade them from going into a very good thing. We had no influence to prevent them. They came in, however, and they are now reaping the harvest in getting probably a lower dividend than we ourselves are getting to-day. As long as you are dealing with men who put aside all ideas of political economy and the question of profit, resolved to spend their money, no combination of men will prevent them from doing so. That has been the case with the Commercial Company. As to the income-tax, Mr. Newton has been consistently in opposition as regards that matter for some considerable time. But I am obliged to say this, that we are bound to respect the law, and bound to go to the very best authorities to read that law for us. That law has been read to us, and it is in accordance with that reading that we are now dealing with this matter. We have taken the very highest authority in the law, and we are obliged to respect their decision, notwithstanding that you hold other views.

Mr. NEWTON: Would you give us your authority?

The SOLICITOR (Mr. Burt): Sir Richard Webster and Mr. John Rigby. These are two of the authorities that I remember, but I do not know that there were not others. I was not prepared for the question.

The CHAIRMAN: There were differences of opinion at the Board with regard to that question, but it has been thoroughly threshed out, and we are acting in accordance with the highest legal opinion in the way in which we have dealt with this matter. I think Mr. Newton has good reason to complain that this meeting and that of the Anglo-American Company should be held on the same day.

The SOLICITOR: I believe they were both fixed on the same day.

The CHAIRMAN said it should certainly not occur again. He then put the resolution, and it was carried unanimously.

On the motion of Sir DANIEL GOOCH, seconded by the Marquis of TWEEDDALE, Mr. John Pender was re-elected to his seat at the Board.

The CHAIRMAN: I am very much obliged to you for the honour you have done me in again re-electing me. This is one of the hobbies of my life. I am particularly pleased to have the confidence and support of the shareholders in conducting this business.

On the motion of the Marquis of TWEEDDALE, seconded by the CHAIRMAN, Sir James Anderson was re elected a Director.

Sir JAMES having acknowledged his re-election,

Mr. NEWTON proposed the re-election for the ensuing year of Mr. J. G. Griffiths, F.C.A., and of Mr. Wm. Griffith, B A., as auditors. He said that, notwithstanding what the Chairman had observed, he would ask the auditors to search for the voucher for the payment of income-tax. He ventured to say they would not find it, and also that, in spite of the opinion which the Chairman had mentioned, the proceeding was illegal.

Mr. FULLER seconded the motion, which was carried unanimously.

Mr. GRIFFITH, having returned thanks, said that he had considered the question of income-tax, and there was unfortunately no doubt that that had been paid; but he rather agreed with Mr. Newton as to the legal opinion. That, however, was not a question for the auditors. They had looked at the securities, which were all safe, and they had examined the books, which were all well kept, and he thought that they could well certify not only what they had certified, but also that the Company was in a sound position as far as the books and the securities showed. Continuing, he proposed a vote of thanks to the Chairman, whose name and reputation he said extended all over the land. Mr. Pender was a gentleman well known in parliamentary, commercial, and still more in telegraph circles, and he thought they were fortunate in having him as their head. It was Mr. Pender who had conceived the idea of the Company, who had founded it, and under whom for so many years it had been successful. He hoped that Mr. Pender's life would be long spared, and that the success of the Company would continue to be greater, and that their dividends would grow.

The motion having been carried,

The CHAIRMAN said: I have very great pleasure in thanking you on behalf of my colleagues and myself. It gives us great pleasure to meet you again, and it would give us greater pleasure still if we received larger returns, so that we might pay you a more satisfactory dividend than you are getting to-day. Your interests will be carefully watched in the low rates that are now being experimentally tried, and I hope that when we meet you a year hence we shall be able to give you a better account than we have given you to-day.

The Anglo-American Telegraph Company.

The ordinary general half-yearly meeting of the proprietors of this Company was held yesterday (Thursday) at the Cannon-street Hotel, Viscount Monck (Chairman of the Company) presiding.

The SECRETARY (Mr. T. H. Wells) read the notice convening the meeting, and the report was taken as read.

The CHAIRMAN: It is now my duty to move the adoption of the report. In doing so I shall not take up your time with any comparison of figures, because from the circumstances of the case anything of that kind would be completely illusory. The rate of tariff has been changed since the last meeting, or since this time last year, and it would therefore be absurd to compare the figures. I may say, however, in passing, that if you compare the expenditure of the two half years you will find that economy has been studied as far as possible consistent with the maintenance of the efficiency of the service. I have also to state to you, as you will see in the report, that your plant is all in good condition and working order, and that you are carrying a very large, though I am sorry to say at present a not very remunerative, traffic. Well, gentlemen, the truth is, the question we have really to consider to-day, which dominates the whole situation and appears in almost every line of this report, is the mode in which we must meet the competition in which we are engaged. Nevertheless, before I come to that subject, there are one or two topics to which I would wish to draw your attention. You will remember, as you have been reminded by the minutes which have just been read, that at the last meeting we entered into an arrangement for suspending contributing to the renewal fund from revenue as soon as that fund should have reached one million sterling. Speaking roughly, at the time that meeting was held we calculated that that state of things would have arrived at the end of the present year. Now, circumstances have considerably changed since that time. Our revenue has diminished, and we shall not be able, in all probability, to put by to renewal fund within the current half-year—the half-year which is just beginning—as much as we should have done if our income had remained the same. Notwithstanding this, we shall be able, I hope, to put by a considerable sum to that fund, and if it will not probably attain to the entire amount of one million by the end of this year, it will come very near to it—it will come so near to it that your Directors are disposed, as at present advised, not to disappoint the hopes of those who took that view of the matter, and they will suspend, if circumstances continue the same, any addition from revenue to the renewal fund at the end of the year 1886 [applause]. Gentlemen, of course I need not say that this proposition is dependent on the same conditions which attached to the original agreement, viz., that we should not meet with any extraordinary disasters in the meantime [hear, hear]. Well, gentlemen, there is another matter which was alluded to at the last meeting. Some gentleman in the room attached to some words that dropped from me a meaning which I never intended them to bear. He imagined that we were going, in case of a war of rates or of competition, to make use of the renewal fund to tide over that opposition. I at the time stated to you my opinion that any use of this fund beyond that for which it was originally intended, viz., the renewing of your plant, would be a gross case of malversation on the part of the Directors. I still adhere to that opinion, and I believe the great body of the shareholders would be disposed to trust the present Board in the matter [applause] At the same time contingencies might arise—we might pass from the stage and others take our place; but I am authorised by the Board to assure you that no expenditure of this fund shall take place, except for the purpose of repairs, without the shareholders being consulted on the subject [applause]. There is yet one other matter. I dare say some of you have noticed the decision in one of the courts of law, that it is not legal for Directors to pay the expense of proxies out of shareholders' money. That has been so decided, and having been so decided your Directors, of course, are bound by the law, as long as that case remains undisturbed. We have therefore come to the conclusion that all expense of proxies, stamps, printing, posting, and so on, shall be paid for by the Directors out of their own individual fees, and that no portion of that expenditure shall any longer be charged to the shareholders. I now come to what is really the great question, and that is the competition in which we are engaged with the Mackay-Bennett cable. We were often denounced as monopolists; but, to be candid wth you, that is an accusation that sits my very lightly on my conscience. I have always held that my first duty to the stockholders of this Company was to obtain for them the best return for their money that could be obtained. If that could be done by securing a monopoly, I see no reason why we should not take that course, and in truth the people who accuse us of being monopolists suggest to us that we should create a natural monopoly by reducing the cost of our work, so as to enormously increase our receipts. Hitherto we had acted on the principle that where combination is possible, competition is not likely to occur. If you cast your eyes back for 20 years, when this Company was first established, and when telegraphic communication across the Atlantic was first brought into existence, you will find that the charge for a message across the Atlantic at that time was £20. Well, no one objected to that at that time. We had never been used to telegraphy, and we were overjoyed to be able to send a message across the Atlantic in a minute or two at any price. However, not long after that occurred, people began to think that those who were carrying the messages at £20 a message must be making rather a good thing of it, and a rival company started up. I am sorry to say I had something to do with that company myself, and we found when we laid our cable that we were not at all mistaken in our speculation, and that it was a very good thing. However, after a very short time, proposals were made to us, and we were amalgamated with the original Anglo-American Company, and for a short time we continued to have a monopoly of the telegraph trade to America. But other people began to think there was something more to be made out of it, and not long after the Direct Cable Company arose. That was treated in the same way, because though we did not amalgamate with it, we had a tariff arrangement, and it came to practically the same thing. That immediately led to the laying of other cables, and I need not pursue this history further, because you are all aware that each one of these arrangements was succeeded by the institution of a new company. A new competition arose, people thought there was something good to be got out of it, and they went in for additional cables. Naturally it has now come to pass that there are cables enough in the Atlantic at the present day to do about ten times the work that they are called upon to transact. When the Mackay-Bennett cable was started we determined to try the effect of fair competition. After a short time we found—and I do not want to complain of the Mackay-Bennett people, because they were perfectly justified if they thought they could get a good thing in getting it any way they could—but we found they were giving exceptional advantages to individuals, and that they were completely undermining our *clientele*. Therefore we found that we must come to a tariff that would lead to a regular competition and hostile

Digitized by Google

proceeding on both sides. We put down, therefore, our tariff to 6d. a word, as you are aware. Well, the Mackay-Bennett Company continued to charge 1s., and, wonderful to relate, I believe they are getting people to pay 1s. for what they can get for 6d. at this moment. I do not believe that such a thing will last. I believe they adopted a low tariff, supposing that we had merely adopted a temporary measure which would not be persevered in. We have determined now to try an extensive and persistent low tariff, with the view of stimulating the increase of traffic, and seeing if we cannot make a good living on a basis that cannot be upset [applause]. We have some encouragement, as you will see by the report, in that policy, for within a very short time of the institution of the 6d. a word tariff our traffic more than doubled—the report states it is 110 per cent. increase. Well, we determined to try whether that increase cannot be made greater, and whether we cannot bring the traffic under a low tariff to such a point as will enable us to make a dividend for you in a way that will not encourage future competition, and will be permanently beneficial to your Company. Gentlemen, that is the policy which your Directors have at the present moment adopted, and which they are thoroughly determined to persevere in until they see whether it can be worked with advantage to you. I will not conceal from you that it is a policy which will draw largely on your forbearance, and it cannot be carried into effect without your giving an extended support to your Directors. Therefore I hope, in the interests of this Company and of the stockholders themselves, that you will join as one man with the Directors in instituting and maintaining this policy, and in giving it a fair, extensive, and complete trial. I do not think it is necessary for me to trouble you with any other matter. I have described as succinctly and as clearly as I could what our intention is, and I shall now, therefore, move "That the report of the Directors and accompanying statement of accounts to the 30th June, 1886, submitted to this meeting, be, and the same are hereby, received and adopted."

The Marquis of TWEEDDALE seconded the resolution.

Mr. THOMAS SMITH said that, as the representative of nearly a million of stock, he supported the adoption of the report. It was encouraging under the circumstances to find that the traffic at the reduced rate of 6d. should have more than doubled in the first month after its introduction. The result was not so unsatisfactory also if they thought of the continued depression of trade and the unfair competition they had to contend with. At the last meeting the Chairman had indicated that an agreement for an amicable arrangement of traffic with the Bennett-Mackay Company might be arrived at upon equitable terms. The Bennett-Mackay Company, however, had been most outrageous in their claims of 40 per cent. of the whole traffic and other preposterous terms based on their traffic, obtained by rebates and otherwise. Of course such terms could not be entertained, and the Bennett-Mackay Company declared war upon this Company by immediately reducing the rate from 1s. 8d. to 1s. per word. The Board of the Anglo-American then wisely reduced their charge to 6d., thus checkmating the game of rebates, which would have been carried on had the rate been made a shilling one. In the case of this Company the war was one of defence, and their rights of twenty years had been invaded without just cause. The policy of the Board had hitherto been one of conciliation to all comers, but the time had now arrived when company promoters should be taught that there was no room for fresh cable schemes across the Atlantic, and that no further concession would be made. If the Bennett-Mackay Company reduced their charge to 6d., this Company must immediately put down the rate to 3d., or lower still if necessary. The Company is in a sound financial position, without mortgage or debenture bonds of any kind to provide for, and with a renewal fund sufficient to meet all contingencies, while all the cables, with one small exception, were in good working order. The other Company, he believed, had not yet been able to place their stock, and as the public would not have them these millionaires had been obliged to borrow a large sum of money at 6 per cent. in debenture bonds, he believed. The shareholders of the Anglo-American Company must, therefore, exercise a little patience. He had no doubt the present contest must soon end. Their action at present was one of self-defence, but if the Directors now allowed their opponents to escape without making such an example of them as would deter all promoters for the next twenty years interfering with their just rights, they were not the friends of the shareholders. He only regretted the Board had not adopted this policy much earlier [applause].

Mr. GRIFFITHS said that the last speaker had come forward as representative of an association called the Anglo-American Shareholders' Association. He (the speaker) happened to be a member of that association, but he differed altogether from the policy advocated by the last speaker. He would therefore protest as to Mr. Smith appearing as the advocate of the association. It had been said that they possessed a renewal fund, which was shortly to cease; but what was the advantage of the renewal fund when they already had more cables than was sufficient to transmit ten times the present amount of business? Why should not this renewal fund, therefore, be utilised for the purpose of equalising dividends? The proprietors had it in their power to do this. They were told that the traffic had increased by 110 per cent., but they were not told at the same time that during that particular period there was a great political crisis in this country, and that the press messages arising from that cause would increase the business enormously. The Directors in their report stated that they only desired a reasonable return upon the capital subscribed, and to prevent further wasteful competition; but the Board should not, as business men, be satisfied with it, as it was their duty to obtain the highest dividend they could for their shareholders. It was said that sooner or later a low tariff would be necessary; but the past showed that the Company had wasted its resources and brought no return into the pockets of the shareholders. He should have liked if the Board in their report had expressed a little more sympathy with the sufferings of those who had lost their dividends. The shareholders of the French Company in Paris had said that they would not permit their funds to be squandered uselessly, and for no purpose.

Sir CHARLES SWINBURNE asked if the Board intended to add the interest of the reserve to increase that fund after this year?

The CHAIRMAN: Yes.

Mr. HERON asked why so large a sum as £50,000 should be set aside to the reserve at one time.

Mr. JACKSON repudiated the idea that Mr. Griffiths represented the feelings of the Anglo-American Shareholders' Association, as he had not attended the sittings of that body. He was glad to find that the management of the Company was waking up to the duty of studying the convenience of their customers. This Company had been a pioneer company, and pioneers too often sowed for others to reap; but they had the future in their hands, and a traffic at a low tariff would employ all the cables. Some of them, too, would be surprised to learn that the average dividend for the last ten years had been £3. 10s. per cent.

Mr. NEWTON thought that Mr. Griffiths had a perfect right to give his opinion as a member of the Shareholders' Association. Mr. Jackson had said that the average dividend for the last ten years was £3. 10s. per cent., but those shareholders who had joined the Globe Submarine Trust received not that amount, but 5¼ per cent. from that day to this. Knowing that this Company was not prepared for the present fight, he had sold his stocks at 60. By the manner in which the renewal fund was dealt with they were placed before their competitors like an army without weapons.

Mr. STOCKDALE endorsed the policy of the Board in meeting the competition, and in adopting a 6d. tariff, and believed that they might justly call upon the shareholders for a little forbearance.

Mr. CHESTER said he was accustomed to strange changes, but the policy the Chairman had that day advocated was the strangest change he had ever seen. For years they had been told from the Chair that a 1s. or 2s. rate was not a paying rate, and that any step in the direction of reducing the tariff was entirely out of the question. The policy of monopoly and of increased rates had led to the introduction of fresh cables, while the present policy was attended with no profit. The interests in this Company which ought to be considered were those of the ordinary and preferred shareholders, for the deferred shareholders had accepted their position.

The CHAIRMAN: Gentlemen, I do not think there remains very much to say in reply to what has been said. The gentleman who has just sat down has put words into my mouth. I do not like to put my memory against his, but certainly, as far as my memory carries me, I do not remember that. I have often said that we have tried different rates of tariff, and that up to this time we have never found the lowest rate we tried so sufficiently remunerative as to go on. But we have never before tried for any length of time so low a tariff as at present, and the Board were astonished, I am bound to say, at the extraordinary rise which took place in the traffic of the Company immediately on the institution of so low a tariff as sixpence. The gentleman has sneered a great deal at the past policy of the Board, but we acted according to the best of our lights. We do not claim any character of infallibility, and if we find we have been wrong we are ready at any time to retrace our steps [applause]. There was one observation made by Sir John Swinburne, which, though I have often explained the matter in this room, I should like to explain again. He says I stated, and he states truly, that I said that we have the capacity of carriage of traffic across the Atlantic very far beyond the traffic that we have to carry. Therefore, he says, why build up a reserve or renewal fund for the purpose of renewing cables when you have too many?

The CHAIRMAN went on to say that if all the cables in the Atlantic belonged to the Company it would be a very good argument, but they had only four out of eight, and the retention of their portion of the income depended on their keeping up those four cables [hear, hear.]. If one of these failed their portion of the income would be immediately reduced, and that was the reason why, notwithstanding the fact that they had a greater power than was absolutely requisite for the traffic, they were bound to keep up the number. A question was asked as to adding the interest of the renewal fund to that fund. That action was based on an arrangement come to in that room with the shareholders generally at the last meeting (hear, hear), and it would not be acting rightly if this arrangement was not duly carried out. The placing of the £50,000 to the renewal fund was also part of the arrangement entered into with the shareholders at the last meeting.

The resolution was then put and carried.

On the motion of Mr. SMITH a vote of thanks was passed to the Chairman, and the meeting separated.

The Direct United States Cable Company (Limited).

The eighteenth ordinary general meeting of this Company was held at Winchester House, 50, Old Broad-street, E.C., on Friday, the 23rd July, 1886, under the presidency of John Pender, Esq.

The SECRETARY and TRAFFIC MANAGER (Mr. J. W. Fuller) read the notice convening the meeting.

The CHAIRMAN: Gentlemen, before putting the resolution asking you to approve of the report and accounts, which have been in your hands for some days, and which I presume you will take as read, I will, as usual, give you some details. The revenue for the half-year to 30th June, after deducting out payments, amounted to £28,445: and the working and other expenses, including income-tax (but exclusive of cost of repairs), absorb £15,867, leaving a balance of £12,578 as the net profit of the half-year, making, with £5,967, brought from the previous half-year, a total of £18,545, which has been appropriated as follows:—

Digitized by Google

Interim dividend of 3s. per share to 31st March, £9,106. 10s.; proposed final dividend of 2s. per share to 30th June, £6,071; transferred to reserve fund, £316. 13s. 2d., leaving a balance to be carried forward of £3,050. 19s. 3d., making a total of £18,545. 2s. 5d. The revenue shows a reduction of £7,661, as compared with the June half of last year, owing entirely to the introduction of the sixpenny tariff on 5th May last. As stated in the Directors' report, the result of the reduction, so far, has been to more than double the volume of traffic, without developing a remunerative revenue. The working expenditure in London and at stations shows a reduction at the rate of £600 per annum, notwithstanding the expenses of advertising and otherwise making known the reduction of rates, and in spite of the cost of working additional joint stations at Glasgow, Bristol, and Havre, which were not in operation prior to June, 1885. The result of the expenditure, on the whole, shows a reduction of £1,340 in favour of the present half year. The important economies effected by the Company from year to year since its reconstruction in 1877 have now brought the normal working expenditure down to the lowest point consistent with the efficient working and maintenance of the Company's system. No further reductions can, therefore, reasonably be looked for; but every possible economy will continue to be exercised. The reserve fund, after being credited with interest on investments and profit on sale of security, and being debited with cost of repairs, now amounts to £325,000. The present market value of the Company's investments continues considerably higher than the amount of their cost to the Company.

Now, gentlemen, these are some of the details connected with the working of the Company during the past half-year. For the last 18 months when I have met you at these half-yearly meetings I have told you that there was looming in the distance a competition, and a very active competition it was likely to be, if we really began to fight. My colleagues and myself earnestly desired to prevent that fight, and I believe the associated companies also were equally earnest in that desire. We did everything we possibly could consistently with our duty to our shareholders and the position which we hold as the great pioneers of Atlantic telegraphy. The result has been that no arrangement could be come to whereby such a rate could be agreed upon that would be fair to the public, and give the shareholders a moderate dividend. As you know, you have never had a very excessive dividend, because, what with the competition and what with cables springing up right and left, and with the coding system at work at the same time, we have never been able to get at the point in dividend which such an enterprise as Atlantic telegraphy was entitled to. If we have not been able to make an arrangement that would give a satisfactory dividend, we have endeavoured to do the next best thing—to utilise our cables to such an extent, at a low price, as would test the telegraphing public and throw the responsibility of low rates on them. The result has been, gentlemen, that in reducing the tariff to 6d. we have more than doubled the number of messages passing over our system. In fact, I believe to-day that it may be said to be 110 if not 118 per cent. above the previous traffic. That, gentlemen, is still insufficient to give the dividend which we consider that you are entitled to, but nevertheless we think that having begun this 6d. rate, and seeing such an enormous development in so short a space of time—for we have not been competing for more than three months—I think we may expect, having done that in three months, to do a great deal more in twelve months. While we were anxious to avert this lowering of the dividend, I think we have struck a vein in submarine telegraphy which we are determined to see to what extent we can work; therefore, we have made up our minds to do that, and I hope it will meet with the approval of the shareholders, because our shareholders during the last eighteen months have encouraged us to go in to this fight, if a fight was necessary. It is, however, a fight which I hope will result in an enormous increase of our traffic, and I hope in the permanent establishment of low rates. At all events, as business men, we have determined to give it a fair and proper trial, and we hope we shall meet with the support of the telegraphing public, and that our shareholders will also be patient, and contented during the next twelve months and approve the very modest dividend which we are going to declare to-day; and if we have the support of our shareholders depend upon it there is a considerable future in the policy which we are advocating. My reasons for saying that are these: We have eight cables. I put the Commercial cables out of the question altogether. If the matter had been seriously and well considered by the Commercial Company, their cables ought not to have been in the Atlantic to-day. There was no call for them; there was no necessity for them; and every cable that is put down in the Atlantic makes it more difficult to lower the rate, because you are putting a larger amount of money at the bottom of the sea, and, consequently, you are less able to give a return upon that additional capital. Telegraphy does not grow so as to give, even at very reduced rates, the return which these additional cables would require in the way of increased traffic. But as I have said, we have eight cables, and these eight cables, which are capable of carrying over forty million words per annum, are at the present moment carrying only about fifteen million words. That shows that there is an enormous margin of cable power, and we think it better to use that cable power, at all events for a time, in giving an opportunity to the telegraphing public to double, treble, and I hope quadruple the amount of the present traffic. If that is the case I think it will be unnecessary to return to rates much higher than those charged at the present moment. I may mention another fact—that I doubt if we should have been in a very great hurry to reduce the rate from 1s. 8d. had it not been that the competition was carried on on a principle which we could not approve. In fact, our traffic was being taken away from us under pledges and promises that we have never been any party to, ourselves, and consequently when we saw that practice going on to an extent that was interfering materially with our traffic, we thought the time had come when we must put our feet down and take a firm stand. That we have done, and, as I say, I hope with the prospect of considerable success. I may mention that while we have reduced the rate to 6d., the Commercial Company have only reduced theirs to 1s. We learn that a very large amount of the support they are receiving comes from America—that their principal traffic from this side is influenced by the same public. Now, I know something of the American public, and of American mercantile life, and I do not know of any community who appreciate more accurately the value of a dollar than the American public do. They have gone on for a short time paying this 1s. on the promise that 6d. was to be returned to them if they ever return to a tariff exceeding 1s. 8d. I think we may give up the idea of 1s. 8d., and I think that when the American people find out that they can get their work done—I will not say better, but as well—with our eight cables, the American people are not likely to pay 1s. when they can get the work done for 6d. I have made a remark that the Commercial Company came into a field of which they had very little knowledge, but of which their experience by now must have satisfied them that they would have done better to leave their money in other investments than put it in telegraph competition; but I think before this competition is at an end they will find that the representations made to them—as I believe they were—that enormous dividends were to accrue from these cables were all fallacious—that probably those who promoted them were the only parties who got any benefit out of these new cables. I hope, at all events, it will be a lesson to those who enter on telegraphy in the future that they should understand the business thoroughly, and its conduct from all points of view before they put such large sums of money at the bottom of the sea as these gentlemen have. I may say that the competition, while it has been going on, has been conducted in such a spirit that there is no reason to complain of. I see that our customers are coming back again, that we are doing our work in a way that is commanding the confidence and respect of the public generally, and as we have made up our mind to give this 6d. rate a fair trial I think we shall very soon find that the bulk of the Atlantic telegraphy is passing over our system. Now, gentlemen, with these remarks I beg to move the following resolution:—

"That the report of the Directors dated 9th July, 1886, together with the statement of accounts to 30th June, 1886, annexed thereto, be and the same are hereby received and adopted, and that a final dividend be now declared of 2s. per share, free of income-tax, making, with the interim dividends already paid, a total dividend of 2¾ per cent. for the year ending 30th June, 1886."

Mr. WILLIAM FORD: I beg to second the resolution.

The CHAIRMAN having invited discussion,

Mr. JACKSON said he was glad that the Company had decided on cheap rates. In the past the old companies had been held *in terrorem* over the heads of the public, and it had been said of them that when they had succeeded, by cutting rates, in crushing the opposition brought against them, they would raise the rate to 2s 6d., or 3s., or higher, and he believed that was at the bottom of the competition of which the chairman had complained. He thought, under the circumstances, that the directors had been justified in entering on a war of rates. He did not think that the dividend proposed ought to be paid, and that the Directors should have done what the Anglo-American Company had done, viz, the amount proposed to be distributed should have been put to the reserve fund. If, as he trusted, the shareholders would support the united Board—and especially the Anglo-American Board—in the present struggle the Company would be able to assume a position which they had never done before. They would be acting on commercial principles in developing traffic. He trusted that the shareholders would support the Directors, even to the extent, if it were necessary, of going without a dividend for a short time [no, no]. He did not say that it would be necessary, but they had to compete with a company that was very keen.

Mr. JOHN NEWTON congratulated the meeting on the bellicose tone of Mr. Jackson, of whose remarks as to the way in which the Directors were meeting the competition he heartily approved. He thought they should sympathise with the shareholders of the Anglo-American Company in having to go without a dividend, but he did not think that they in the Direct Company would have to do so. The constitution of the two companies was quite different. The Anglo-American Company could not use its reserve fund, but the Direct Company could do so in a proper way, and they could rely upon it for the maintenance of their income. The Direct Company could pay a dividend in the face of any competition so long as it had a substantial reserve fund, which was the backbone of the company. It was that fact which maintained the value of their shares.

Mr. W. GRIFFITH said he did not wish at the present critical period of their history to criticise in a harsh spirit the policy adopted by the Board; but at the same time the shareholders had to pay for it, and pay very heavily. Their dividends had fallen, and they appeared likely to fall. One reason why he objected to the present warlike policy was that they had to pay heavily for it, and that they had adopted it in the past and had not found it pay. He thought the unclaimed dividends might be utilised for the purposes of the Company, following the example of some other companies.

Mr. E. M. UNDERDOWN: The quotation would be stopped if you did.

Mr. GRIFFITH dissented.

The CHAIRMAN pointed out that the amount at present was only £227. Now I will reply to Mr. Jackson. Probably no question has had more serious consideration by your Board than that of paying a dividend at the present time; but what we felt was that having made up our mind to this low tariff, and having determined to continue it for a very considerable period—at least, for such a period as would thoroughly enable us to judge whether these low rates were going to give us the required amount of traffic to pay moderate dividends—we thought it would only be just and right, not only to the interests of the Company, but to the shareholders, that we should try and give them a small dividend (hear, hear) to encourage them with us to fight this battle; because if you have reluctant shareholders behind you, you never can fight with the same success that you will if you have every share-

Digitized by Google

holder heart and hand with you. Therefore we resolved to do this, and thought we might fairly do it. Our Articles of Association entitles us to take from the reserve fund such an amount as the Directors would consider necessary for equalising our dividends. We have, therefore, considered it desirable during the present competition to be generous as well as just to the shareholders, and instead of carrying the net earnings for the past half year, viz., £12,578 to the reserve fund, which we might have done so as to keep up our annual contribution to it, we have paid that amount to the shareholders, and have carried to the reserve fund as usual the full interest earned on that fund. Therefore we have been alike just to the shareholders by giving them a dividend—a dividend making up the rate for the year to 2¾ per cent., being equal on the market quotation to-day to 5½ per cent. Having established for you a very sound reserve fund—I would not say "ample," because that is not the word—an amount of £325,000 ———

Mr. UNDERDOWN: £5. 7s. a share.

The CHAIRMAN (continuing): Having done that we are in a position, for a short time at all events, to suspend adding to the reserve fund preferring to keep our shareholders in good heart, and give them some return while the fight is going on. That is the reason we have been anxious to meet you in this respect, at the same time doing equal justice to the reserve fund. We have placed ourselves in a position that I am quite sure you will be prepared to fight for. I am not going to say for what period; but as long as we are able to show you that we are increasing our traffic enormously, or largely, and have a prospect of being able to give you a dividend in future out of these reduced rates, I think you will encourage us to go on. I believe myself that telegraphy is yet comparatively in its infancy. The development that has taken place is something enormous in this instance. I have been asked the question why we did not get the same result when the rate was 6d. before. I cannot give you a better argument than this—that telegraphy since then has taken such a hold of the public—the commercial, social, and political life of the world, not only in small things, but also in large things—that this rapid development at the low rates is simply from the effect of what I state. Every man must have telegraphy. He cannot do without it. I believe there is scarcely a man in this room who does not use telegraphy many times daily in the course of the year. I have told you that we are strong from our reserve fund. Our associates, the Anglo-American Company, are equally strong in their reserve fund, and if ever there were two companies in a position to work out this problem, we are in that position; and we are determined to do it, and we will place the matter in such a way before the public that they will not be able to cry out for reduced rates if they do not support us. As to the proxies, I may say that we have passed a resolution to-day that our proxies should be paid for by the Directors, but having done that to meet the law, let me answer this gentleman, who says that if people do not come to the meetings they have no right to be represented. We have 1,450 shareholders, and I suppose there are not 100 here. A great number of those shareholders have three, five, seven, or ten shares. Surely their interests are entitled to be protected. If we had no proxies—this occurred the other day in France—people might combine against us, unknown to us, and upset your business. Men who are your enemies, who are antagonistic to your interests, might do this, and before the danger could be averted, the whole thing might be upset. You must have confidence in your Board. I would very much rather that proxies went out and that every man would put a stamp on himself. We do not want to do anything that our shareholders do not thoroughly approve of. It will come to this—that one of these days if I find difficulties arising in anyway I may ask you to pass a resolution to support the Board by authorising the Directors at public meeting to issue proxies. We must not be taken by surprise. We are protecting your interests. We have shown you that we have protected them from the very first of our taking office, and we will continue to do so. If you think that in sending out proxies we are doing an unjust thing or anything to hurt you at your expense, you are making a mistake. We only ask you for your confidence and support by giving us your proxies, and I am pleased to say that we are getting a large number of proxies. However, to be in perfect accord with the law the Directors will pay for these proxies; but I hope that a gentleman such as Mr. Jackson will later, without my saying anything more, propose a resolution, authorising the Directors to pay this expenditure. That would throw the responsibility upon the shareholders, and show that the shareholders had perfect confidence in their Board. He then put the resolution in the usual way, and it was carried. Continuing, he proposed the re-election as a director of Rear-Admiral R. C. Mayne, C.B., M.P.

Mr. UNDERDOWN seconded the motion.

A discussion followed, at the instance of a shareholder, who thought that in the present crisis the Directors' remuneration of £3,000 a year should be reduced to £2,000, or that the number of Directors should be reduced from eight to six, a corresponding diminution being made in the amount of the fees.

Mr. JACKSON and Mr. NEWTON, on the other hand, argued that the proposal was inopportune, and, that it would be unjust at the present time, when more work than usual was thrown on the Directors, to reduce their remuneration.

The CHAIRMAN, in reply, stated that an alteration in the number of the Directors would require an alteration in the Articles of Association. If, however, a resolution to that effect were brought forward at a meeting of the Company, and was approved by the great body of the shareholders, the Board must submit. At present the Directors were acting in accordance with the Articles of Association. He might add that the first act of the present Board on taking office, having after a very hard fight rescued the Company from wreck, was to reduce the remuneration of the Directors from £4,000 to £3,000 a year. Previous to that the Company had been in existence three years, and had not paid the shareholders one penny, the Directors at the same time taking £4,000 a year. In the time of the present Board the fees had been reduced by £1,000, they had built up a very large reserve fund, and until the last year they had paid a dividend of 5 per cent. If any crisis should arise in this Company rendering it necessary for the Directors to make a sacrifice they would be the very first to offer to do so.

The resolution was carried; and a similar result attended the election of Mr. Charles Meara, who was proposed by the CHAIRMAN and seconded by Lord HAWKE.

On the motion of Mr. JACKSON, seconded by Mr. WEAVER, Mr. John George Griffiths and Mr. John Sawyer were re-elected auditors for the ensuing year at a remuneration of £50 each.

Mr. GRIFFTH then proposed a vote of thanks to the Chairman, Directors, Secretary, and staff, whose services he warmly acknowledged.

Mr. JACKSON seconded the motion, which was carried unanimously.

The CHAIRMAN, in reply, said that at the present time a great deal of care and attention were required in watching over the affairs of the Company, and he was pleased to state that the Directors received the very greatest support from the secretary and traffic manager and staff in the conflict that was going on. The remarks which had been made in the course of the discussion had been in a very proper and courteous spirit, and the Directors received them in the same spirit. He would only add that if shareholders desired their business to be well conducted they should pay Directors well and hold them responsible, and then if Directors did not do their business well, shareholders should get quit of them as soon as possible.

The proceedings then terminated.

Edison and Swan United Electric Light Company (Limited).

The annual general meeting of the shareholders in this Company was held at the Cannon-street Hotel on the 27th inst., under the presidency of Mr. James Staats Forbes.

The SECRETARY (Major S. Flood Page) read the notice convening the meeting, and the report of the Directors was taken as read.

The CHAIRMAN, in the course of his remarks in moving the adoption of the report, said: It would be very gratifying to us in a concern of this sort, not yet emerged from trouble, to have a larger attendance of proprietors, but such as the meeting is we shall be very glad indeed to put before it all we have got to say. The report is not as satisfactory as we hoped last year to have been able to present, and yet it is not entirely unsatisfactory upon some other points of view upon which I shall have to enlarge as I go through it. We wound up our meeting last year by wishing on both sides of the table that the prosperity which then for the first time had seemed to have been achieved for the company would continue. Well, it has not continued, but perhaps when we come to the details of the report we shall see there are some reasons, which, although not entirely satisfactory as regards the financial outcrop, still leave us with some grounds for satisfaction upon other points. The whole story is told in the second paragraph, which states that there has been a considerable diminution in the number of lamps sold in the year. The diminution is so considerable that it is the difference between a considerable profit and a very inconsiderable—in fact, quite nominal—profit which is shown by the accounts themselves. We have had a reduction in the year in our sales of lamps of no less than 125,000 compared with the present year. Well, we have tried, of course, to find reasons for that. One principal reason is that in the previous year we were the manufacturers for a great foreign trade. That foreign trade is in the hands of another corporation with which we are allied, and in their discretion—whether it will turn out a wise discretion or not we need not discus here, we shall have to discuss it later on—they, following their undoubted right, thought it more in their interest to manufacture lamps abroad than to take them from us. That accounts for the greater part of that deficiency—74,000 lamps which we sold last year to the Swan Company for their foreign business they have manufactured for themselves this year. Of course that has this effect upon our business with regard to the number of lamps, that the greater the volume of lamps you put out the less is the relative cost of the lamps; I mean to say that the fixed charges of producing a small number—relatively small number—are the same fixed charges as for producing a larger number, and the profit upon those 74,000 lamps realised last year would have been as great this year if we had made them, without any appreciable addition to the fixed charges. Of course, there would have been the charge upon the mere material of the lamp. Well, then, on the home consumption there has been a decrease of 41,000, and I think that must arise from two causes. First of all there has been the infringing. No doubt everybody makes lamps—a great many people rather—and infringers, like other sinners, got bolder by immunity, and we were not in a position until very recently to call those gentlemen to account. Of course you know what patents are, and with regard to yours, at great cost you have established their legal validity. Everybody knows in this country that the law marches very slowly, and the wrongdoers get a great pull, because it takes a long time to get justice. That has been our case, and we have in the interim between our last meeting and now been successful, notwithstanding a great many evasions of the issue and postponements of our anxiety to have the case tried, and we succeeded at the trial upon every point which we contended for. In both of what may be called the key patents of this undertaking—the Edison patents and what are called the Cheeseborough patents, the only two patents out of a great number of others, including the Swan, which were brought up for consideration, attack and defence—the issue was in our favour. If you turn to paragraph four you will see we have told the story in much more concise words than I have explained it, but the two actions which the Company brought against Messrs. Woodhouse and Rawson for

Digitized by Google

infringement have been tried, and Mr. Justice Butt has decided both suits in our favour. Well, then we have a little laudation and congratulation, of course. If these judgments are upheld no doubt a great benefit will be secured to the Company. In fact, it secures to the Company, for what it is worth, the value of these patents as commercial machines, and puts, so to speak, a muzzle on infringers. As I said before at the last meeting, there are plenty of people who are quite willing when somebody has taken the risk of producing a serviceable thing to step in between the man who has taken the risk and his profit, and you can only keep them in order by these proceedings and getting these judgments. Well, then, what is going to ensue upon that? The Directors are obliged to take the responsibility of expressing opinions. They say that "the result cannot fail to have a favourable influence on the prospects of the company." Well, we know as a matter of fact, there have been an enormous number of lamps made by different people—Messrs. Woodhouse and Rawson, and a great many others—which have found their way into use, and are in competition with ourselves both in price and as used materials. We do not not know if the people who make them get any profit, or not; but we at all events lose that profit which we should get if we made and supplied them. Well now, that judgment is all specifically in our favour, but of course these gentlemen have the right to appeal. We only wish they would; we are very anxious they should appeal. We are advised by the same eminent counsel who have conducted these proceedings so far, and whose predictions about the result of the proceedings in the first instance have been verified—we are persuaded that if appeal is sought the result will be the same. We have a little inkling of the effect of these judgments from the fact that the orders which have since been received for lamps have materially increased, and we know also as a matter of fact that Messrs. Woodhouse and Rawson themselves have withdrawn their advertisements, and I suppose are not pushing a trade which is under ban, and the pushing of which would entail some rather serious consequences. That is a crumb of comfort one finds in the report. Anyone can do a sum, and will see, to boil it all down, that it comes to this—that notstanding infringements, notwithstanding the slow progress which is being made in electric installations, and notwithstanding the competition which has been going on in virtue of these infringements, we have managed during the year to hold our own. We have not made such a profit as we thought we might have made, but we have not gone back, and in the course of the year, as the accounts reveal, we have been able to get rid of the more dangerous parts of the business—bad contracts in what they call installation rents, and so forth, as I shall explain presently—and also to effect considerable economies in mere working cost, and you will see what results. With a largely diminished sale, and with fixed charges which must necessarily be high, plus the cost of manufacture, we have got pretty nearly an even balance. Well, now, we believe we are treading very safe ground; and it comes to this—every gentleman can induct it from his common sense, the same as we can—if we can increase the output of our lamps, and the sale of our lamps from 161,000, which is what we have sold in 1886, to 286,000, or any other figure you like over 161,000, at practically the same fixed cost—then it does not want any very great arithmetical power to prove that the capital of the Company, which is in round numbers £300,000, is not very far off a dividend, because there is a fair profit upon each lamp. Suppose we put it at 1s. 6d.—100,000 lamps at 1s. 6d. profit—everybody can do that sum, and having got 100,000 in your mind, you can add to that by 25,000, 50,000, 75,000, or another 100,000, and that is really what we ourselves are trying to do. I think I can speak for my colleagues. Mr. Leyland is very much interested in the matter, and takes an enormous amount of pains to follow this out. Lord Anson and other Directors are not indifferent as regards either their pockets or their reputation in regard to this thing coming out right. I think we are all satisfied that what they call "humanly speaking," with these patents secured, with the slow—rather too slow—but still certainly, growing appreciation of the public as to the advantages of this light for the purposes to which we intend to apply it—domestic purposes, factories, and so forth—there is a reasonable prospect that at no distant date, perhaps in this very year, there will be a tangible profit to handle. I have administered this "song of the swan" so often that I sometimes doubt whether I am quite sincere about it, but I assure you that I know I am. I am quite certain about this; I believe this thing is now in such a position that there is a reasonable future—an immediate reasonable future—for the Company, and I am not sure that my conviction and that of my colleagues does not go a little beyond that—that in the course of a moderate number of years there may be a very excellent outlook for this Company, because I am not at all aware that the prosecution of our business to the manufacture of a very large number of lamps involves the outlay of any more money, and I am not aware that the fixed charges of conducting your business—such as rent of premises, rent of offices, and establishment charges—are likely to be at all influenced by a very much greater output of lamps than we are producing now. The only additional cost that I can see attending doubling or trebling the number would be the material and wages incidental to the mere production of the article, and as the profit on the article so produced is a reasonable one—1s. 6d. or something of that sort—if you can produce a quarter of a million one and sixpenses, you can do the sum and see how much dividend that will pay on a capital of £300,000. I know shareholders like to have a little detail. I have told you about the lamps—that there has been a large diminution in the number sold. I have explained that of that number 74,000 is foreign and 41,000 at home; and that I think we are very likely to alter those figures in the course of the present year. That is based on the fact I have just told you, that since the judgment our orders have come in in a much larger proportion than in the corresponding period of last year. In paragraph 5 we state that we have given, as was our duty, notice of the judgment to manufacturers of incandescent lamps who have infringed. Some of these caved in, as it is vulgarly called, at once; they saw it was no use attempting to disregard such a judgment. Others are negotiating with the company, and the shareholders may rest assured that every effort will be made to uphold their rights, which have suffered so seriously by infringements. Of course that is our duty, and it is our right under these judgments; but I see Mr. Sellon looking at me. We are not going to do that in a manner which would be offensive to the public or injurious to our character as men of business dealing with a matter of this sort. We have succeeded already in inducing one at least, and perhaps other large consumers, to adopt the views we put before them, so that they will be left in undisturbed possession of the infringing lamps, merely recognising our right to have the profit instead of the infringing manufacturer. I dare say that is the spirit in which we shall treat all people who meet us in a reasonable way, but if they do not we shall know how to meet them. As long as people are reasonable we shall be reasonable, but if we are driven to defend our rights we shall do so against all comers. There is one other branch of our business which has been a very sad story. I am afraid the history of every man's own career shows that there are many things which he could wish undone, and combinations of men of business are not always wiser, I have found, than individuals. Our combination is one in which we could wish many things undone. One of the worst things we ever did was to believe—well, what shall I say?—on something like speculative knowledge that installation work at rentals was going to be a very excellent business. We have found that not a single installation that our Company has been concerned in from first to last has been anything but a tremendous loss, and when it fell to the lot of the present united Board to sit down after the amalgamation—which after all took place not so very long ago—and "bottom" all this sort of thing, we were face to face with the serious results of mistakes of both companies. Now, we have been working these things down, and last year I had to report that we had got rid of some of these bad things. This year I am happy to say we have got rid of others. Practical experience—other people may be more happy—but our experience may be used for illustrating this proposition: That no installation for the supply of the electric light on rental, on the principles laid down for our guidance, and accepted by the Board under the advice of experts, can possibly land the undertaking in anything but ruin. Of course I am only saying upon our principles. We were told, and it was drummed into us over and over again, and I think I took myself an active part in the proceedings before the Board of Trade and in Parlianent, and every inventor connected with this business had but one fixed idea—that the supply of electricity for lighting could be safely undertaken at about the price of gas. Well, that has turned out to be utterly illusory, and, in our case, the long and short of the matter is that we have lost very heavily upon all those contracts in the mere maintenance—that is to say, that after you have put in the machines and sunk your capital, the mere running of the machines in every case swallowed up all the rent you had got, and you are left with the machinery on your hands high and dry to get rid of at an enormous loss. That is what we have gone through. We have got rid this year of the installation at the Holborn Restaurant to Mr. Gordon. We came out of it very badly indeed, at a very large sacrifice of capital on the original installation, and a very serious loss through the running. Another gentleman, Mr. Gatti, rented an installation, and the results were so bad that, having an opportunity of terminating the agreement in the autumn, we have given notice to do so, and we shall come out of it, I dare say, with a loss. We must pocket it, for it is no good crying over it. The sooner you know where you are in these matters the better. We have one legacy of that kind remaining on hand—that is the Victoria Station—of a distinguished railway company with which I have some connection. Well, that one has some elements about it of consolation, though at the present moment it involves a loss. It was installed for the purpose of lighting not only Victoria Station, but to supply some neighbours, the Brighton Railway, the Grosvenor Hotel, and others. It has not been extended to that for the reason that the machinery first put down was not sufficient to produce the power. We are now supplementing that machinery by other machinery of our own, and we hope the result will be to extend the area of supply, which we can do without infringing or interfering in any way with the Electric Lighting Act, or having to get the sanction of the local authorities, because it is all on private ground, and we hope the result will be, if not to realise any brilliant profit on the outlay, at all events to remove any serious loss. Therefore, what we are going to do is very much this—we know with regard to the lamp business there is good reasonable hope that that will largely increase, and will bring us considerable profit; with respect to the installation business, we know that the heavy loss resulting from that up to the present time is now nearly wholly removed. The seventh paragraph says that installation work on payment has been very slack during the past year. There is no doubt that is so. You will remember that last year, under the inspiration of the Board of Trade, a committee of the House of Lords was appointed to consider the Electric Lighting Act of 1882. There are still some people so sanguine as to believe that electric lighting for public purposes on a large scale can be carried on under the conditions of that Act. There was a long inquiry. Lord Camperdown was chairman, and we had a great many distinguished men on the committee. Sir Frederick Bramwell said that it was quite impossible that electric lighting on anything like a large scale could be conducted in London—at least, under the provisions of that Act. The Board of Trade seemed to think that all that was wanted was an extension of the period from 21 to 42 years. That was all that they could concede. In regard to all the other vital questions they were left exactly were they were. The insertion of a clause, which the committee declined, was wanted in the Bill which was promoted in the House of Lords. The result of it all was that the Bill was withdrawn, and therefore the Electric Lighting Act stands exactly as it did before the Bill was introduced, and electric lighting, in London, at all events, remains practically impossible. Of course, while people were believing that they were going to have very

Digitized by Google

soon, under some amended legislation, a kind of public supply of lamps in their houses, it was not a very good time for private installations. I think it not improbable that that may account for a period when the installation business was practically suspended. Well, then, the secretary reminds me—I do not know whether I ought to confide this to an appreciative public through the press; but the fact is, and of course everybody can see it—that if you make a lamp to last for ever, there can be no renewals of it; and really our lamps under improved processes are made to last so long that when once an installation is equipped, the percentage of renewals is generally diminished. Whereas it used to take, let us say, 25 per cent. in the shape of new lamps in the course of a year, renewals are now down to something like 12½, so that there is at once a factor rather telling against ourselves. Perhaps it is not impossible that when a lamp becomes so greatly improved in life and efficiency by the application of skill and science the price may go up. I dare say every man of business here can understand that the percentage of renewals has diminished with the improvements in the lamps, but the price of the lamp remains the same. I do not know that I have anything more to say on the report. If anybody would like to analyse the accounts or to ask any questions upon them, I shall be happy to go through them. I will first advert briefly to them. The proprietors have got them before them; they are pretty simple. About the share capital, I may say that remains exactly as it did last year. There are 17,000 odd A shares paid up, 89,261 A shares £3 paid, and 23,564 B shares fully paid—£5 each. The B shares are entitled to one-fourth of the profits after a cumulative preferential dividend of 7 per cent. has been paid to the A shares. That is not an immediate contingency, for there is a very large amount of preferential interest due. Then there are sundry credit balances—£13,350, and the profit and loss balance of account for the current year is £24. 5s. 6d. Now, I thought myself, when I saw that, that it was surely very humiliating that we should have spent the whole of the year in making only £24. 5s. 6d. I have, however, explained the reason of that, and I cannot attribute to any gentleman in this concern responsibility for the falling off in the sale of lamps which might have made that £24. 5s. 6d. £12,000 or £15,000. On the other side of the accounts is the investment of your money. Well, that is a very old story. As I said before, what is the good of crying over spilt milk? When that money was invested in that way the people who did it were very unwise; but they were only unwise in common with the rest of mankind. Everybody thought that it was to be a gold mine, and very large sums of money were paid for patents, which turned out to be exceedingly doubtful, and involved a very large expenditure to establish them legally, and on the theory that those patents would realise very large results. Up to this time they have not done so. I do not know whether the consciences of those people who received the money are at all tender, or if they are affected by the present outcrop; if they are, they would immediately proceed to refund a large amount of the sovereigns which we paid for what has turned out to be almost worthless. I do not know whether any of them are here; I am afraid not. We have reduced, in the manner shown, the cost of patents, preliminary outlay, loss on working, &c., to £298,354, plus the B shares, £117,820. I have now told you the whole story, and I shall be happy to answer any questions which may be asked.

Mr. F. R. LEYLAND seconded the motion.

Mr. PORTER thought that the Chairman had made a very lucid statement, and had clearly shown that the reason for the small profit last year had been the diminution in the sales of lamps. Were the foreign sales likely to increase?

Mr. PRIOR inquired whether a large sum was not hanging over them for legal expenses, and whether a call might not be necessary.

A SHAREHOLDER asked if the Directors had taken the trouble to find out the value of any reliable asset at the present moment.

The CHAIRMAN, in reply, stated that litigation was going on in connection with the patents abroad, and there was no doubt that while that was pending the sale of the lamps was affected. So far, however, the sales abroad had not decreased. In some of the proceedings they had got the best of it, and in some cases they had got the worst, but no definite result had yet been arrived at, as had been the case with the Company in this country. They were trying to patch up peace between the contending parties. It was a curious fact that the most severe contest abroad should be taking place between the two interests which were happily united at home—the Edison and the Swan. He hoped that the result would be to bring the two together. As to the legal expenditure, the further expenditure "by cost of patents," &c., last year had been £8,104, a considerable portion of which had been for legal expenses on the patent cases. They had decided that it was not fair to charge the income of one year with the cost of establishing this patent, and therefore part of that outlay would be borne by revenue of future years. There was nothing very serious hanging over them. In connection with this matter it would be remembered, as stated in the fourth paragraph of the report, that "the amount due from Messrs. Woodhouse and Rawson under the judgment cannot yet be estimated, and has not been brought into the account." They would now be able to go into the matter, and they had reason to believe that they would have to receive a considerable sum from that firm on account of the lamps sold by them; and of course they would receive the costs of the proceedings. As far as they could see at present, they did not think that there was the slightest possibility of any further call being made. They had a considerable cash balance in hand, and debts and other assets. They had no intention of making a call, and should it be necessary the shareholders would first be consulted. He feared that if they were to wind up to-morrow, the value of the patents and of the B shares—together representing in the balance-sheet an amount of £416,000—would not be much. Then they had their freehold property, standing at £32,000 (less mortgages, £20,300), plant, debtors, cash, &c., amounting altogether to about £70,000, all of which were really good. The resolution was then unanimously adopted.

On the motion of Mr. PORTER, seconded by Mr. PRICE, the retiring Directors, Viscount Anson and Mr. Ernest Villiers, were re-elected; as were also subsequently the auditors, Messrs. Quilter, Ball, and Co.

A vote of thanks to the Chairman and Directors then terminated the proceedings.

Submarine Telegraph Company (Limited).

Report of the Directors to be submitted at the meeting of the proprietors of the Submarine Telegraph Company, to be held at the offices of the Company, 2, Throgmorton-avenue, E C., on Tuesday, the 3rd August, at 1 o'clock p.m:—

The accounts for the six months ending 30th June, 1886, show that the joint receipts amounted to £62,643. 4s. 1d., and the expenses to £27,303. 13s. 3d. The receipts are less than those for the corresponding six months of 1885 by £4,152. 12s. 10½d., and the expenses are greater by £3,006. 5s. 9d. The net profit is therefore reduced by £7,158. 18s. 7½d. The result of the half year's business enables the Directors to add the usual proportion of the gross receipts to the reserve fund; to recommend a dividend at the rate of 12 per cent. per annum; and to carry over a balance of £523. 5s. 7d. to the new account. The falling off in the receipts is due in a considerable degree to the reduced length of the messages. The average length of the messages in 1886 was 11·05 words, against 11·72 words in 1885, and the number of messages transmitted in the half-year was 20,777 more, but the number of words was 747,315 less than in 1885. The falling off in the receipts is also partly due to the diminished traffic received from the Indo-European Company and the Eastern Telegraph Company. The increase in the expenses is to be accounted for chiefly by the increase in the salaries of clerks; an additional amount paid to the French Government for the services of their staff; and by the increased cost of the repairs to the Company's cables, amounting to £2,095. 12s. 11d. This increased cost arises from the insertion of a new length of about five miles in the Havre cable to remove some faults in the conductors, and from the repair of four other cables broken on more than one occasion in the half year in the usual manner, viz., by dragging of ships' anchors. During the whole of the years 1884 and 1885 there was a remarkable immunity from these accidents. The result was that the drawback paid by the insurance company for the time the repairing vessel was in port extinguished the usual half-yearly charge for insurance in the accounts for the six months ending December, 1885, and left a balance, which has greatly reduced the ordinary charge for the present half-year. The cables belonging to the Government in the North Sea have not been interrupted in the half-year. All the Company's cables, as well as those worked by the Company, are at the present time in good working order.

NOTES.

VALPARAISO.—The Edison electric light system is about to be introduced in the City of Valparaiso, Chili.

PERSIAN CABLE.—The cable between Fao and Bushire, which has been interrupted for about three months, is now restored.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 30th inst. amounted to £2,461.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending July 31st were £3,050.

THE CITY AND GUILDS OF LONDON INSTITUTE.—The honour of knighthood has been conferred on Mr. Magnus, the secretary and manager of this institute.

INSURANCE.—The American electric light companies are taking steps with a view to forming an association for the mutual assurance of their stations.

THE TELEPHONE IN SWITZERLAND.—Direct telephonic communication will shortly be established between the little town of Aarau and the exchange at Zurich.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of July amounted to £43,708, against £48,081 in the corresponding period of last year.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of July amounted to £1,270, against £1,284 in the corresponding period of last year.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of July amounted to £34,931, and to £46,099 in the corresponding period of 1885.

TELEPHONE CONVERSATIONS AS EVIDENCE.—In a recent case at the St. Louis Circuit Court, U.S.A., the Judge decided that telephone conversations are admissible as evidence, even when the speaker's voice is not recognised.

THEATRE DU PALAIS ROYAL. — The electric lighting apparatus which is now being put up at the Theatre du Palais Royal is rapidly approaching completion. It is expected that by the time the house reopens the installation will be finished.

WEST AFRICAN CABLES.—We learn that the Silvertown Company's telegraph ship, the "Dacia," has laid the shore ends at Accra for the Accra-Grand Bassam and Accra Porto Novo sections of the West African Telegraph Company's system.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 30th July were £2,037, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE ELECTRIC LIGHT IN THE CANARY ISLANDS.—Spanish advices from the Canary Islands state that, should the proposals made by an English firm be accepted by the authorities, the whole of the city of Las Palmas will shortly be illuminated by the electric light.

INCANDESCENT LAMP PATENTS IN AMERICA.—It is stated the Consolidated Electric Light Company of the United States are about to bring an action against the Edison and other companies for infringement of the U.S. patent of Sawyer and Mann, of which they are the owners.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 31st July were £2,376, as compared with £2,602 in the corresponding period of 1885. The April receipts, estimated at £5,762, realised £5,699.

EXTRAORDINARY TRANSMISSION OF POWER.—A friend writes:—"I think the most astonishing thing I saw in the [Indian and Colonial] Exhibition was a dynamo which the placard stated was supplying current to drive two motors, 'one in South Africa and the other in New Zealand.'"

DAMAGING TELEGRAPH POSTS.—At the Worksop Police Court, last week, George Jackson, John Hanstock, and Chas. Whitehead, all of Carlton-in-Lindrick, were charged by Police-constable Empson with damaging insulators on telegraph posts on the 25th July. They were discharged on payment of costs.

THE TOWER SYSTEM.—A tender has been submitted to the Municipal Council of Columbus, Ohio, for lighting the town upon the tower system. It is proposed to erect forty-three towers, each carrying four lamps of 200 candle-power. The price asked for the maintenance was slightly under $4,000 per month.

HONOUR TO TELEGRAPHISTS.—On the proposition of the French Minister of War, M. Glin and M. Jacques have been nominated for the grade of Knights of the Legion of Honour, the former for 23 years and the latter for 27 years' distinguished service in connection with the military telegraphs of France.

THE TELEGRAPH IN ALGERIA.—The telegraph system in Algeria has recently been extended by the establishment of several permanent heliographic stations. By this means communication is now maintained with the Dabila Oasis, which is 200 kilometres to the south of Biskna, where the electric system terminates.

ELECTRIC LIGHTING IN BANKS.—The Union Bank of Australia, a portion of which is being rebuilt, has decided at the same time to adopt the electric light. The order for this work has been entrusted to the Electrical Power Storage Company, in view of the success which they have already obtained with this class of lighting.

HOTELS LIGHTED BY ELECTRICITY.—The Hotel Schweizerhof, at Lucerne, is now lighted by means of 600 Edison incandescent lamps, and the installation is about to be increased by 600 more of the same kind. The Hotel National of the same town, following the example set by its rival, will shortly be lighted by the Edison system.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of July was 3,411, estimated to produce £2,800, against 3,058 messages, producing £2,517 in the corresponding month of last year. The traffic receipts for the month of April, estimated at £3,300, realised £3,349.

BOOKS RECEIVED.—We have received a small *brochure*, entitled "Electric Lighting for Private House," from Mr. Wilson Hartnell, of Leeds. The pamphlet directs attention principally to the superiority of the electric light from a sanitary point of view. A sheet of drawings of electroliers is appended; some of these show new designs of much elegance.

WANT OF CONFIDENCE.—The new theatre at Halle is to be lit by electric light. It appears, however, that the management has no great confidence in the system, for in the whole of their contracts with their *employés* it is expressly stipulated that in the event of any performance being interrupted by the

Digitized by Google

extinction of the electric light no payment shall be made for that night.

CORED CARBONS.—Cored carbons are now being made in America by a new process. The harder carbon is first moulded in the form of a hollow cylinder and thoroughly baked. The soft material is then introduced to form the core, and after this the rod undergoes a further process, the details of which are not made known. These carbons are said to have given very satisfactory results.

A TELEPHONE COMPANY SUSPENDED.—The operations of the Meucci Telephone Company at New Jersey have been stopped by the Courts, in consequence of a charge of infringement preferred by the Bell Telephone Company, of Boston. The subscribers already connected with the central offices of the company have been required not to make use of their telephonic apparatus pending the trial.

THE RECENT FIRE AT CLERKENWELL-GREEN.—In reference to the fire which took place at Clerkenwell-green on the 23rd ult., and by which the works of Messrs. Eck, Callow, and Co., and Frederick Young and Co., were entirely burnt out, Messrs. Eck, Callow, and Co. desire us to state that pending the re-establishment of their works all communications should be addressed to No. 11, Clerkenwell-green, E.C.

THE TELEPHONE IN WURTEMRURG.—About sixty verbal communications are made daily between Stuttgart and Heilbronn, by the Van Rysselberghe system. In presence of this success, the telegraph line between Stuttgart and Boeblingen has also been arranged for the telephone. Several Ministers and high functionaries, who were present at the inauguration, expressed a wish for telephonic communication to be established between Stuttgart, Ulm, and Friedrichshafen, a distance of 200 kilometres, or 124 miles.

ELECTRICAL INDUSTRIES IN THE STATES.—A New York correspondent of the *Mechanical World* says that the demand for electrical machinery continues to be the feature of the American market. Within three months twenty-three electric appliance manufacturing companies have been organised, and over 100 cities and towns are now having electric light plants put in. A great deal of experimental work is also being done, and although up to the present the application of electricity as a motor has not been entirely successful, yet experiments continue to be made in this direction.

THE ELECTRIC LIGHT AT HADFIELD.—The enterprising firm of Messrs. Rhodes have decided upon the introduction of the electric light into their large mill at Hadfield. For some time they have been dissatisfied with the price of gas—about 3s. 1d. per 1,000 to mills—charged by the Glossop Gas Company, and having failed after application to get a reduction, have decided upon the alternative named, and have given an order to the Edison Company to that effect. The adoption of this system will involve in the first instance an expenditure of about £3,000, for which outlay they will obtain about 1,400 lights.

THE GAS QUESTION IN CADIZ.—The dispute between the Municipal authorities and the Government with respect to the lighting of Cadiz, to which we referred a few weeks back, appears to be as far from being arranged as ever. The Ayuntamiento maintains that it has a perfect right to authorise the local company to lay pipes, while the Governor, acting upon instructions from the Minister of the Interior, refuses to allow the works to continue. Meanwhile, the dispute is, according to the local papers, becoming daily more acute. The Mayor has resigned and public disturbances are threatened.

THE TELEPHONE AT OSTEND.—The Belgian administrators of the Government telegraphs have, since the 1st of July last, successfully worked a telephone exchange in Ostend. The subscription is 170fr. per annum within a radius of a kilometre from the central office, and for each half kilometre beyond that distance an additional charge of 17fr. 50 is made. The price for a conversation in the public office is fixed at 25 centimes for the uninterrupted space of ten minutes. The exchange is connected with that of Brussels, and subscribers may conduct their communications from seven in the morning till nine at night.

THE LIMIT OF TELEPHONIC COMMUNICATION.—Speaking at a recent meeting of the Belgian Society of Electricians, M. Van Rysselberghe summarised the conclusions to which he had been led both by his own experiments and by observation of what had been done in America. He considers that telephonic communication can be carried on in a manner capable of satisfying commercial requirements over a phosphor bronze wire of 2·1mm. diameter for a distance of 500 kilometres, with a wire of 2·7mm. for 940 kilometres, and with a wire of 5mm. diameter over a length of 1,625 kilometres. He is also of opinion that with the 5mm. wire conversation is "sufficiently good" over a length of 3,250 kilometres.

WHAT IS ELECTRICITY?—We mentioned last week that this question is propounded by Prof. Le Corguillé as the title of some elementary lessons which he is writing in the *Moniteur Industriel*. The Professor now sums up the question as follows:—"Electricity may be considered as the whole range of phenomena which arise from the condensation, the rarefaction, or the movement of the ether either around or in the interior of masses of matter. But, inasmuch as any movement of the ether necessarily implies both rarefaction and condensation, the above proposition in reality attributes the phenomena of electricity to one, unique, primordial cause—a variation of the normal force of elasticity of the ether at any point."

MINERS' LAMP.—At the meeting of the South Wales Institute of Engineers at Cardiff on July 29th, Mr. Sydney F. Walker exhibited a model of the Regent (Maquay) electric portable safety lamp, consisting of four cells of the Regent battery in a case, with an incandescent lamp and switch attached. The battery, weighing 3lb., was stated to be capable of maintaining a 3 candle-power lamp for 10 hours, and of afterwards furnishing sufficient light for the miner to find his way out of the pit. The lamp was very much appreciated by the members of the institute, and so much interest was taken in it that Mr. Walker was requested to prepare a paper upon it to present to the institute at the next meeting.

IMPROVEMENTS IN ACCUMULATORS.—M. Emile Reynier has succeeeded by very simple means in overcoming the difficulty which sometimes arises from the swelling of the plates of accumulators during the process of charge. The plates constructed by M. Reynier are bent to and fro so as to present a succession of shelves or corrugations, and the active material is strongly compressed into the spaces thus provided. This particular feature is not new in itself, but the present improvement consists in bending the plates into the form of an arc of a cylinder whose axis is perpendicular to the direction of the corrugation. A battery of this construction has undergone a trial of some duration at Marly (Switzerland), and is said to have been perfectly successful.

ELECTRIC RAILWAY AT MINNEAPOLIS.—Minneapolis is one of the mushroom cities of the United States, and as such is

Digitized by Google

bound to go in for all the latest "developments." Consequently, they have discarded steam for their elevated railway, and have adopted the Van Depoele system of electric railways. The change gives great satisfaction both to the dwellers along the route and to the passengers and servants of the company. The trains are capable of carrying as many as 600 passengers at one time, and this, with the weight of the cars, represents a load of 91 tons. Only very meagre technical details have been supplied, but it is stated that a speed of 17 miles per hour is attained, and that the consumption of coal at the generating station is 3,000lbs. per day of 18 hours.

ELECTRIC LIGHTING AT BRUSSELS.—We understand that Mr. Aylmer has been authorised by the authorities at Brussels to lay underground conductors necessary for the lighting of the central part of Brussels. For some time past the Grand' Place has been lighted by arc lamps, and now the central boulevard, the Place de la Monnaie, the Galleries St. Hubert, and the Place de la Bourse, in addition, are to be lighted. The system adopted is to be that of Messrs. Gaulard and Gibbs, who will furnish the electric light at the same price as gas, but the amount of light which will be given will be far greater than that of gas. The district to be lighted includes five theatres, as well as the largest cafés and shops. It is expected that the installation will be ready by October.

A NEW METHOD OF CONSTRUCTING SCREWS FOR SMALL VESSELS.—In the course of his experiments upon the electrical propulsion of boats, M. Trouvé has devised a cheap and simple method of constructing screws, which appears to be well adapted for the case of vessels of small size. M. Trouvé takes a cylinder of the size required for the shaft of the screw, and he turns an helicoidal groove of some depth upon its surface. In this groove he fixes a series of metal spokes. These spokes are wedge-shaped in longitudinal section, and at the same time they slightly broaden out at the thinner end like a narrow fan. By this means, when the groove has received the full number of spokes their edges are in contact throughout. The adjacent spokes are then soldered together and a brass band is soldered around their outer ends. The screw is thus completed.

ELECTRIC LIGHTING IN ST. LEONARDS.—The Hastings and St. Leonards-on-Sea Electric Light Company are now extending their mains up Warrior-square, with the intention of supplying the electric light to those who require it. On Wednesday evening the light was supplied for the first time to some private houses, and those who saw it were struck by its great brilliancy and steadiness as compared with gas. We understand that further extensions will be made, and mains laid on both sides of the square, to supply the increasing demand. We need scarcely point out the immense saving by using the incandescent lights effected as regards ceiling and wall decorations, paintings, drapery, &c. The Robertson-street Congregational Church is lit up every Sunday evening for Divine service with the lights, which have given entire satisfaction.

A NEW AMPERE METER.—This ammeter, which is the invention of Mr. H. A. Streeter, of Chicago, possesses some claim to novelty. It consists of a cylindrical cup containing a coloured liquid. The bottom of this vessel is made of very thin iron, and has a soft iron armature fixed upon the inner side in the shape of a short cylinder about one-third of the diameter of the cup. Above this vessel is a solenoid provided with an iron case which extends into the cup, almost reaching the armature. A narrow tube enters the lower part of the cup, and then bending upwards is provided with a scale, upon which the height of the liquid can be read. When a current passes through the solenoid, it attracts the armature, and diminishes the capacity of the vessel, thus causing the liquid to rise in the tube. We presume that glycerine or some other non-volatile liquid is employed.

M. TROUVÉ'S ELECTRICAL BOAT.—M. Trouvé has lately been working very hard upon the general question of electrical navigation, and has designed several new features in this connection. His latest motor is said to develop one-half horse-power and to weigh only eight kilos; another weighing 15 kilos yields one horse-power. A speed of 15 kilometres, or over nine miles per hour, is reported to have been attained. At this speed it is desirable to have some means of heralding one's approach. M. Trouvé has therefore designed an electric siren which gives a particularly strident blast. The siren consists of two discs pierced with numerous holes, which are placed close together and rotated at a high speed in opposite directions. A blast of air driven by a circular fan is directed upon the discs, and the whole apparatus is driven by a small motor. The boat is also provided with several incandescent lamps and an arc light projector.

ACCUMULATORS.—Our contemporary the *Revue Internationale de l'Electricité* for June has a translation of an Austrian patent for accumulators. We do not know that it absolutely follows, but it seems to us that this patent savours very closely of English practice. The negative plate is said to be made of 95 parts by weight of litharge finely divided, with five parts of pumice. The latter is used to render the mass less dense and more porous. A leaden grill is used, as with some English makers. The positive plate consists of 95 parts of litharge, 95 parts of minnim, and 10 parts of coke. It will be seen that in this plate the coke takes the part of the pumice stone in the other plate. The manipulation of the materials before the plates are used may, perhaps, differ from our methods, rather tending to a little of the practice of the E.P.S., combined with a little from Franklin, Fitzgerald, and various other makers, and this constitutes a patent.

CHURCH LIGHTING.—The new Herrington Church in County Durham, which has recently been consecrated by the Bishop of Durham, is to be lighted by incandescent electric lights, the current being obtained from the dynamo used for lighting the new Herrington Colliery about a quarter of a mile distant. The cables, which are Messrs. Callender's bitumenised, are carried on poles to the neighbourhood of the church and thence underground into the building. Fifty incandescent lamps in all are used, the centre aisle and chancel being lighted by lamps affixed to ornamental brackets depending from the pillars, and the side aisles by lamps enclosed in Trotter's dioptric diffusers suspended from the roof. The contractors for the work are Messrs. Walker and Olliver, and Messrs. Verity Bros., of Regent-street, have supplied all the fittings. It is understood that this is the first church to be lighted by the electric light in the North of England.

ELECTRIC LIGHT AT ELSWICK WORKS.—A large installation has just been completed at the new steel works of Sir W. G. Armstrong, Mitchell, and Co., at Elswick. As the sheds to be lit were built almost entirely of iron it was considered desirable to employ a low tension system. It was also required that the lamps should be entirely independent of one another, so that in the event of an accidental breakage of a cable no great harm would result. These two conditions are readily fulfilled by the Gülcher system, and the work has been carried out by that company. Two dynamos are supplied, each having an output of 30,000 watts. They are compound wound and run at 460 revolutions, giving 70 volts. The arc lamps

Digitized by Google

will be 50 in number when the installation is complete; each lamp requires 15 amperes, and gives 3,000 candles. About 40 incandescent lamps are also hung, and provision is made in certain cases for cutting out an arc lamp and substituting an equivalent number of incandescents. The Elswick Works are carried on night and day, and the improvement is much appreciated by the night gangs.

THE MADRID TELEPHONE SERVICE.—We learn from Madrid that tenders for the telephone service of that city were adjudicated upon in the Ministry of the Interior, on Friday last, the 30th ultimo, when the proposition accepted was that of Mr. Ibo Bosch, banker, of Paris, according to which it is stated the Government will receive 20 per cent. of the profits. Only four proposals were received. A proposal of Señor Aramburu, offering 22 per cent., was refused, owing to the conditions not having been complied with. It is stated that a protest against the adjudication was lodged by the representative of the Spanish American Electric Telephone Company, Señor Rotondo Nicolan. At the time tenders were invited the Madrid periodical *Las Occurrencias* published a series of articles on the telephone service which attracted some attention. The author has now republished them in pamphlet form, under the title of "La Cuestion de los Teléfonos." The author appears to have incurred the displeasure of the Director of Posts and Telegraphs, but his views are said to meet with the approbation of a large section of the public, and his pamphlet has a wide sale.

"A NEW DEPARTURE IN TELEGRAPHY."—Under this heading, a daily paper announces with much *éclat* the discovery of a method of transmitting by wire facsimile reproductions either of sketches or of handwriting. The subject is introduced with the following remarks:—"Hitherto messages have been sent along the wire by means of signs, and these sometimes difficult to understand. Attempts have been made by means of puncturing paper at the far end to make the messages more definite. This has not been found, on the whole, to answer well, nor has it been generally adopted." After the knowledge which the writer thus displays of the "attempts" which have hitherto been made, we are quite prepared to learn that "the difficulty has now been got over, and a discovery has been made which will about complete the mode of transmission, and make it as perfect as can be." But unhappily "the *modus operandi* cannot be explained at present, the patents not having been fully secured" Nevertheless, we are assured that no time is being lost, and "ere long the discovery will be in full operation wherever the telephone or telegraph is employed."

THE NAVIGATION OF THE SUEZ CANAL BY NIGHT.—The question of conducting the traffic of the Suez Canal by night as well as by day came before the directors as long ago as the year 1881, although it was not until December, 1885, that permission was finally granted to mail boats and to men-of-war to proceed through a certain portion of the canal by night. The conditions under which this authorisation has been given have already been published. During the four years from 1881 the directors have carried out a series of experiments with a view not only to permit the regular traffic of the canal to proceed by night, but also to enable them to carry on the work of dredging. This arrangement has been in regular and successful operation for the last two years. The steam barges for removing the slush are each provided with a Brotherhood engine, of 3 horse-power, which drives a Gramme machine, which supplies three arc lamps. These lamps are connected in series, and take a current of 24 amperes. One of these is provided with a Mangin reflector, and is mounted upon the bow, the others being placed upon either side. The steam dredgers are provided with an almost similar plant.

COLONIAL SCIENCE.—In the Canadian Section at the Indian and Colonial Exhibition, many of our readers have probably noticed the Library of Canadian Literature, which has been furnished by the Dominion Government. In the shelves devoted to science we find several Canadian reprints of the standard English authorities; but the original work of the colony, as might be expected, is almost solely confined to geology. In the two volumes of *Transactions* of the Canadian Royal Society—which was founded by the Marquis of Lorne, in 1884—there are, however, a couple of electrical papers, one upon the resistance of a solution of sulphate of copper of different strengths, and one upon a modification of the Wheatstone bridge. The electrical exhibits of the colony are not numerous. Although Canada possesses over 47,000 miles of telegraph lines and about 200 telephone exchanges, yet the exhibit in this section is confined to a few Morse keys and a direct ink writer or two. Under the head of Government Telegraphs there will, however, be found a full-sized model of a semaphore station, such as is used for the lighthouse service. There is also a really fine display of frictional apparatus, including a very large plate machine, which shows evidence of careful design and construction, although of course we are obliged to consider the whole thing quite out of date.

GAS AND ELECTRICITY IN PARIS.—It is reckoned that there are now in Paris 16,044 incandescent lamps, and 2,225 arc or Jablochkoff lights. The *Bulletin Internationale de L'Electricité* of this week gives an interesting analysis of the effect of this large number of lights on the Parisian Gas Company. Admitting that each incandescent lamp replaces one jet of gas, and that each arc light is equivalent to ten ordinary burners, an estimate—which our contemporary considers very moderate, and one which gas manufacturers themselves cannot regard as exaggerated—this would represent in round numbers 38,300 gas burners lost to the Paris Gas Company. At the rate of 140 litres of gas per hour these burners would consume 5,362 cubic metres, taking them to be lighted on an average for four hours a day during the whole of the 365 days of the year. This would amount to 7,755,520 cubic metres, which at the rate of 0·30 centimes per cubic metre would put into the coffers of the company 2,326,656 francs. This sum is very considerable, but there has to be added to it what would be obtained from the sale of residual productions in the manufacture of this great quantity of gas if the electric light did not exist. In the face of such facts it is not surprising that the progress of the new illuminant is attracting in an unusual degree the attention of persons interested in the Parisian Gas Company.

A HUGE LIGHTNING CONDUCTOR.—Most of our readers are probably aware that one of the principal features of the Exhibition which is to be held next year in Paris is to be a tower constructed of steel, and 300 metres in height. The question of protecting the tower from the effects of lightning has been considered by a small committee of French electricians, and they have just presented their report to the Minister of Commerce. They point out that the tower itself, being constructed wholly of metal, will play the part of a gigantic conductor, and will serve to protect a very large space around its base. But in order that its action may be efficient it will be necessary to take great care to make thoroughly good metallic connection with the subsoil, at a depth sufficient to ensure the presence of moisture all the year round. If this be properly done the interior of the tower will be absolutely safe during the most severe electrical disturbance

Digitized by Google

of the atmosphere. The earth plates are to be of copper, and they will be connected to each angle at the base of the tower by substantial copper cable. The summit of the tower itself is to be surmounted by a tall copper rod having a gilded point, and supplementary conductors are also to project from the angles of the building near the summit; but these rods are merely attached to the walls of the tower, and will not be continued to the ground as in ordinary cases.

ELECTRICAL ARMY SIGNALLING.—Mr. Eric Bruce made some successful experiments at Lillie Bridge Grounds, at the end of last week, with his remarkable invention for long-distance signalling in time of war. Although we have on a previous occasion fully described Mr. Eric Bruce's balloon in *The Electrician*, we may mention, for the benefit of those who are not familiar with the principle upon which it is worked, that it is made of translucent cambric with a capacity of 4,000ft. It contains six incandescent lamps, perfectly isolated from the gas which surrounds them, and connected with the battery on the ground by a cable which helps as a captive rope. When the balloon is at an elevation of 500ft.. the flashes are visible to the naked eye at a distance of 16 miles, and a message delivered by the Morse code can be read by troops stationed at that distance. The experiments were designed to show the feasibility of attaching lamps to the outside of the balloon, whereby they attain a much higher penetrating power. It has been pointed out by some officers of the Royal Engineers, to whom the invention has been submitted, that it would be useful not only for signalling purposes, but as a preconcerted signal, and as giving a point to march on, or to guide a retreat or advance at night. It has also been shown that it would be of high value as a light for working parties. When the balloon was 15 or 20ft. from the ground, it shed over a wide area, a light by which it was quite possible to read the smallest type.

THUNDERSTORMS.—From certain meteorological statistics recently published in Germany we learn that thunderstorms in that country have during the last thirty years been steadily increasing both in frequency and severity. The number of deaths per annum from lightning has increased in a far greater ratio than that of the increase of population. In the present state of our knowledge of the whole subject of atmospheric electricity the cause of the phenomena of thunderstorms is confessedly obscure. It is, however, very possible that some light would be thrown upon the question by a comparative study of the frequency and severity of storms during a lengthened period and over a wide geographical area. The German *savants* incline to the opinion that the increase is to be attributed to the enormously increased production of smoke and steam which has taken place during the last three decades. But although we may admit this to be to some extent a probable *vera causa*, yet when we consider the very local character of thunderstorms we should naturally expect to find that it would follow that the neighbourhoods of large cities, and especially of manufacturing districts, would suffer the most severely. But the statistics referred to show distinctly that the very reverse is the case. The number of storms attended by fatal results from lightning is far larger in the agricultural districts than in the towns. Upon the other hand, we ought to take into consideration the protective action of lightning conductors with which the prominent buildings in the towns of Germany are well provided.

TEMPORARY INSTALLATIONS.—On Friday evening, July 30th, the dining room at the private residence of Sir Spencer Wells at Hampstead was temporarily installed with the electric light, the current being supplied by means of a Regent primary battery. A 20 candle-power lamp enclosed in a dioptric shade, suspended from a chandelier over the centre of the table, served to illuminate the dining room. The room had formerly been lighted by four gas brackets; but after only a few years the ceiling and walls had been so blackened by the gas that its use had been given up and candles substituted, repainting at a considerable expense having been necessary. Sir Spencer will most probably adopt the electric light permanently. The installation was carried out by Messrs. Swete and Main, of Queen Victoria-street.—On the occasion of a garden party given at the residence of Mr A. P. Montgomery, at Isleworth, on Wednesday last, Messrs. Nalder Bros., of Westminster and Brentford, carried out a very successful temporary installation. About forty 5 candle-power lamps were hung in the trees, and a hand fed arc lamp was also employed. The lamps were supplied from E.P.S. cells, and the effect was, as usual, much admired.—Again Mr. Storey, of Oundle, has recently carried out a temporary installation of 100 incandescent lamps at Barnack, near Stainford, on the occasion of the opening of a Constitutional Club and *soirée*, 60 being used to light a large marquee, and the remainder were distributed among the adjacent trees. Also an installation of about 250 lamps on the occasion of a grand Primrose Demonstration at Burghley Park, the seat of the Marquis of Exeter; about 90 coloured lamps were used in the gardens, and the remainder in the marquees used for dancing, refreshments, &c. The whole of the lamps in both installations were fed by Gramme dynamos driven by portable engines.

UNDERGROUND WIRES.—The following remarks on underground cables by Herr Siemens are given in the *Elektrotechnische Zeitschrift* for last month:—"It will appear wonderful to many that jute is employed as an insulating material, and this is frequently ascribed to economical grounds only, but such is not the case. It is known that Sir W. Thomson has found that the plant fibres themselves are a perfect insulator. This induced us to employ this plant fibre for cables, whilst we made use of a special preparation to insure perfect freedom from damp. But the insulation would not be completely attained if the pores of the jute were not filled after the drying with some substance which is rendered liquid by heat, is a good insulator, and besides is not hygroscopic. It was already known to physicists that caoutchuc oil, obtained by the distillation of caoutchuc, possesses these properties in a high degree. It is a matter of essential importance to fill the pores of the dried insulating layer, and at the same time to make the lead case perfectly compact, which serves to cut off the damp of the ground. The lead pipe is now almost perfect. With underground telephone cables there are two evils to be combated, namely, electrostatic induction, and electro-magnetic induction. The action of both phenomena is to give rise to disturbances in neighbouring wires. The first kind of disturbance may be avoided by surrounding each wire by a conducting coat. This, however, does not entirely ward off the electro-magnetic induction, which can only be obviated by the simultaneous action of currents of opposite direction. To get rid as far as possible of the electro-magnetic induction, we must either use double wires twisted so as to often change their position relative to one another, or an investing coat of good conductivity in order that compensating currents of opposite direction may be called forth. This is carried into effect by means of a closed copper sheath, which wards off the effect of static induction, and to a great extent that of the magnetic too. Alas, this also occasions a weakening of the currents, consequently also of the sound in the telephone. This can, however, never be avoided, since it depends on unalterable natural laws.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XXX.

BY OLIVER HEAVISIDE.

(Continued from page 213.)

Impedance formulæ for short lines. Resistance of tubes.

In the case of a short line, a very high speed is needed in general to make it necessary to take electrostatic induction into account in estimating the impedance. Keeping below such a speed, the impedance per unit length is simply

$$(R'^2+L'^2n^2)^{\frac{1}{2}}$$

This is greater than the common $(R^2+L^2n^2)^{\frac{1}{2}}$ at first, when the speed is low, equal to it at some higher speed, and less than it for still higher speeds. Thus, for simplicity, let the return contribute nothing to the resistance or the inductance; then, using (44*b*), we shall have

$$(R'^2+L'^2n^2)-(R^2+L^2n^2) = \frac{R^2g}{6}-\frac{R^2g^2}{24}\left(\frac{L}{\mu}+\frac{1}{10}\right)+\frac{R^2g^3}{48.90}\left(13\frac{L}{\mu}+\frac{79}{56}\right)-\ldots; \quad (47b)$$

R and L being the steady flow resistance and inductance of the line per unit length (the latter to include L_0 for the external medium), R′ and L′ the real values at speed $n/2\pi$ per second, μ the inductivity of the wire, and $g=(\mu n/R)^2$.

Thus the first increase in the square of the impedance over that of the linear theory is $\frac{1}{6}\mu^2n^2$, independent of resistance; large in iron, small in copper. But as the speed is raised, the g^2 term becomes sensible; being negative, it puts a stop to the increase. We can get a rough idea of the speed required to bring the impedance down to that of the linear theory by ignoring the g^3 term. This gives

$$n^2=4R^2\div\mu^2\left(\frac{L}{\mu}+\frac{1}{10}\right) \quad . \quad . \quad . \quad (48b)$$

The real speed required must be greater than this, and taking the g^3 term into account, we shall obtain, as a higher limit,

$$n^2=4\tfrac{2}{13}R^2\div\mu^2\left(\frac{L}{\mu}+\frac{3}{28}\right) \quad . \quad . \quad . \quad (49b)$$

approximately. We see that the simpler (48*b*) is near enough.

If the wire is of copper of a resistance of 1 ohm per kilom., making $R=10^4$, we shall have, using (48*b*)

$$n=20^4\div\left(L_0+\frac{3}{5}\right)^{\frac{1}{2}}.$$

If the return is distant, we can easily have $L_0=9$. Then the speed required is about 100 waves per second. This is a low telephonic speed, so that we see that telephonic signalling is somewhat assisted by the approximation to surface conduction.

If the wire is of iron, then, on account of the large value of μ, a much lower speed is sufficient to reduce the impedance below that of the linear theory; that is, an iron wire is not by any means so disadvantageous, compared with a copper wire of the same diameter, as its higher resistivity and far higher inductivity would lead one to expect.

But it is not to be inferred that there is any advantage in using iron, electrically speaking, from the fact that the impedance is so easily made much less than that of the linear theory. Copper is, of course, the best to use, in general, being of the highest conductivity, and lowest inductivity. Nor is any great importance to be attached to the matter in any case, for, on a short line, to which we at present refer, it will usually happen that the telephones themselves are of more importance than the line in retarding changes of current.

We also see that in electric light mains with alternating currents there may easily be a reduction of impedance if the wires be thick and the returns not too close. On the other hand, the closer they are brought the less is the impedance, according to the ordinary formula. It should be borne in mind that we are merely dealing with a correction, not with the absolute value of the impedance, which is really the important thing.

Now take the speed midway between 0 and the second speed which gives the linear theory impedance. Then $R^2+L^2n^2$ becomes $R^2+n^2\left(L^2+\frac{1}{24}\mu^2\right)$, wherein use the value of n^2 given by (48*b*). The increase of impedance is not, therefore, in a copper wire, anything of a startling nature.

Impedances are not additive, in general. We cannot say that the impedance of a wire is so much, that of a coil so much more, and then that their sum is the impedance when they are put in sequence, at the same speed.

In passing, I may as well caution the reader against the false idea somewhere prevalent. The increased resistance of a wire is not in any way caused or evidenced by the weakness of the current in the variable period compared with its final strength, a result due to the back E.M.F. of inertia. No matter how great the inertia, and how slowly it makes the current rise, there is no change of resistance, unless there be changed distribution of current. There must always be some change, but it is usually negligible. When, however, as notably in the case of iron, the central part of the wire is inoperative, of course this changed distribution of current means a large increase of resistance, though not of impedance, which is reduced. It is a hollow tube, not a solid wire, that must, to a first approximation, be regarded as the conductor. There cannot be said to be any definite resistance unless the current distribution is definite.

Thus, in the rise of the current from zero to the steady state there is, presuming that there is large departure from the regular final distribution, no definite resistance, and it is clearly not possible to balance a wire in which the above takes place against a thin wire, a conclusion that is easily verified. But the case of simple harmonic impressed force is peculiar. The distribution of current, though not constant, goes through the same regular changes over and over again in such a manner that the total current at every moment is the same as if a true linear circuit of definite resistance and inductance were substituted. This is very considerably departed from when mere rapid makes and breaks are employed.

Consider now the resistance of a tube at a given speed. It depends materially upon whether the return current be within it or outside it. Let there be two tubes, a_0 and a_1 the inner and outer radii of the inner, and a_2 and a_3 of the outer. By an easy extension of equation (28*b*), the form quoted in the last section, the differential equation of the total current is

$$0=L_0p+\frac{\rho_1s_1}{2\pi a_1}\frac{J_0(s_1a_1)-\frac{J_1}{K_1}(s_1a_0)K_0(s_1a_1)}{J_1\ldots-\ldots K_1\ldots} - \frac{\rho_3s_3}{2\pi a_2}\frac{J_0(s_3a_2)-\frac{J_1}{K_1}(s_3a_3)K_0(s_3a_2)}{J_1\ldots-\ldots K_1\ldots} \quad . \quad (50b)$$

the dots indicating repetition of what is above them. The first term is for the insulator between tubes, the second for the inner tube, the third for the outer. Or,

$$0=L_0p+(R'_1+L'_1p)+(R'_2+L'_2p)$$

where R'_1, R'_2, L'_1, L'_2 are functions of p^2, and therefore constants when the current is simple harmonic. The division of the numerators by the denominators, a simple matter in the case of a solid wire, becomes a very complex matter in the tube case. I give the results as far as p^2. It is not necessary to do the work separately for the two tubes, for, if we compare the expressions carefully, we shall see that they only differ in the exchange of the inner and outer radii, and in changed sign of the whole.

For the inner tube we have

$$L'_1=R_1\frac{\mu_1\pi a_1^2}{\rho_1}\left\{\frac{1}{2}-\frac{3}{2}\frac{a_0^2}{a_1^2}-2\log\frac{a_1}{a_0}\cdot\frac{a_0^4}{a_1^2(a_1^2-a_0^2)}\right\} \quad . \quad (51b)$$

where R_1 is the steady flow resistance per unit length. This is the coefficient of p, and is therefore nothing more than the inductance put unit length of the tube in steady flow, the first correction to which depends on p^3. This may be immediately verified by the square of force method.

Digitized by Google

The resistance of the inner tube per unit length is

$$R'_1 = R_1 + R_1\left(\frac{n\mu_1\pi a_1^2}{\rho_1}\right)\left[\frac{1}{12} - \frac{2}{3}\frac{a_0^2}{a_1^2} + \frac{7}{12}\frac{a_0^4}{a_1^4} + \frac{2a_0^4\log\frac{a_1}{a_0}}{a_1^2(a_1^2-a_0^2)} + \frac{4a_0^6\left(\log\frac{a_1}{a_0}\right)^2}{a_1^2(a_1^2-a_0^2)^2}\right] \quad . . (52b)$$

To obtain, from (51*b*) and (52*b*), the corresponding expressions for the outer tube, change R_1 to R_2, ρ_1 to ρ_3, μ_1 to μ_3, a_1 to a_2, and a_0 to a_3. The change of sign is not necessary, because it is involved in the substitution of R_2 for R_1. Or, simply, (51*b*) and (52*b*) holding good when the return is outside the tube, exchange a_1 and a_0, and we have the corresponding formulæ when the return is inside it.

Let $a_0 = \frac{1}{2}a_1$. This removes a fourth part of the material from the central part of a solid wire of radius a_1. The return being outside, the resistance is

$$R'_1 = R_1 + R_1\left(\frac{n\mu_1\pi a_1^2}{\rho_1}\right)^2 \times \cdot 012.$$

If solid, the ·012 would be ·083; or the correction is reduced seven times by removing only a fourth part of the material.

But if the return is inside, all else being the same, the resistance is

$$R'_1 = R_1 + R_1\left(\frac{n\mu_1\pi a_0^2}{\rho_1}\right) \times \cdot 503$$
$$= R_1 + R_1\left(\frac{n\mu_1\pi a_1^2}{\rho_1}\right) \times \cdot 031,$$

so now the correction is reduced less than three times instead of seven times, when the return was outside.

This difference will be, of course, greatly magnified when the ratio a_1/a_0 is large; for instance, consider a solid wire surrounded by a very thick tube for return; the steady resistance of the return will be only a small fraction of that of the wire, but the percentage increase of resistance of the outer conductor will be a large multiple of that of the wire. Thus the earth's resistance, which, in spite of its low resistivity, is so small to a steady current, will be largely multiplied when the current is a periodic function of the time.

Now, as regards the high speed resistance of the tube. If the return is outside it is

$$R'_1 = (\mu_1\rho_1 q)^{\frac{1}{2}} \div a_1 \quad . . . . . (53b)$$

q being the frequency. But if the return is inside, it is

$$R'_1 = (\mu_1\rho_1 q)^{\frac{1}{2}} \div a_0 \quad . . . . . (54b)$$

thus depending upon the inner radius when the return is inside, and on the outer when it is outside, for an obvious reason, when the position of the magnetic field where the primary transfer of energy takes place is considered.

Suppose we fix the outer radius, and then thin the tube from a solid wire down to a mere skin. In doing so we increase the steady resistance as much as we please. But the high speed formula (53*b*) remains the same. Now, as it would involve an absurdity for the resistance to be less than that in steady flow, it is clear that (53*b*) cannot be valid until the speed is so high as to make R'_1 much greater than R_1, which is itself very great when the tube is thin. That is to say, removing the central part of a wire, when the return is outside it, makes it become more a linear conductor, so that a much higher speed is required to change its resistance; and when the tube is very thin, the speed must be enormous. Practically, then, a thin tube is always a linear conductor, although it is only a matter of raising the speed to make (53*b*) or (54*b*) applicable.

To get them, use in (50*b*) the appropriate $J_0(r)$, &c., formulæ when x is very large. They are

$$\left.\begin{aligned} J_0(x) &= -K_1(x) = (\sin x + \cos x) \div (\pi x)^{\frac{1}{2}} \\ J_1(x) &= \quad K_0(x) = (\sin x - \cos x) \div (\pi x)^{\frac{1}{2}} \end{aligned}\right\} \quad . \quad (55b)$$

These, used in (50*b*), putting the circular functions in the exponential forms, reduce it to

$$0 = L_0 p + \frac{\rho_1 s_1 i}{2\pi a_1} + \frac{\rho_3 s_3 i}{2\pi a_2}$$

where $i = (-1)^{\frac{1}{2}}$. Here

$$-s_1^2 a_1^2 = 4\pi\mu_1 k_1 a_1^2 p, \quad \therefore \quad \tfrac{1}{2}s_1 a_1 i = (\pi\mu_1 k_1 p)^{\frac{1}{2}} a_1.$$

and similarly for s_3; so we get

$$0 = L_0 p + (\mu_1 p/\pi k_1)^{\frac{1}{2}}/a_1 + (\mu_3 p/\pi k_3)^{\frac{1}{2}}/a_2,$$

Here, since $p^2 = -n^2$, $p^{\frac{1}{2}} = (\frac{1}{2}n)^{\frac{1}{2}}(1+i)$; which brings us to

$$0 = (R'_1 + R'_2) + (L_0 + L'_1 + L_2')p, \quad . \quad . \quad (56b)$$

where

$$\left.\begin{aligned} R'_1 &= (\mu_1\rho_1 q)^{\frac{1}{2}} \div a_1, \qquad L'_1 = R'_1/n, \\ R'_2 &= (\mu_3\rho_3 q)^{\frac{1}{2}} \div a_2, \qquad L'_2 = R'_2/n. \end{aligned}\right\} \quad . \quad (57b)$$

as before given, except that the inner tube was a solid wire.

If, however, the speed was really so high as to make these high speed formulæ applicable when the conductors are thin tubes, it is clear that we should, by reason of the high speed, need, at least in general, to take electrostatic induction into account even on a short line, and therefore not estimate the impedance by the electromagnetic formulæ, but by the more general of the last section, in which the same R′ and L′ occur. As for long lines, it is imperative to consider electrostatic induction. There is no fixed boundary between a "short" and a "long" line; we must take into account in a particular case the circumstances which control it, and judge whether we may treat it as a short or a long line question. To the more general formula I shall return in the following section, merely remarking at present that there is a curious effect arising from the to and fro reflection of the electromagnetic waves in the dielectric, which causes the impedance to have maxima and minima values as the speed continuously increases; and that when the period of a wave is somewhere about equal to the time taken to travel to the distant end and back, the amplitude of the received current may easily be greater than the steady flow current from the same impressed force. And, in correction of the definition in XXIX. of V as the surface potential of the wire, substitute this definition, $Q = SV$, where Q is the charge and S the electrostatic capacity, both per unit length of wire.

(To be continued.)

THE ELECTRO-CHEMICAL EQUIVALENT OF SILVER;

TOGETHER WITH

An Experimental Trial of Methods of Measuring the Intensity of Terrestrial Magnetism.*

BY F. AND W. KOHLRAUSCH, in *Wiedemann's Annalen*, Vol. XXVII., 1886.

The paper contains an account of two series of measurements carried out in 1881 and 1883 respectively. The primary object of the inquiry was to obtain an accurate method of determining electro-chemical equivalents, but during its course a number of subsidiary investigations were made, including a very careful comparison of different methods of determining the horizontal intensity of the earth's magnetism, an inquiry into the efficiency of some new and handy instruments for determining the variations of the magnetic intensity with time and place, and an inquiry as to the accuracy attainable in determining the strength of an electric current by means of the tangent galvanometer. The authors consider, as the result of their observations, that when all possible precautions are taken, the absolute measurement of current-strength can be carried out by the Gauss-Weber magnetic method with an accuracy unattainable by any other means.

The final value obtained by the authors for the electro-chemical equivalent of silver is

$$1{\cdot}1183 \frac{\text{mg. silver}}{\text{sec. amp.}}$$

The result obtained by Lord Rayleigh and Mrs. Sidgwick (*Phil. Trans.* 2, p. 411, 1884), who measured the current-strength by an electro-magnetic method, was 1·1179, which shows a very close agreement with the present value, espe-

* Abstracted from the German by G. de Tunzelmann.

Digitized by Google

cially considering that entirely different methods of measurement were employed.

The chief objection advanced by the authors against the direct electro-magnetic measurement of the current-strength was the disturbing effect introduced by the heating of the fine suspending wires of the electro-dynamometer by the strong and long-continued currents required for the voltametric measurements. They therefore decided to confine themselves to the magnetic method of measuring the current strength, for which it was necessary, in the first place, to obtain an accurate determination of the horizontal magnetic intensity at the place of observation, and of its variation during the tangent galvanometer measurements. The observations were carried out in the observatory belonging to the Physical Laboratory at Wurtzburg, which was very free from iron, and from mechanical disturbances. All measurements were made at least twice, and the presence of two observers enabled them to be made with greater rapidity, and gave increased security against slight oversights. Entirely different instruments were used for the two sets of measurements. In the first series a tangent galvanometer with a thick copper ring was employed, and the horizontal intensity was determined by Gauss's method, and also by a bifilar galvanometric method which has been previously described by F. Kohlrausch (*Wied. Ann.*, Vol. XVII., p. 737, 1882). In the second series the current was measured by a specially constructed tangent galvanometer with a single copper wire wound round a turned glass disc, and the horizontal intensity was determined by means of a bifilar magnetometer. The magnetometer used for the second determination differed entirely both in construction and material from the one used for the first.

The hundred Gramme standard of mass and the standard metre employed were both supplied by the Imperial Commission of Weights and Measures, and the standard metre was supplied with a table of errors calculated to 1/200mm. When the investigation was completed it was again compared with the imperial standard length, and it was found to have remained unaltered within 1/24000.

For exact measurements of distance a kathetometer was used, having its rod divided on silver into millimetres, and the telescope which it carried was adjusted by means of a microscope. Glass scales were also used, and were compared with the standard by laying them directly upon it and measuring the differences with the kathetometer, or with a microscope and micrometer.

The chronometer used had its rate determined by Dr. Strecker by astronomical observation.

For the weighings two delicate balances were used, their weights having been previously compared with the standard, and a table of errors drawn up. The correction required for the difference in density between silver and brass was of course allowed for, but the changes in temperature and atmospheric pressure between two weighings were in every case too small to produce an appreciable effect.

In the determination of the weight of the magnets employed, they were too far from the small amount of iron in the balance to be affected by it, and the results were controlled by the use of the second balance.

Measurement of the Scale Distance.

The distance between the mirror and scale was about 3,000mm. or 3,050mm. respectively, and was measured by means of a 4-metre rod of rectangular section, which rested cornerwise upon two supports about 1/5 from its ends. The rod was divided into millimetres, and was frequently compared by means of a 2-metre glass scale with the standard metre.

The distance was determined by two different methods.

In 1881 a small reflecting millimetre scale was fixed to the rod so as to lengthen its scale beyond the zero point, and the silk fibre by which the magnetic needle was suspended was reflected in the scale. In front of the scale on which the deflections of the mirror were observed a weight was suspended by a fine silken fibre; the distance of the fibre from the mirror was measured and added to its small distance from the scale, which gave the distance between the mirror and the scale.

In 1883 this method was improved upon as follows:—Two small reflecting millimetre scales were provided, each having one of its ends sharpened to a point. The points were brought into contact with the mirror and the scale respectively; two silk fibres kept vertical by small weights were then placed so as to coincide with one of the divisions of each of the reflecting scales, and the distance between the fibres was measured by the wooden rod, as shown in Fig. 1.

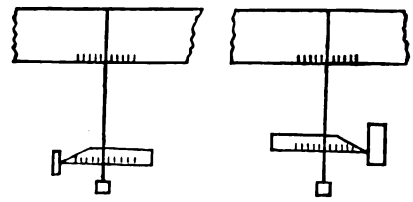

FIG. 1.

The scale was fixed in the vertical by means of a fine stretched fibre, or, if preferred, its deviation from the vertical was allowed for.

It is hardly necessary to point out that in allowing for the thickness of the glass of the mirror 1/1·53 of the actual thickness should be taken.

The thickness of the mirror of the absolute bifilar magnetometer was not known exactly, and therefore the optical thickness was measured directly by taking half the distance through which a microscope had to be moved to bring into focus the image, in the hinder surface, of a point on the front surface previously in focus. The curvature of the mirror and its deviation from the vertical, though usually neglected, may sometimes appreciably affect the observed deflection, and therefore they were allowed for in estimating the distance between the mirror and the scale.

Scale Readings.

In 1881 paper scales were used for the magnetic measurements, but were afterwards discarded in favour of glass ones, owing to the frequent comparison with the standard rendered necessary by their variability. Glass scales were used from the beginning for reading the deflections of the tangent galvanometer. The portions of these scales from which readings were taken were always compared with the standard, and the reduced readings may be depended on to the hundredth of a millimetre.

Local Magnetic Disturbances of the Instruments.

The wide distribution of iron rendered it necessary to test with great care all materials which would have to be in the neighbourhood of the magnetic needles. Metals were avoided as far as possible, and where they were essential electrolytically deposited copper was employed. Brass, especially, was found to be an unsafe material. Some brass screws were found to be magnetic to such an extent that they would adhere to a magnet. Some pieces of brass, on the other hand, were found to be slightly diamagnetic, while others showed no appreciable magnetic susceptibility.

Electrolytic copper usually showed slight traces of magnetism or diamagnetism, which were, however, considerably increased by the process of working up the metal. Great care had to be taken with regard to articles of dress, such as neckties and buttons, also to avoid the proximity of modern note books. Even paper articles were found to be slightly magnetic, but paper and wood were generally found to be practically harmless in this respect.

Ivory, horn, also wood to a slight extent, and marble to a greater extent, were generally found to be slightly diamagnetic. Glass showed slight signs of attraction, which may have arisen from electrical action.

The materials were usually tested by means of a bifilar variometer, used for observations of the earth's magnetism, arranged so that one pole of its strong magnet came close to a thin glass plate. The substance to be tested was then brought within 3mm. of this pole. The delicacy of the instrument was such that a piece of the finest iron wire, 1mm. in length and whose mass was ·05 mg., produced a deflection of 50°.

Digitized by Google

This widespread distribution of magnetic and diamagnetic action made it almost impossible to entirely eliminate local disturbances. As, however, this magnetic action of the materials used in the construction of the instruments is always due, in the first place, to external induction, and therefore increases with the magnetism of the needle, it could be very much diminished by using only weak magnets. This being done, the instruments were tested by turning the whole instrument in opposite directions through the same measured angle, and observing the position of the needle in each case. If, after allowing for the effect of the original torsion of the fibre, there was found to be a perceptible disturbing effect, the requisite correction was applied.

Local Differences in the Magnetic Intensity.

The magnetic field in the different places occupied by the absolute measuring instruments was compared by means of the local intensity variometer with four deflecting magnets described by F. Kohlrausch (*Wied. Ann.*, Vol. XIX. p. 130, 1880, and *The Electrician*, Vol. XVII., p. 14). These observations were made alternately with the observations with absolute measuring instruments, and in effecting the interchange gloves were worn to avoid heating the instruments.

Time Changes in the Magnetic Intensity.

These were determined by means of a portable bifilar-magnetometer (F. Kohlrausch, *Wied. Ann.*, Vol. XV. p. 334, 1882), with brass suspension wires 1/20mm. in thickness, and which rested on solid masonry. Before placing the magnet in position it was heated thirty times from 10° up to 50°. Its temperature coefficient was determined by Weber's compensation method.

To test the invariability in the position of the instrument the reading telescope was turned by means of a screw adjustment about its horizontal axis until the image of the scale was seen in the mirror attached to the supporting pillar.

The changes in the intensity were found to be slow and regular, so that it was only necessary to take readings with the instrument at regular intervals.

In 1883, besides this instrument, the time changes in the intensity were also determined by means of the instrument used for determining the differences in the intensity at the different positions of the absolute measuring instruments.

Voltametric Measurements.

The silver solutions were obtained by dissolving nitrate of silver (obtained from two different sources) in pure water. No traces of impurity were found in the salt in either case. The anodes consisted of pure silver. At the conclusion of the measurements solutions of the silver deposit were tested with ammonia and showed no signs of blue coloration.

Crucible Voltameter (Fig. 2).—This voltameter was of the form due to Poggendorff. The cathode consisted of a platinum crucible, with an available surface of about 20 sq. cm. (A silver crucible also was tried, but was found to be unreliable, as even when the washing was repeated many times it continued to undergo a diminution in weight each time.) The crucible rested within a sheet of platinum bent into a cylinder, to which a binding screw was attached. On testing with a delicate galvanometer there was found to be no perceptible short circuiting through the wooden base. To prevent loosened portions of the anode from falling upon the platinum, the former is generally surrounded by filter paper or woollen material; but as it was thought desirable not to have organic substances in contact with the silver solution, the same object was attained by suspending under the anode a small glass cup by means of three glass threads blown into it, and which rested upon the edge of the crucible, an arrangement which was found to answer very well.

Fig. 2.

Siphon-Voltameter (Fig. 3).—Another form of voltameter was tried, in which the cathode consisted of a silver plate with an available surface of about 10 sq. cm. resting upon a plate of spongy platinum, and dipped into the silver solution contained in a small beaker, and the silver anode was placed in the same vessel at a distance of about 3cm. When, however, this was used for an experiment small grains of silver were found at the bottom of the beaker, and as there were no means of knowing whether they came from the anode or the cathode this form had to be abandoned.

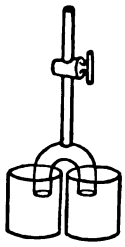

Fig. 3.

Two beakers were then used, connected by a siphon tube, which could be filled by sucking the solution up through a tube attached to the siphon, and provided with a stopcock. A difficulty which occurred in using this voltameter was that directly after the current began to flow it showed a considerable increase in strength, in consequence of the liquid in the siphon tube becoming heated, and consequently having its resistance diminished. This was overcome by using a higher E.M.F. and bringing the strength of the current down by the introduction of external resistance.

Single Beaker Voltameter.—Ultimately the use of a single beaker was reverted to, but the cathode was made to rest in a semi-circular glass cup (Fig. 4), and the cathode and cup were removed together.

Fig. 4.

Before a voltameter measurement was made, a fresh silver deposit was obtained, if not already present, in order that the surfaces should be similar for the two weighings. From time to time the deposited silver was scraped off.

After a silver deposit had been obtained for measurement it was washed, first, with cold, and then with hot water, until the water used, after being allowed to cool, showed no signs of turbidity on treatment with hydrochloric acid. The silver cathode was kept throughout in a small beaker to avoid losing any small portion. It was then dried in an air bath at about 150°, and allowed to cool. It was then weighed several times, until the weight, which at first increased slightly, had attained a constant value, when the final weighing was made. The drying of the crucible was effected by holding it over a flame with the usual precautions.

Tangent Galvanometer used in 1881.

The tangent galvanometer used in 1881 was the one described by F. Kohlrausch (*Wied. Ann.* Vol. XV. p. 552, 1882). The ring was turned out of a copper plate, and it had a rectangular section with a thickness of ·41cm, and a width of ·86cm., with a diameter of about 40cm. The ring was stiffened by means of a wooden triangle. Six different diameters were measured, as a slight distortion was inevitable in removing the ring from the plate of the lathe, and attaching it to the wooden triangle. The temperature was noted at the time of measurement, and the mean diameter determined from these measurements was corrected for the observed temperature of observation. The current was introduced into the ring by making a division in it, and attaching to the two ends so formed conducting leads of copper, to which the connecting wires were attached, as shown (Fig. 5). The requisite correction was applied for the replacement of the small portion of the ring cut away, by these leads.

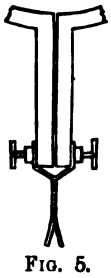

Fig. 5.

It was found by observation with strong currents that the twisted wires exerted no effect upon the needle; their insulation was carefully tested by a delicate galvanometer.

The magnet consisted of a circular steel mirror of diameter $d = 2\cdot08$cm. According to Hallock's researches (*Wied. Ann.*, Vol. XXII., p 411, 1884), the length of the equivalent needle was taken as $2r = \cdot80\ d$, so that the correction factor for the current strength due to the length of the needle will be

$$1 + \frac{3}{4}\frac{r^2}{R^2} = 1 + \cdot12\,\frac{d^2}{R^2}$$

where R is the mean radius of the ring at the temperature of observation, viz. 13°.

The correction for the deflection from the mean plane of the current is small, and for uniform magnetisation of the steel disc we may take it to be the same as for a needle of length $2r$, which gives, for a deflection ω, the factor

$$1 - \frac{45}{16}\frac{r^2}{R^2}\sin^2\omega = 1 - \cdot45\,\frac{d^2}{R^2}\sin^2\omega.$$

Digitized by Google

Let h be the thickness of the ring, b its width, l the length of the conducting leads, a the distance between their median lines, Θ the coefficient of torsion, i the strength of the current, and H the horizontal intensity. The equation of equilibrium of the magnet is

$$H(1+\Theta)\sin\omega = \frac{2\pi i}{R}\left(1+\frac{1}{6}\frac{h^2}{R^2}-\frac{1}{8}\frac{b^2}{R^2}-\frac{a\,l}{2\pi R}\frac{R+\frac{1}{2}l}{(R+l)^2}+\cdot12\frac{d^2}{R^2}\right)\cos\omega\left(1-\cdot45\frac{d^2}{R^2}\sin^2\omega\right)$$

which gives, on substituting the values

$$R=20\cdot144,\ h=\cdot41,\ b=\cdot86,\ l=13,$$
$$A=\cdot52,\ d=2\cdot08,\ \Theta=\cdot00021.$$

$$i=3\cdot20724\,H\tan\omega\,(1+\cdot0048\sin^2\omega).$$

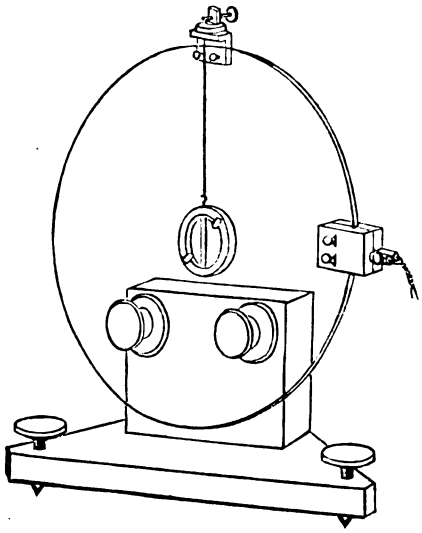

Fig. 6.

Tangent Galvanometer used in 1883.

As the currents employed were not strong enough to require a thick conductor, a single copper wire would suffice for the ring if its shape were kept invariable. A galvanometer was therefore constructed as follows :—

A glass disc about 8mm. in thickness, and 20cm. radius, was turned in a lathe, and a shallow groove made round the edge. Two pieces of ebonite (Fig. 7), grooved to allow the ends of the wire forming the ring to pass through them were attached by copper rivets to the glass plate. The wire being placed in the groove, and the ends drawn through the binding screws attached to the ebonite plates, it was heated by the passage of a strong current, and while still hot the ends were drawn tight by a pair of pliers, and clamped in the binding screws. At the centre of the glass disc a circular aperture was made 5·8cm. in diameter; in this was fixed a small case consisting of an ivory rim (made in two parts to allow of the introduction of the magnetic needle) with glass sides.

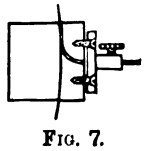

Fig. 7.

The needle was made of a small piece of watch spring attached to a light glass mirror. The suspending fibre was attached to a small copper torsion circle, and hung at a distance of about 1mm. from the surface of the glass, passing through a small aperture in the ivory rim. It was protected from air currents by means of a half cylinder, which could be fixed to the glass disc when required. In order to increase the damping effect two strips of ivory were fixed inside the case about ¾mm. in front of and behind the mirror.

The radius was obtained by measuring the circumference of the disc before the wire was in place. A brass wire ·006cm. in diameter was stretched straight by a weight, a length taken on it nearly equal to the required circumference, and the ends marked. The wire was then rolled round the groove, stretched by the same weight, and the difference between the circumference and the measured distance between the marks on the wire was read off by a millimetre scale. As the diameter of the wire used for the ring was ·058cm., the radius determined from this measurement had to be increased by half the difference in the thickness of the two wires. A second determination was made after the copper wire was in position by measuring four diameters to the outer surface of the wire by means of the kathetometer. The mean of the two results was then taken, and reduced to the temperature of observation.

The ends of the wire, after leaving the binding screws of the instrument, were, as before, insulated and twisted together, and on being tested were found to exert no action on the needle, and to be perfectly insulated.

Where the circuit left the ring a small portion of it was replaced by the curves formed by the portions of wires between the ring and the binding screws. The projection on the plane of the meridian of the surface included between these curves and the portion of the ring which they replaced was $f=\cdot1$ sq. cm. The effect was, therefore, to reduce the force $2\pi i/R$, which the complete circular current would exert at the middle point, by if/R^3 giving the correcting factor

$$1-\frac{f}{2\pi R^2}.$$

The displacement of the needle from the plane of the current was $e=\cdot41$cm., giving the correcting factor

$$1-\frac{3}{2}\frac{e^2}{R^2}.$$

The length of the magnet was $l=1\cdot88$cm. The distance between the poles was taken as $\lambda=\frac{5}{6}l$, giving the correcting factor.

$$\left(1+\frac{3}{16}\frac{\lambda^2}{R^2}\right)\left(1-\frac{15}{16}\frac{\lambda^2}{R^2}\sin^2\omega\right)=\left(1+\cdot13\frac{l^2}{R^2}\right)\left(1-\cdot65\frac{l^2}{R^2}\sin^2\omega\right)$$

Thus the equation of equilibrium of the magnet was

$$H(1+\Theta)\sin\omega = \frac{2\pi i}{R}\left(1-\frac{f}{2\pi R^2}-\frac{3}{2}\frac{e^2}{\pi^2}+\cdot13\frac{l^2}{R^2}\right)\cos\omega\left(1-\cdot65\frac{l^2}{R^2}\sin^2\omega\right)$$

Now at temperature 15°, that of the observations, $R=19\cdot8474$ cm., also $e=\cdot41$ cm. $l=1\cdot88$ cm. $f=\cdot1$ sq. cm. $\Theta=\cdot00004$, so that finally

$$i=3\cdot15739\,H\tan\omega\,(1+\cdot0058\sin^2\omega)$$

The mercury commutator of the tangent galvanometer was arranged so that the direction of the current was changed without breaking it, the galvanometer being momentarily thrown out of the circuit. This short-circuiting did not last more than a tenth of a second, and as the resistance of the galvanometer was a small fraction of the whole resistance it would not produce an appreciable effect.

Magnetometers.

The instrument used in 1881, both for observations of the earth's magnetism and for observations with the tangent galvanometer, was the one described by F. Kohlrausch (*Wied. Ann.*, Vol. 15, p. 550, 1882). Its magnet consisted of a steel mirror, suspended by a silk fibre 14cm. long from a torsion circle, and it was provided with a Töpler damper made of tissue paper, fixed to a light metallic frame.

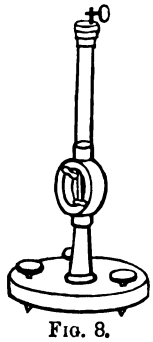

Fig. 8.

The instrument used in 1883 (Fig. 8) contained no metal except the magnetic needle and the copper levelling screws.

The needle consisted of a piece of steel spring, 1·88cm. in length, and it was fastened to a light mirror 2·5cm. in diameter, and swung in an ivory case exactly like the one used for the glass disc tangent galvanometer. The torsion head was made of ivory, and the pillar of horn.

Absolute Measurement of Magnetic Intensity—Gauss's Method, 1881.

The magnet was a solid steel cylinder, 16·01cm. in length, 1·48cm. in diameter, and having a mass of 216·16g. At the middle of the cylinder a conical hole was bored at right angles to its length, in which a small copper cone was placed

Digitized by Google

when it was used to produce deflection, and a copper rod carrying a light mirror when it was used for vibration.

After magnetisation, and before being used, it was heated ten times from 12° up to 50°.

Coefficient of Induction.

1. *Weber's Method.*—A coil of copper wire, 40cm. in length and 3cm. in breadth, originally pointing north and south, was turned through 180° about a vertical axis, first empty and then with the magnet within it, and the deflection of a Meyerstein galvanometer in circuit with the coil observed in each case. After the removal of the magnet the value of the scale reading was found by thrusting into, and withdrawing from the coil a small magnet whose moment was known.

F. Kohlrausch has shown (*Wied. Ann.* Vol. XXII. p. 415, 1884) that the increase and the decrease in the magnetic moment due to small forces are practically equal, and therefore the increase in the magnetic moment which would be produced on moving the magnet from the east and west position to the position of vibration, was assumed to be half the change produced by the rotation through 180°.

With reference to a magnetic field of unit strength the increase of the magnetic moment in the normal position was found to be $\mu = 46$[cm.g.].

2. An artificial magnetic field was produced of known strength, about ·2[cm.g.], by winding a known number of turns of wire outside the first coil, and sending through the outer coil a current whose strength was measured by means of a tangent galvanometer in its circuit. The galvanometer readings were observed on breaking, and on closing the battery circuit, both with the magnet inside the coil, and with the empty coil, and the difference taken. The value of the galvanometer readings was determined by the same means as before. This method gave $\mu = 45$.

The value of μ was taken to be the mean of the two results, viz., 45·5.

Moment of Inertia.

The moment of inertia of the magnet was calculated, and also determined by the ordinary experimental method, but the results were found to differ considerably. It was therefore determined by means of a bifilar suspension, and it was afterwards redetermined by the ordinary method with the corrections which Kreichgauer has shown to be necessary owing to the loose attachment of the auxiliary weight (*Wied. Ann.*, Vol. 25, p. 301, 1885), and the three results were in close agreement.

Final Result.

The value E of the electro-chemical equivalent of silver was found to be

As the mean of the observations in 1881

$$E = \cdot 0111833 \text{ [cm.g]} = 1 \cdot 11833 \frac{\text{mg. silver}}{\text{sec. amp.}}$$

and

As the mean of the observations in 1883

$$E = \cdot 0111822 \text{ [cm.g]}.$$

Giving the final mean result

$$E = \cdot 011183 \text{ [cm.g]}.$$

Or a current of 1 ampere will decompose in 1 second 1·1183 milligrammes of silver, ·3280 milligramme of copper, ·010386 milligramme of hydrogen, and ·09327 milligramme of water.

PELTIER'S PHENOMENON IN LIQUIDS.

BY E. NACCARI AND A. BATTELLI.

Two glass cylinders, 16 centim. in width, were placed near each other in a vessel of water, and a paper disc fastened in each half way up. At the bottom of each cylinder was a copper disc 13 centim. in diameter. Solution of blue vitriol was poured in up to the disc, and on this solution of zinc sulphate; in each of these solutions a zinc plate perforated in the centre was suspended. Both zinc plates were connected by a copper wire and a current passed through the apparatus, the intensity of which was determined by a reflecting galvanometer, one division of the scale of which represented an ampere. A very thin perforated glass plate was brought in the centre of each of the paper discs. In this aperture was accurately fitted the bulb of a thermometer, which was surrounded by a caoutchouc tube as far as the part in the aperture. The current of one or two Bunsen elements was sent through the apparatus in either direction, and the course of the thermometer observed every minute. If i and i_1 are the intensities of the current, y and y_1 the corresponding thermal effects, the magnitude of the Peltier phenomenon is given by the formula

$$h = (yi_1^2 - yi^2)/(ii_1^2 + i_1i^2).$$

Only those experiments were taken into consideration in which i and i_1 were not greatly different from each other. With the following intensities were obtained:—

i	63	123	148	187
$10^6 h$	71	64	72	67

The value of h is therefore almost independent of i, and thus Peltier's phenomenon proportional to the intensity of the current.

If when solutions of Glauber's salts of various concentration were superposed on each other, and the bulb of the thermometer was not at the surface of separation of the liquids, or if the same liquid was above and below the diaphragm, no appreciable value was obtained for h, so that the above results are not limited by other influences of heat.

From the experiments as a whole, the value of h is obtained when solutions of the following sulphates are combined with solution of $CuSO_4$ of specific gravity s, and in like manner the solutions of the chlorides with solution of cupric chloride of sp. gr. 1·10. The values of h are positive when the greater heating effect takes place, *i.e.*, when the current passes from the lower and more concentrated solution to the one above it.

Formula.	s.	h.	Formula.	s.	h.
N	—	—	$NiCl_2$	1·115	−60
NiSO.....	1·13	−49	HCl.....	1·029	−46
$Ni(NH_4)_2SO_4$ ...	1·07	12	$MgCl_2$	1·12	−36
$CuSO_4$	1·13	29	$ZnCl_2$	1·19	−23
$(NH_4)_2SO_4$	1·06	29	MCl_2	1·29	+14
Na_2SO_4.....	1 057	52	KCl.....	1·08	24
$MnSO_4$	1·1	64	NaCl	1·068	27
$MgSO_4$	1·09	74	$CaCl_2$	1·15	38
K_2SO_4	1·07	91	$MnCl_2$	1·167	38
$ZnSO_4$	1·137	101	NH_4Cl.....	1·026	52
$FeSO_4$	1·12	106			
H_2SO_4	1·05	120			

The series do not agree with each other. With solutions of various strengths, apart from H_2SO_4 and HCl, h is always positive.

If the entire apparatus was filled with water, and the thermometer was surrounded by a semicircle which was half of iron and half of zinc wire and the current was passed through, the mean of ten experiments was found to be $h = 18$; so that the Peltier phenomenon between liquids is not of a less order of magnitude than between metals. As according to Bellati the electromotive force between zinc and iron is 0·0024 volts, the absolute value of Peltier's phenomenon may be calculated from this for the liquids investigated.—*Phil. Mag.*

A PHYSICO-TECHNICAL INSTITUTE IN BERLIN.—Since Privy Councillor Siemens gave 500,000 marks towards founding an institution for the carrying out of scientific investigations for technical purposes, proposals have been brought forward for carrying the design into effect. The first suggestion of such an institution was made as long ago as the year 1872. In the year 1876 a memorial on this subject was made to the House of Deputies, and in consequence a space was provided for an institute for the practice of technical measurements in the building of the Technical High School. In the year 1883 an extension of the earlier plan was contemplated, which now, from the above-mentioned generous gift of Herr Siemens, has acquired stability. Profs. Foster and Helmholtz have designed a scheme for the institute to be founded.

UNDERGROUND WIRES IN AMERICA.

The decree which pronounced the doom of overhead street wires in the United States has been enforced with unexpected rapidity and rigour. It was thought in some quarters that compulsory abolition of a system which had grown to enormous proportions during recent years was an empty threat, and that its forcible removal was utterly out of the question. The law, however, has been complied with voluntarily though tardily in most cases, and the few exceptional instances of rebellion have been energetically put down by the local authorities. In New York and Chicago notably electric wires of every description have disappeared or are rapidly disappearing underground; and in other places—Washington, for example—some of the largest companies have already got all their wires out of sight. It is alleged that their progress would have been faster had not an attempt been made to regulate the manner of laying these wires underground, or rather to force upon the proprietors an uniform system agreeable to the recommendations of the local authorities and their advisers. A commission has been sitting to report upon the best means of carrying telephone, telegraph, and electric-light wires in conduits or tunnels below the pavement; and the uncertainty of its final decision has naturally had the effect of delaying the independent action of the various electric companies concerned.

The report of the UNDERGROUND WIRE COMMISSION of New York is now before us, and is precise enough in its recommendations; but for all practical purposes it leaves matters pretty much as they were—that is to say, the companies will be allowed to follow the advice of the commissioners, or let it alone as they please. The commission has no power to enforce its behests, and no funds to carry them out. Its suggestions, moreover, are not of such self-evident value as to certainly win over the authorities to give them the force of law, and the chief indication we can find of their being acted upon to any great extent is the intelligence, which reached us at the same time as the report, that a company calling itself the "Consolidated Telegraph and Electric Subway Company of New York City" has been organised, and is backed by strong financial names, for the purpose of constructing the subways recommended by the commission. The success of this project will depend entirely upon whether the various electric companies choose to make use of it. So far as we have any information on the subject the feeling among the companies has been and continues to be adverse to any scheme which deprives them of independent control over their own particular wires, and over the conduits in which they are severally placed. The leading idea of the Commissioners' Report is to make one conduit or subway serve for all—a very ambitious conception, no doubt, and highly agreeable to the "well-known Wall-street men and bankers," who are said to have "backed" the Electric Subway Company; but not at all satisfactory to the Telegraph and Telephone Companies who have begun operations on their own account, and whose views on the subject of electrical induction appear to have received little attention at the hands of the commission.

As was to be expected, the Electric Lighting Companies are, on the other hand, either favourable to the subway scheme or indifferent. Their position is something like that of the brewer's dray in a crowd of light broughams. Any well constructed conduit is good enough for the electric lighting wires, and if the telegraph and telephone wires do not enjoy the companionship, so much the worse for them. On this point the Report is singularly remiss. A great deal of pains have been taken to discover the best material—asphalted concrete—for constructing the conduits, but little or no attention paid to the necessity for separating the conductors. Indeed, we infer from certain passages that the several classes of wires are to be drawn into one and the same conduit. If we are mistaken in this supposition, then it seems to us the cost of constructing separate conduits for each class of wire, or one conduit large enough to render the proximity of the different wires innocuous, has not been duly weighed. We have nothing to say against the construction of subways made of "asphalte or bituminous concrete" recommended by the commission; they may be cheaper than iron, though the Report is inconclusive on this point; and they may be stronger, though the evidence here is contradictory. They afford protection against external moisture, acids, and gases, no doubt; but the question is, What protection will the respective wires obtain against each other? On this the Report is altogether silent.

It seems also that the wires will require some sort of protection against the asphalte conduit itself, for the composition is found to act injuriously on the insulating material of the wires, so that some quite novel, and probably expensive, process of shielding them from their encasement is admitted to be necessary. One of the objections urged against the alternative of iron pipes is that in case of leakage from an electric wire the current might be conducted to an adjacent telephone or telegraph wire, and start an electric light in somebody's

Digitized by Google

house or office where it was not wanted, and might not be easily extinguished. A good many "ifs" go to realise this contingency; but not more than would bring about an identical catastrophe with wires all huddled together in a single conduit. If each set of wires is to take care of itself, then each company will have to take special measures to protect its customers from accident; and of these measures the asphalted concrete conduit, whatever else it may do, takes no account whatever. The argument, therefore, becomes strong for the several companies concerned doing their own work in their own way, subject only to supervision in the interests of public safety. We strongly suspect that this is what will be done, the Commissioners' Report notwithstanding.

In point of fact, some of the best known Telegraph and Telephone Companies are proceeding on that assumption. The WESTERN UNION COMPANY, which has a large interest in Brooks' system of insulating telephone wires, is pushing it forward with considerable energy in New York; and it is alleged that one chief reason why the commission did not report more favourably of this system was because that powerful company had adopted it. Be that as it may, Mr. DAVID BROOKS' simple and effective expedient has prevailed both in that city and in Chicago, and will probably be widely adopted elsewhere, at all events for telephone wires. In the last-named place, as we reported a fortnight ago, three trunk pipes, each containing 500 wires, are being laid under the principal streets, comprising 2,000 miles of wire, with branches at suitable intervals. The pipes are of small calibre, and the wires perfectly insured against induction either on themselves or from neighbouring conductors. No system that has yet come under our notice is at once so effective and inexpensive as this; and as telephone wires must be, in all cases, provided with separate conduits of some kind, there is small likelihood of their being compelled, against the will of their owners, to take up their abode in the bituminous concrete tunnels recommended by the New York UNDERGROUND WIRE COMMISSION.

CORRESPONDENCE.

ABSOLUTE NEGATIVE CHARGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In a letter in your last issue on the subject of "Ampère's Rule," allusion is made to a theory that "the earth has an absolute negative charge." Evidently, then, this view has some kind of real existence in men's minds. Should there be any among your readers who can claim to have a personal grasp of it, they would gratify me much by explaining where the other boundary of the dielectric lies whose negative terminal is the surface of this earth, "as is supposed." Is there, so to speak, a canal of strained dielectric matter between the earth and Mars? Or is it between the earth and Venus? Though I have met with the theory before, I never regarded it as a serious idea, but merely as one of those grammatical sentences which fetch a high price in marks with the examiner, and with which, accordingly, candidates should charge their memories beforehand.

It appears to me that one absolutely essential feature in all electrostatic phenomena is a canal of dielectric bounded hither and thither by a positive and negative terminal. The sphere of electric strain lies in non-conducting matter. Strain cannot subsist along with yielding, any more than human quarrelling can; and perfect yielding would annihilate strain. Now, in conductors, so far as they are conductors, the particles *yield* to electric force and perform electric motion. When a ball or cylinder of metal lies in an electrostatic field of force, we call those parts negative where the lines of force enter the metal from the dielectric, and the opposite parts, where the lines of force issue from the metal into the dielectric, positive. The dielectric canal is a case of polarity, like a magnet which, when broken, forms parts like the original whole, or like the geometrical polarity of a straight line lying (say) east and west, which exhibits an eastward and a westward end wherever its continuity is destroyed. But I cannot find a meaning in the idea of an "absolute" charge, whether positive or negative, if it excludes this dual or polar conception; such an idea would seem to me to have no place in electrostatics.

I cannot help referring to an excellent letter from Mr. D. G. FitzGerald in *The Electrician* of June 21st, 1884 (p. 127). The writer points out that some mistaken view or other is still held by many "who have not realised that there is an electrostatic *circuit*, which is absolutely analogous to the conductive circuit."—Yours, &c, E. ALDRED WILLIAMS.

37, Burlington-road, W.

RE THE MAQUAY BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The writer of your note on the above hardly appears to appreciate what the inventor has really accomplished. First, the current delivered by the battery is more constant than that of any other battery I am acquainted with. If you make up a cell to give a certain current for a certain time, it will maintain that current absolutely constant for that time, falling very slowly afterwards. Secondly, the amount of energy obtained from a cell of a given size and weight is very largely in excess of that given by *any* other form that can be used for practical works.

As an instance of this, a battery contained in a box 3½in. cube, and weighing only 7lb., maintained a current of one ampere for four hours, and then fell very slowly for a further three hours, the difference in the light given for the fifth hour being inappreciable. The portable miner's lamp, which has been worked out in connection with the battery, which will furnish a 3 candle-power lamp for ten hours and at the end of that period have sufficient energy left to enable the miner to find his way out of the pit, weighs only 3lbs. Thirdly, the metal used requires no re-amalgamation, and there is no local action.

I hardly think that any other bichromate battery has up to the present been able to show advantages in practical working equal to the above.—Yours, &c., SYDNEY F. WALKER.

Cardiff, August 2, 1886.

THE EDGERTON MOTOR.

At the recent Novelties Exhibition of the Franklin Institute this motor was exhibited and was awarded a silver medal. The report says "the company exhibited electric motors of several sizes, from one-twelfth to six horse-power capacity, quite simple in construction. The armature is made in one casting, cylindrical in form, split longitudinally into three parts, each of which is supported on the hub or axle by a wide spoke or flange. Upon each of the three flanges is wound a coil of wire, varying in size according to the work required; these coils are connected together at one end of the armature by means of a metal ring, to which an end of each is attached, and the three opposite ends are connected with the commutator. The special advantage claimed for the division into three portions is that there is no dead point in the revolution of the armature, and the form of connection described permits such an adjustment of the coils that the same electrical result will be produced on each of the coils in turn as it reaches the proper point.

"The weight of metal in the armature is placed as near the surface of the cylinder as is consistent with strength, so as to bring it near the field. The ends of the cylinder project as far beyond the coils as the thickness of the layers of wire on the coils. The wire is sheltered by the iron and cannot be injured by abrasion on the field. The field is a cylinder, split in half longitudinally, and closely fitting the armature, so that

Digitized by Google

a piece of writing paper could hardly be inserted between them; both the armature and field are turned in a lathe. The winding of the field is upon a series of spools attached to the back of the two parts of the cylinder. The whole is enclosed in an iron shell, to which it is screwed, which supports the bearings and the armature, and forms the yoke of the magnet.

"The inventor claims simplicity of construction and durability; that the armature can be run at any speed without displacing the coils, or permitting them to touch the field; that the metal of the armature is brought nearer to the field; that the counter electromotive force in the wire of the armature is much diminished on account of the wire being further removed from the field."

EARTH CURRENTS.

Mr. T. Merncke Holst, Electrician to the Great Northern Telegraph Company at Shanghai, under date May 28, writes us as follows regarding the earth current storm which occurred there on the 30th of March last:—

Storm commenced here on 30th, 4:20 p.m., Shanghai time, and disappeared about 11 p.m., maximum strength of current, on Shanghai-Nagasaki cable = 3·6 milliamperes; 31st, disturbances from 8 a.m. to 1 p.m., and 5 to 10 p.m.; April 1st, from 10:45 a.m. to 12:30 p.m, and 5:30 to 7:15 p.m.; April 2nd, no disturbance. The strength of the current decreased considerably from day to day, as will be seen from the above diagram.

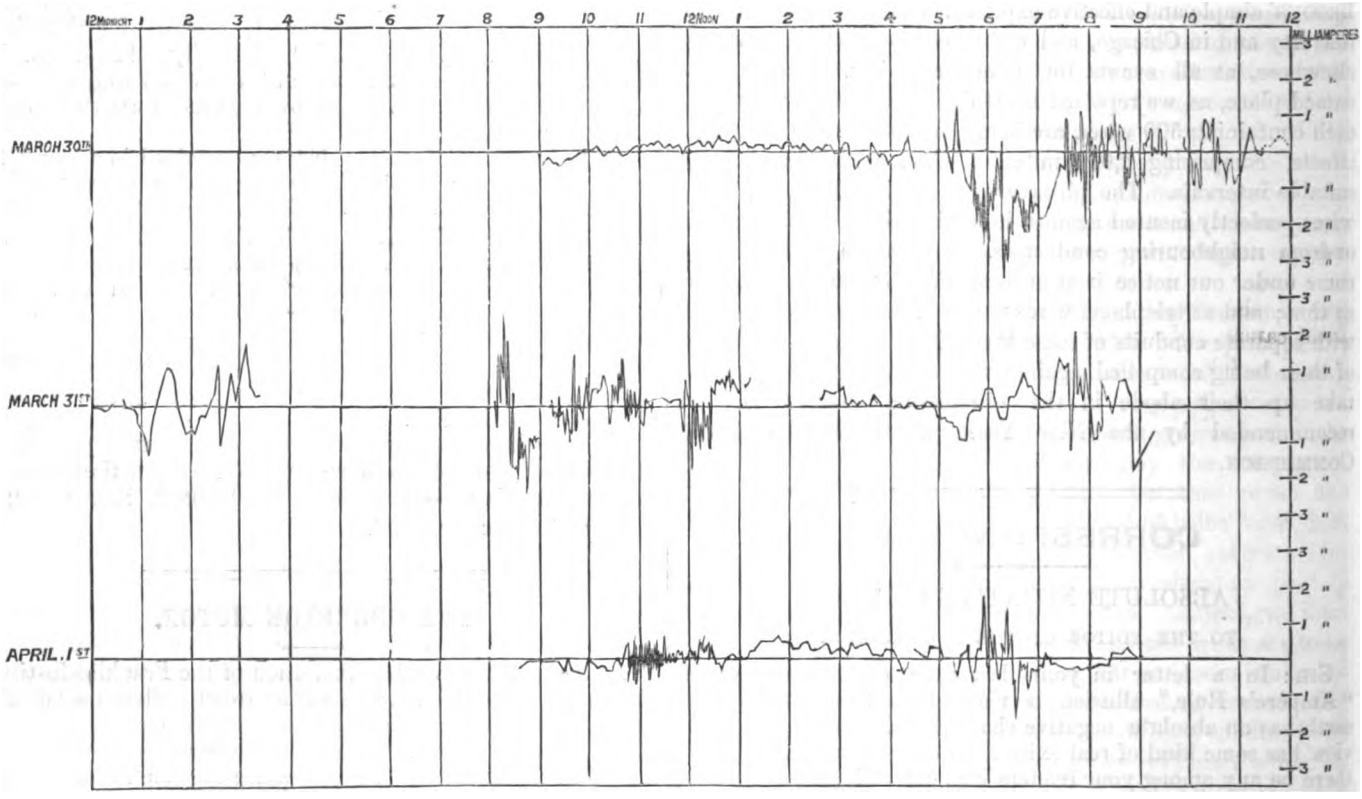

Diagram showing Earth Current Storm on Gutzlaff-Nagasaki Cable.—Shanghai time.

ELECTROMOTIVE FORCE OF VOLTAIC CELLS HAVING AN ALUMINIUM PLATE AS ONE ELECTRODE.*

BY A. P. LAURIE, B.A., B.SC.

In a former number of the *Phil. Mag.* I have given an account of some experiments undertaken with a view of testing whether the E.M.F. of a cadmium-iodine cell was really due to the combination of cadmium or iodine. As there explained, these experiments were made on account of my feeling an increasing distrust of measurements of E.M.F. made in the usual way with infinitely small currents—a distrust not of the measurements themselves, but of our right to assume that the E.M.F. of a particular cell was due to a particular chemical reaction. This doubt is obviously justified when once we realise that impurities far out of reach of analytic detection could easily produce sufficient current for the measurement of E.M.F. in the usual way. On reading the papers published by Dr. Alder Wright in 1885, I was very much struck by the results of his experiments on aluminium-zinc cells, in which he found an E.M.F. actually opposed to that calculated from the thermal data. To quote his figures, he finds that zinc-aluminium cells, with the metals immersed in sulphate of zinc and potash-alum respectively, have an E.M.F. of ·538 volt. According to the thermal data there should be an E.M.F. of ·982 volt in the opposite direction, so that we have a difference of 1·519 volt between the E.M.F. calculated from thermal data and that obtained by actual measurement. Dr. Wright's experiments with other aluminium cells give similar results.

Now, observe that the E.M.F. calculated from the thermal data is obtained by taking the heat of formation of sulphate of zinc and sulphate of alumina respectively, and subtracting the comparatively small heat of formation of sulphate of zinc from the large heat of formation of sulphate of alumina; that, therefore, the assumption is made that this cell is similar to a Daniell cell, and that sulphate of alumina will be formed and sulphate of zinc decomposed, by the passage of the current. The E.M.F. measurement, however, shows an E.M.F in the opposite direction to that calculated on this assumption. How is this to be accounted for? Dr. Wright accounts for it by assuming a "thermo-voltaic constant" of 1·519 volt. By this I understand him to mean that he believes that sulphate of zinc is formed and sulphate of alumina decomposed during the passage of a current, and that an enormous absorption of heat takes place to enable this reaction to go forward. If we believe that we are dealing only with metallic aluminium, sulphate of alumina, sulphate of zinc, and metallic zinc, then we must make the above assumption, and undoubtedly chemical analysis would confirm such a belief.

I think, then, I have said sufficient to show that we have here a point of some importance—that if we have only the above substances to deal with, Dr. Wright has made a surprising discovery. It was to test whether we really had

* From the *Phil. Mag.* for August.

Digitized by Google

these substances present that I have made the following experiments.

Before describing the experiments, however, I must say a few words about aluminium itself. It is a metal with some very peculiar and contradictory properties. Though having a very high heat of combination with oxygen, it does not tarnish in the air or decompose water at ordinary temperatures, nor is it soluble in nitric acid. If used as an electrode at which oxygen is set free by the passage of a current through dilute sulphuric acid, it opposes a very considerable resistance to the passage of the current. This resistance has been called "polarisation," and stated as high as six volts. On amalgamating the metal (which can only be done by immersing first in strong caustic) it becomes capable of decomposing water; and its oxidation in the air is so rapid that if left at rest it becomes covered with a growth of oxide in a few minutes, resembling some fungus growths in appearance.

Now, all these properties seem to me to be very easily explained by supposing aluminium to become rapidly coated with a film of oxide, whether in air or water, which, being very insoluble, protects it from all further action, and practically for chemical purposes converts an aluminium plate into an aluminium-oxide plate, unless some solvent of the oxide is present.

Starting with this view, I prepared a solution of aluminium sulphate and of zinc sulphate, enclosing one in a porous pot, and immersed a zinc rod in the zinc sulphate and an aluminium wire in the aluminium sulphate. I did not note the strength of the solutions, as the experiments were merely qualitative. I obtained a deflection on connecting this cell with the electrometer, amounting to about ·54 volt in the same direction as that obtained by Alder Wright. On removing the aluminium wire, cleaning it with sandpaper, and immediately plunging it into the liquid and connecting with the electrometer, a deflection was obtained in the same direction, but only amounting to ·14 volt. After ten minutes it had risen to ·35 volt. This seemed to show that the complete formation of the oxide film took some time. The introduction of a little caustic potash also brought the E.M.F. nearly to zero, but I had not as yet obtained an actual reversal of the E.M.F. of the cell.

I next amalgamated the wire and plunged it in the solution. I at once obtained a deflection of about ·46 volt in the *opposite direction*. At the same time hydrogen was given off, and the wire above the solution became coated with the growth of oxide already referred to.

The next experiment was an obvious one. I plunged two aluminium wires, one cleaned, the other amalgamated, in a solution of sulphate of alumina, and obtained a deflection of 1·08 volt, showing a remarkable difference in chemical properties between the amalgamated and cleaned aluminium wires. In order to test the effect of short-circuiting on the cell, I left a zinc-aluminium cell short-circuited for some days, but the aluminium plate, except for a slight darkening of the surface, remained unchanged, showing that to whatever reaction the E.M.F. of the cell was due, it was of so temporary a kind, or the internal resistance of the cell was so great, that no perceptible chemical change had been brought about.

These experiments are, I think, sufficient to show that there is no evidence that the reactions in the cell are simply the formation and decomposition of the sulphates of zinc and aluminium respectively, but that there is strong evidence to show that we are not in the cell dealing with aluminium at all, but with *aluminium oxide* supported on an aluminium plate. It is therefore more probable that the E.M.F. of the cell is due to the heat of formation of zinc sulphate, – the heat of formation of aluminium sulphate, + the heat of formation of aluminium oxide, – the heat formation of water. These reactions would result in an E.M.F. in the direction actually observed. It may be noticed that even the amalgamated aluminium gives too low a value for the reactions of the formation and decomposition of the sulphates. As, however, the water is being decomposed by the metal, we can hardly tell what the actual source of E.M.F. may be.

I do not know if Dr. Wright attached any definite meaning to the term "thermo-voltaic constant" in the case of these particular cells, as the assumption that the reactions are formation and decomposition of the sulphates is evidently questionable, even from the results he obtained.

This paper is not of course meant as a criticism on Dr. Wright's work, which I have always admired for its accuracy, but merely gives a new interpretation of certain of his experimental results.

ELECTRICAL THEORIES.

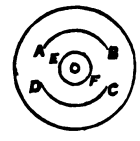
BY PROF. J. J. THOMSON, M.A., F.R.S.

(Continued from page 203.)

There is another way in which the continuity or discontinuity of the current might be tested, and which might perhaps be more delicate than the last. We have seen that at any point of a current at which Σ had a finite value the mechanical force on the element is not at right angles to the element. In addition to the ordinary force at right angles to the element, there is a force in the direction of the vector potential equal in magnitude to the product of the values of the vector potential and Σ.

The existence of this force could be tested by an arrangement of the following kind:—

A B and C D are light movable segments of the same circle, having balls covered with paraffin A, B, C, D fastened to their ends. These segments are connected with a very light framework which can rotate about an axis perpendicular to the plane of the segments; the segments touch at their middle points contact pieces which are connected with a Holtz machine. E F is the section of an electro-magnet concentric



with A B and C D; the whole is surrounded with a metal cylinder to screen it from external electric influences. When current is passing through the electro-magnet it produces a vector potential, whose direction is at right angles to the radius from O, the centre of the electro-magnet perpendicular to its axis. Thus if Σ exists there will be a couple tending to twist the system A B, C D about its axis, but if Σ exists at all it will be when the electrical condition of the balls A, B, C, D is changing, so that unless the currents are continuous we should expect the system to rotate when the balls are being charged up. I have calculated that the system might easily be made sensitive enough to be sensibly deflected on charging or discharging, provided Σ is an appreciable fraction of the rate of change of the surface-density of the electricity on the balls.

*Schiller's Second Experiment.**

Schiller has made another experiment, which shows that Ampère's theory fails for unclosed circuits. The first form of the experiment consisted in having a solenoid placed over a condenser, one of whose plates could rotate about a vertical axis coinciding with the axis of the solenoid. One end of the solenoid was connected to one plate of the condenser, and the other end to the other plate. When the solenoid is connected to a battery the condenser will charge up and there will be radial currents of electricity in the plates; the current passing through the solenoid will produce a magnetic force which will, if Ampère's theory be true, act on the radial currents in the plate of the condenser and set it in rotation. Schiller found that this effect was too small to be observed, so he modified the experiment in the following way. Let us suppose that we have the two plates of the condenser rigidly attached to their axis and placed in a field symmetrical about its axis, in which the vertical component of the magnetic force is not uniform. Then if a current be sent through the upper plate, down through the axis, and out at the lower plate, the couple tending to twist the lower plate will not be equal and opposite to that tending

* Pogg. *Ann.*, CLIX., p. 456; CLX. p. 333.

Digitized by Google

to twist the upper one, as the magnetic force is not equal at the two plates, and thus the condenser will be set in rotation. Conversely, if the condenser be set in rotation in the magnetic field, and two electrodes of a galvanometer be connected with its axis, then if Ampère's theory be true there will be an electromotive force acting round the galvanometer circuit, which will produce a current, and this current could be much more easily detected than the rotation in the first form of the experiment. Schiller calculated the deflection which he ought to get if Ampère's theory were true, and found that he could easily detect it if it existed; as he was not able to see any deflection, we must conclude that Ampère's theory is not the true one.

It is easy to see that, according to the potential theory, there would be no current in the galvanometer; for, as everything is symmetrical about the axis, the potential is not altered by the rotation. The following calculation will show that, according to the dielectric theories, there should be no current through the galvanometer.

For if a, b, c are the components of magnetic induction, F, G, H those of the vector potential, X, Y, Z those of the electromotive force, then

$$X = c\frac{dy}{dt} - b\frac{dz}{dt} - \frac{d}{dx}\left\{ F\frac{dx}{dt} + G\frac{dy}{dt} + H\frac{dz}{dt} \right\},$$

$$Y = a\frac{dz}{dt} - c\frac{dx}{dt} - \frac{d}{dy}\left\{ F\frac{dx}{dt} + G\frac{dy}{dt} + H\frac{dz}{ot} \right\}.$$

Suppose the condenser is rotating with an angular velocity ω about the axis of Z; then the E.M.F. arising from one plate is, if R be its radius,

$$\omega \int_0^R cr\,dr - \left(F\frac{dx}{dt} + G\frac{dy}{dt} \right)$$

Now

$$F\frac{dx}{dt} + G\frac{dy}{dt} = \omega R\,\Theta,$$

where Θ is the component of the vector potential along the direction of motion of a point on the circumference of the plate of the condenser.

But the line integral of the vector potential round any curve equals the number of lines of magnetic force passing through it, so that since the field is symmetrical,

$$2\pi \int_0^R cr\,dr = 2\pi R\,\Theta.$$

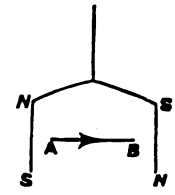
From this equation we see that the E.M.F. due to the rotation vanishes for each plate, so that, according to this theory, there should be no current through the galvanometer.

This experiment of Schiller shows that both Grassmann's and Clausius' theories must be wrong, as well as Ampère's and Korteweg's, for we can easily see that they would make the disc rotate in the way in which Schiller first tried the experiment, and if this were so, it follows from dynamical principles that a current must be produced in the second form of the experiment.

This would seem to be the case even if we take into account the currents in the dielectric, unless we suppose that all the circuits are closed, for if all the circuits are closed then the disc will not rotate, as all the theories agree. If the circuits are not closed we may divide the currents in the disc into two parts, one part being of such magnitude as to form with the dielectric currents closed circuits; then the forces on this part and the dielectric will form a system in equilibrium; and there remains the other part of the currents, the action of the magnet on which ought to set the disc in rotation. Taking Schiller's experiments together, we may say that they show that the dielectric must be taken into account, and that some form of the potential theory is the only one of the theories we are considering which can give the expression for the forces due to a distribution of currents.

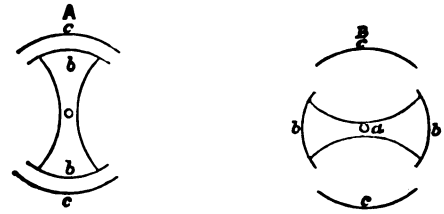
Although these two experiments of Schiller's show that of the theories we have discussed only the dielectric ones can be retained, we shall describe one or two more experiments which have been or could be made to distinguish between the various theories. Clausius' and Grassmann's theories lead to the same expression for the force between two elements of current, so that these theories stand or fall together. Grassmann in his paper* describes an experiment which would distinguish between his theory and Ampère's, or, in fact any other except Clausius', which has ever been published.

Suppose that N S and S N are two magnets whose north and south poles are denoted by N and S respectively, and that these magnets are fastened together by a rod, N S, the system



being suspended by a cocoon thread attached to the middle point of N S. Let A B be an enclosed circuit, say a wire joining the plates of a charged condenser; then, according to Grassmann's and Clausius' theories, the system will rotate in such a way that the sense of rotation is related to a vertical line drawn downwards like rotation and translation in a right-handed screw. According to every other theory it will rotate in the opposite direction.

Another experiment has been made by v. Helmholtz,† which shows that the potential theory leads to wrong results unless the action of the dielectric is taken into account. bb is a rotating conductor, to the ends of which large condenser plates are attached, which, when in rotation, come very near to the similar plates c, c. The plates b and c are segments of coaxial cylinders. In v. Helmholtz's experiments bb was rotated between the poles of a powerful electro-magnet. The plates c, c were connected with a commutator, which put them to earth when the rotating piece was in the position A, and to the plates of a Kohlrausch condenser when it was in the position B. Now suppose there is a difference of potential between b and c; suppose, for clearness, that b is at a higher potential than c, then when the rotating piece is in the position A the positive electricity goes to earth, and the negative is left to go to the Kohlrausch condenser, when the rotating piece gets to



the position B. The change in this condenser was measured by a quadrant electrometer. V. Helmholtz found that the needle of the electrometer was deflected when the piece bb was rotating. Since everything is symmetrical about the axis of rotation, there would be no difference of potential between the plates b and c, according to the potential law, if we neglect the action of the dielectric. According to Ampère's law there will be a difference of potential between b and c equal to $\Theta a\omega$, where a is the radius of the rotating piece, ω its angular velocity, and Θ the vector potential along the direction of motion of the disc. According to the dielectric theory there will also be the same difference of potential between b and c if we suppose that there is no discontinuity in the motion. We shall suppose that, instead of the velocity changing abruptly from ωa to zero as we pass from the rotating conductor to the dielectric, there is a layer of the dielectric next to the conductor in which the change of velocity is very rapid, one side of the layer moving with the velocity ωa, the other side being at rest. Then, using the same notating as before, we have—

$$X = c\frac{dy}{dt} - b\frac{dz}{dt} - \frac{d}{dx}\left\{ F\frac{dx}{dt} + G\frac{dy}{dt} + H\frac{dz}{dt} \right\},$$

$$Y = a\frac{dz}{dt} - c\frac{dx}{dt} - \frac{d}{dy}\left\{ F\frac{dx}{dt} + G\frac{dy}{dt} + H\frac{dz}{dt} \right\}.$$

* Pogg., LXIV. 1, 1845. † *Wissenschaftliche Abhandlungen*, Vol. I., 783.

Digitized by Google

Integrating across the thin layer of the dielectric, in which the velocity is changing rapidly, we see that the difference of potential between b and c equals

$$F\frac{dx}{dt}+G\frac{dy}{dt}+H\frac{dz}{dt},$$

where dx/dt, dy/dt, dz/dt are the velocities of a point on the boundary of the moving conductor. This equals $\Theta\alpha\omega$, the same value as that given by Ampère's theory, so that in this case the two theories lead to identical results, which are in agreement with the result of Helmholtz's experiments.

Rontgen has recently published* a preliminary account of some experiments which seem to prove directly that the variations in the dielectric polarisation produce effects analogous to those due to a current.

This completes the account of the experiments which have been made to test the various theories. As the result of them, we may say that they show that it is necessary to take into account the action of the dielectric, but they tell us nothing as to whether any special form of the dielectric theory, such as Maxwell's or Helmholtz's, is true or not.

I have described two experiments which would decide whether Maxwell's theory that all circuits are closed is true or not. It seems to me, however, that even if Maxwell's theory be wrong, Helmholtz's is not the only alternative. I have given a sketch of a theory in which I have tried to make as few assumptions as possible; all that I have assumed is that when a dielectric is acted on by a changing electromotive force, it behaves like a conductor conveying a current whose intensity is proportional to the rate of change of the electromotive force. We know from experiment that it produces effects of the same character, and I have assumed as the simplest assumption I could make that for the same dielectric the equivalent current is proportional to the rate of change of the electromotive force, so that the equivalent current $=\eta$ (rate of change of electromotive force).

Both Maxwell and Helmholtz assume that η depends only on the specific inductive capacity of the dielectric, but I think it is preferable, until we have seen more experiments on this point, to look on η as the measure of a new property of a dielectric, and not to assume that it is merely a function of the specific inductive capacity, the only experimental evidence for this being the by no means perfect agreement between the refractive index and the reciprocal of the square root of the specific inductive capacity. To prove Maxwell's theory of closed circuits it would not be sufficient to prove that for one medium, say air, $\eta=K/4\pi$, for it is quite conceivable that electrical phenomena may be simpler in a dielectric like air, where the electric behaviour of the ether seems to be but little affected by the presence of the dielectric, than in such a one as glass or other substance possessing a comparatively large specific inductive capacity, when the effect of the ether is seriously modified by the presence of the medium.

Since in the theory I have sketched the values of

$$\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz},$$

and $$l(u_1-u_2)+m(v_1-v_2)+n(w_1-w_2)$$

are not zero, but arbitrary, inasmuch as they involve η, in order to find the value of the force between two circuits where there is any discontinuity in the currents we shall require to know the value of the quantity k which occurs in v. Helmholtz's theory.

The most pressing need in the theory of electrodynamics seems to be an experimental investigation of the question of the continuity of these dielectric currents; we have experimental proof that they exist, but we do not know whether Maxwell's assumption that they always form closed circuits with the other currents is true or not. If Maxwell's assumption should turn out to be true, we should have a complete theory of electrical action; if, on the other hand, it should turn out to be wrong, then we should have to go on to determine the quantity k. This quantity is difficult to determine, as its influence on all closed circuits disappears. It influences, as v. Helmholtz has shown, the rate of propagation of the electric potential along conducting wires, and I think we can see that it would influence the time of oscillation of an irregular distribution electricity over a conducting shell. The easiest way, however, of determining this quantity would seem to be the straightforward one of measuring electrostatically the value of the electromotive force due to a variation in the charge of a condenser; the expression for the vector potential, as we saw on p. 140, involves k, so that if we measure the electromotive force, which is equal to the rate of variation of the vector potential, we shall determine the value of the vector potential, and consequently of k.

Appendix I.

Since the report was written I have had through the kindness of the author an opportunity of seeing the advance proofs of a paper by Professor J. H. Poynting, of Mason's College, Birmingham, "On the Connection between Electric Current and the Electric and Magnetic Induction in the surrounding Medium," which is about to appear in the *Philosophical Transactions*.

The views expressed in this paper are rather a new way of looking at Faraday and Maxwell's theory than a new theory of electrodynamic action; as, however, it brings the action of the dielectric into great prominence it is instructive to consider it.

The paper is largely based on a previous one by the same author on the "Transference of Energy in the Electromagnetic Field,"* it is therefore necessary to give a brief account of this paper.

In it the author shows that the rate of increase of the energy inside any closed surface equals

$$\frac{1}{4\pi}\int\int\{l(R'\beta-Q'\gamma)+m(\gamma P'-\alpha R')+n(\alpha Q'-\beta P')\}\,dS$$

where dS is an element of surface, l, m, n, the direction cosine of the normal to dS, α, β, γ the components of magnetic induction, and P', Q', R' given by the following equations:—

$$P'=-\frac{dF}{dt}-\frac{d\psi}{dx},\quad Q'=-\frac{dG}{dt}-\frac{d\psi}{dy},\quad R'=-\frac{dH}{dt}-\frac{d\psi}{dz},$$

where F, G, and H are the components of the vector potential and ψ the electrostatic potential; thus if the medium is at rest P', Q', R' are the components of the electromotive force at the point.

Prof. Poynting interprets this equation to mean that the components parallel to the axes of x, y, z of the flow of energy across *each* element of surface are respectively

$$\frac{1}{4\pi}(R'\beta-Q'\gamma),\quad \frac{1}{4\pi}P'\gamma-R'\alpha),\quad \frac{1}{4\pi}(Q'\alpha-P'\beta),$$

so that according to this view the energy flows in the direction which is at right angles both to the magnetic and electromotive forces, and in the direction in which a right-handed screw would move if turned round from the positive direction of the electric intensity to the positive direction of the magnetic intensity; the quantity of energy crossing in unit time unit surface at right angles to this direction being

$$\frac{1}{4\pi}\cdot\text{Electromotive force at the point}\times\text{magnetic force}\times\text{sine of the angle between these forces.}$$

This interpretation of the expression for the variation in the energy seems open to question. In the first place it would seen impossible *à priori* to determine the way in which the energy flows from one part of the field to another by merely differentiating a general expression for the energy in any region with respect to the time, without having any knowledge of the mechanism which produces the phenomena which occur in the electro-magnetic field; for although we can by means of Hamilton's or Lagrange's equations deduce from the expression for the energy the forces present in any dynamical system, and therefore the way in which the energy will move, yet for this purpose we require the energy to be expressed in terms of co-ordinates fixing the system, and it will not do to take any expression which happens to be equal to it. The problem of finding the way in which the energy is transmitted in a system whose mechanism is unknown seems to be an

* *Phil. Trans.*, 1884, Part 2.

Digitized by Google

indeterminate one; thus, for example, if the energy inside a closed surface remains constant we cannot, unless we know the mechanism of the system, tell whether this is because there is no flow of energy either into or out of the surface, or because as much flows in as flows out. The reason for this difference between what we should expect and the result obtained in this paper is not far to seek. Though the increase in the energy inside a closed surface equals

$$\frac{1}{4\pi}\int\int\{l(R'\beta - Q'\gamma) + \ldots .\}dS,$$

it does not follow that the components of the flow of energy across *each* element of surface are $(R'\beta - Q'\gamma)/4\pi$, &c., for we can find quantities u, v, w which are of the dimensions of rate of change of energy per unit area, and for which

$$\int\int (lu + mv + nw)\, dS = 0.$$

(To be concluded.)

MEASURING GALVANIC CURRENTS IN ELECTROPATHY.

Prof. Erb was the first to point out the necessity for using a galvanometer in electropathy, as an indication of the number of cells is not only insufficient but also frequently incorrect. Bichromate batteries are also very uncertain in their action, on account of the continual variation of their electromotive force, which depends not only on the greater or less depth of immersion of the electrodes, but also on the rapid alteration of the surface of the zinc and the chemical composition of the exciting liquid. Horizontal galvanometers possess great advantages over vertical, as the latter are constantly subject to the action of terrestrial magnetism, and even when correctly set at the commencement of an operation they soon give incorrect readings; their sensitiveness also depends on the position of the centre of gravity of the needle and its magnetisation, which latter is subject, under the action of the current, to constant variation.

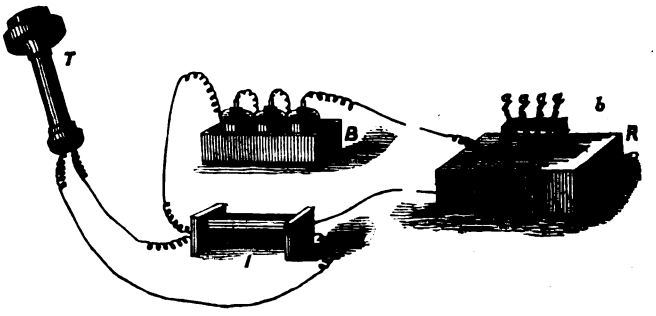
The correctness and constancy of horizontal galvanometers are independent of the magnetisation of the needle, which always returns to zero in the direction of the magnetic meridian, whatever be the force of magnetisation. When the spot is determined where the instrument is to be used, it is easy for the constructor to adjust the galvanometer to the horizontal intensity of the terrestrial magnetism of the locality in question. In order to give horizontal galvanometers the advantages of a vertical reading, which is more convenient than the horizontal for medical use, Dr. Edelmann suggests bending downwards the end of the horizontal needle, and placing a vertical scale on the curved surface of the galvanometer case, thus combining the good qualities of both systems.

A PRACTICAL USE OF THE MICROPHONE.*

In the summer of 1878, the author says that he was at the town of Canton in the eastern part of the State of Ohio, and that he was told by a person concerned, that the main conduit, which brought the water from the lake about three miles off to the town, leaked, without their being able hitherto to ascertain where the faulty place was. The conduit was a clay pipe of about 24in., and lay about 2m. deep underground in a gravelly soil, through which the issuing water trickled and never rose to the surface. The only way to ascertain where the faulty place was, appeared to be to dig at different places till they found it.

The author, however, proposed to observe the noise of the water by means of a microphone, whilst the conduit in question was closed at the end of exit in the pumping station, so that, if the conduit was in good condition, the water in it would be brought to a perfect stand-still, whilst he conjectured that above the place of leakage a sound of the motion of the water would be audible.

The accompanying sketch shows the kind of microphone used. R is a wooden box about 20cm. square, open underneath, and shut at top by a resonance board of thin wood; on this is fixed the piece of bent brass *b*, which is provided above with holes to receive thin sticks of graphite, which fit loosely in them, and the lower ends of which rest in little hollows of the carbon plate K. The battery B is united by one pole to the piece of bent brass, and from this the primary circuit passes through the graphite sticks, the carbon plate, and the primary coil to the other battery pole. The Bell telephone was connected in the customary way with the secondary coil.



After the water had been shut off in the pumping works at the town end, he began operations half-way between the lake and the town. A rushing noise was at once plainly heard in the telephone, which was at first attributed to the wind, but which remained unaltered after the microphone had been sheltered from the wind. The author had taken up a position with the telephone about 5m. on one side, whilst the microphone was directly over the water conduit.

To remove every doubt that the noise arose from the flowing of the water, the microphone was moved gradually farther from the conduit, when the noise became gradually less and less, and finally completely disappeared. Consequently it was clear that the leakage was nearer the town.

The observations were now continued at distances of 40 to 50m., and the noise remained constantly the same for some distance, till at last a sudden diminution in it was observed. Consequently the leak had been passed. The diminution of the noise signified on the author's conjecture a damming of the water. And here he was not mistaken, since the farther back again he went with the apparatus the louder the noise became. In this way he determined the place of leakage within less than 10m. On digging it up the conduit was found to be much damaged at the spot.

ON A NEW MEANS OF CONVERTING HEAT ENERGY INTO ELECTRICAL ENERGY.*

BY WILLIARD E. CASE, OF AUBURN, NEW YORK, U.S.A.

It was shown by M. Henri Loewel (see *The Chemist*, Part VIII., p. 476) that the addition of a solution of chromous chloride to stannous chloride caused a precipitate of metallic tin, the reaction forming chromic chloride. On heating the solution to the boiling point, 212 deg. F., it was found the precipitated metal was in a great measure redissolved, forming the original solution, chromous chloride and stannous chloride, without the liberation of hydrogen. On cooling this solution the tin was again precipitated, the action continuing as often as the solution was heated and cooled.

As chromous chloride has a great affinity for oxygen, it is necessary the air should be excluded from the solution, otherwise the chromous chloride would be reduced to oxychloride of chrome, as Leowel states, and the reactions would cease to take place after a time, the stannous chloride formed during each heating remaining in solution.

I constructed, in the form of a simple galvanic cell, a small element with this solution, chromic chloride,† as the electrolyte, using tin as the positive, and platinum as the negative metal. At 60 deg. F. this element gives no electromotive force, although in this case, when the cell was first set up, it gave 0·0048 volt, owing probably to the presence of some foreign substance.

On the elevation of its temperature by the application of heat, the electromotive force rose and fell, as indicated in the diagram; the curves A, B, C, D, E represent its increase during the rising temperature, and the curves F, G, H, I, J its fall while cooling. The irregularity of the curves A, B, C, D, E was probably due to unequal heating. At the termination of the experiment, when the cell had cooled down to 60deg. F., no electromotive force was

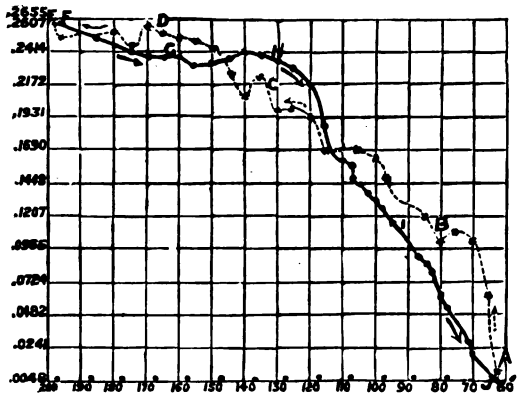
* By Ph. Seubel, in the *Centralblatt für Electrotechnik*.

* Paper read before the Royal Society.

† The solution used was made by combining chromium trioxide with hydro-chloric acid, and heating.

Digitized by Google

observed, as indicated on the diagram, of which the abscissæ are proportional to the electromotive forces, the ordinates to the temperatures Fahrenheit. The highest electromotive force was 0·2607 volt at 197deg. F., the highest degree to which the temperature was raised. If the platinum be replaced by a negative electrode of carbon, the electromotive force will be higher. It may be of interest to mention that the action of this element during heating is entirely different from that of the galvanic battery during a similar elevation of its temperature.



W. H. Preece, Esq., F.R.S. (*see* "The Effects of Temperature on the Electromotive Force and Resistance of Batteries," *Proc.* Roy. Soc.. Vol. XXXVI., p. 48), states "that changes of temperature do not practically affect electromotive forces, but that they materially affect the internal resistance of cells." When the temperature of this element was lowered to about 145deg. F., the reactions before mentioned took place. The tin taken up by the solution during heating commenced to precipitate, increasing as the temperature lowered, and the metal fell to the bottom of the cell in a form to be again utilised in the generation of the current. The amount of local action or chemical corrosion which took place above 150deg. F. was excessive, but the metal taken up by the solution was very much less when the temperature of the electrolyte was not raised above the point of precipitation, 140deg. F. The metal taken up below this point appears to be precipitated under the same conditions as that taken up at higher temperature, and seems to be precipitated whether the circuit be open or closed.

It will be seen on the curves F, G, H, I, J, with failing temperature, that the electromotive force increased between 150deg. F. and 140deg. F.; this might have been due to the reactions which took place during the precipitation of the metal.

Further investigations to determine the efficiency of this element would be of interest.

ALTERNATING CURRENTS AND THEIR PRACTICAL USES.*

At first only battery, and consequently continuous and constant, currents were known. Their E.M.Fs. are small, and for a single arc light they needed an army of cells which filled a whole room.

Later, after the discovery of induction, when they recognised the physiological action of the current, they made use of induction to generate higher E.M.Fs. They transformed battery currents, which possessed so low an E.M.F. that they could not touch the nerves at all with them, into currents of high E.M.F., which were capable of strongly affecting the nervous system. These currents were either extra currents or secondary currents, produced with a sliding apparatus or Rhumkorff coil. These currents of higher E.M.F. were induction currents, and, what induction always generates, alternating currents.

Hence arose the misconception, somewhat prevalent in Germany, that alternating currents were dangerous.

If we close a battery of a few elements by a circuit in which there is little induction, such as, for instance, a series of glow-lamps, we can break this circuit a hundred times quickly or slowly, without any action being felt. But if the same battery is closed by a conductor of considerable self-induction—for example, by a coil of many windings with an iron core in it, then every interruption will be felt plainly enough. The interruption of one and the same current is in one case physiologically actionless, in the other of strong effect. The interruption itself exercises no action, but the strong E.M.F. and current generated by the induction does.

To illustrate the matter further, let us consider a dynamo machine, with powerful magnetic fields—for example, an Edison machine. The arms of the magnets are wound with immense long coils of copper wire, and these coils are united with the binding screws of the machine to form a shunt circuit. The potential difference at the binding screws amounts to about 100 volts. The magnet coils consequently experience an E.M.F. of only 100 volts. Nobody need be afraid of laying hold of the ends of the wires of these coils with their naked hands, for we know that an E.M.F. of 100 volts is harmless. On the contrary, let any one beware of touching these wire ends at the instant when the circuit of the magnet coil is suddenly broken. By the sudden demagnetisation of the iron there arises in the long coil an instantaneous current, whose E.M.F. may reach many hundred volts. But if we break the outer circuit which is formed of glow lamps the interruption is scarcely perceptible.

Other chance circumstances have assisted to confirm this erroneous opinion. The period, about eight years ago, is remembered, when the division of the electric light, as it was called, was found out, viz., that they could keep up several arc lights in series by one dynamo machine. First came the Jablochkoff lamps, for which Lontin and Gramme invented their alternating machine, and then the division lamps of Siemens, which were fed by Siemens alternating machines. Thus there came for the first time currents with great E.M.Fs. into practical electric lighting, since it is evident that a series of lamps must have a higher E.M.F. than a single one. We now heard for the first time, "Take care, you are warned not to touch the conductors," and, because these currents of high E.M.F. were also alternating currents, they again thought that the danger lay in the currents being alternating. That the continuous currents of Brush, which were soon after introduced with their 1,000 and 2,000 volts., brought more danger than all the alternate currents was not noticed.

It is not the quality of the current, not its duration, direction, &c., which is the test of its danger, but solely the *difference of potential or E.M.F. to which the body is exposed, that is the difference of potential between the two points where the body is in contact with the circuit.* Consequently, an electric current, be it uniform, intermitting, or alternating, may be dangerous if it possesses a high E.M.F., and every electric current is perfectly harmless if it possesses a small E.M.F.—for example, 100 or fewer volts.

From the point of view of safety it is a necessity with all electric currents, whatever their name and origin, that in house conductors and lamps, which are tended by unskilled persons, only such currents should be used as have not a high E.M.F., and that such conductors as carry currents of high E.M.F. should be made inaccessible to unprofessionals.

Again, many think that alternate currents are not so effective as continuous currents. This opinion is also in most cases erroneous.

Let us consider a single coil of wire which we move in a magnetic field. Its plane cuts the lines of force. As long as the number of force-lines inside the coil remains unaltered there is no resistance to the motion, and no current is generated in the coil; only when the motion alters the number of lines of force does the magnetic field offer a resistance to the motion and awake an electric current either in one direction or the other. If the coil move from a weaker to a stronger field, an electric current circulates in one direction; on the other hand, if the motion is from a stronger to a weaker, the current is in the opposite direction.

If we had an infinitely extended magnetic field in which the intensity varied continuously, we could by a continuous motion of the circuit call forth a continuous current. But since this is impracticable in reality, and we have only a limited field in which the coil must move, it is impossible but that we should have currents which alternate more or less rapidly equally whether the motion is rotatory or oscillatory. Consequently, we have always alternate currents in the armature of a dynamo machine, never continuous ones like those of batteries and thermopiles. It is only outside the machine that the current of a dynamo can be made continuous. The commutators serve for this purpose, or the ingenious collectors introduced by Gramme.

There is, indeed, a practical difference between continuous and alternating machines, and in this difference the alternating machines have an advantage. This difference does not exist inside the machine, but in the manner of collecting the currents. The continuous machine must have a commutator or collector, by which its whole current is taken, and that is its weak part. The currents of the alternating machines, on the other hand, are caught in their natural state, and as they have arisen they go out into the circuit, either from contact rings, which have uninterrupted and constant contact, or still better by fixed binding screws direct from the armature.

Even with alternating machines the tiresome process of commutation, alas, is not quite avoided, for these machines also need continuous currents for the excitation of their magnets. But the evil here is much smaller than with continuous current machines, other things being equal. With a 100 horse-power continuous machine, for example, we have to reverse 600 to 700 amperes; with a machine which differs only in being alternating only 20 or 30 amperes, the E.M F. being the same in the two cases.

* Abstract from a paper by Max Deri, in the *Zeitschrift für Elektrotechnik*.

Digitized by Google

On this account one is less trammelled in the construction of large alternating machines than in the case of continuous machines. An Edison 1,000-light machine is looked upon as a colossus. On the other hand, an alternating machine for 4,000 to 8,000 lights is no particular masterpiece.

The reason of this lies in the fact that the induced coils need not be brought together to a collector by an innumerable number of connecting wires in an alternating machine like in a continuous machine. The armature wires can rather be so conveniently distributed on the outer periphery of the whole construction as is most suitable for the efficiency. These wire coils may, if we please, be made stationary, whilst the more massive parts of the machine are made to rotate. Such arrangements have hitherto been sought to be made in vain with continuous machines.

Hence arises the fact that alternating machines do not require such rapid rotation as continuous machines. Continuous machines which make less than 500 turns per minute are not frequent. Alternating machines require for the same performance about half the number of revolutions. There are plenty of alternating machines which work with only 150, and even fewer revolutions. That this property from a technical point of view is very valuable, nobody can doubt.

The alternating machines have another advantage over the continuous machines, which in my opinion cannot be enough insisted upon. It is well known how difficult it is to generate with a dynamo machine currents of high E.M.F., for example, of many 1,000 volts. In the armature of a continuous machine, which must form the most compactly constructed part of the apparatus, it is unavoidable pushing very close to one another such points of the current-yielding wires as have very considerable differences of potential. The wire coils themselves are mounted very closely together; their connecting wires and the sectors of the collector are pushed still closer together. The danger of a current of great E.M.F. leaking through from weakness of the insulation is consequently very great.

The relations of rightly constructed alternating machines are much more favourable on these points.

There is no argument to show that alternating machines should not work with just as good, useful effect, and should not be as satisfactory in their performances as continuous machines, and, indeed, I have shown you properties of alternating machines which may enable them to surpass other dynamo machines.

What has just been said refers rather to the alternating machines than to the currents which they generate. Before speaking of the currents we will return to induction. It was shown how electric currents are induced by the motion of a conductor in a magnetic field, and that such currents are in practice always alternating currents. It may be added that this induction, as is well known, is very much strengthened by the use of iron.

The author goes on to speak of the rapid reversal of the magnetic force lines of the iron by an alternating current, and of how this rapid reversal may generate currents in any conductor in their field. He speaks of the great advantage of transformators in the conversion of electric energy.

He says the negative E.M.F. of a coil traversed by a current and consequently also the E.M.F. of a secondary coil depends evidently on the course of alternation of the current and on the properties and dimensions of the matter in which the force lines develop themselves. In induction of force lines iron far surpasses all other bodies. Its permeability for magnetic force lines it has been shown is many hundred times greater than that of air. Consequently, the more iron is employed and the more fully the space in which the force lines describe their path is filled with it the stronger is the action. When the force lines issue into the air, poles are formed and the force lines are dispersed. For the strongest action closed iron circuits should be used which have no poles.

To avoid losses in the induction care must be taken to avoid any metal work (except the secondary coil) coming into the range of the force lines, else the parasitical currents known as "Foucault's currents" will be induced in it.

Good conductors should be used for each kind of induction—iron for the magnetic and copper for the electro-magnetic. It is simplest to employ wires of small cross-section for both. The iron wires are arranged parallel to the force lines engendered by the current, that is perpendicular to the current, and the copper wire of the secondary circuit parallel to that of the primary one. All the wires should be insulated. In such an arrangement no parasitical currents can arise, for the insulation of the iron wires prevents their formation in the core.

He then quotes as an example of a transformator one in which for a consumption of 7,560 watts by the primary coil, the secondary gives 7,200 useful watts, that is, it has an efficiency of 95·2 per cent.

He says that a dynamo machine must always have two defects in comparison with a transformator:—(1) The loss by friction in the motion; (2) the dispersion of the force lines in the air.

The action of alternating currents is to be very much valued, in that it renders transformation possible. It is a benefit to be able to work with high E.M.Fs., which are indispensable to overcome distance, and then to be able to get rid of them, and transform them into comparatively low ones when we no longer require them or they are inconvenient.

The alternating current can be employed just as well as the continuous current for the production of light and warmth. In the production of light there is to be sure some difference in the working, but only with the arc light. The continuous current has here the advantage that it hollows out a crater in the positive carbon, which acts as a natural reflector, and so produces downwards a more favourable lighting effect. On the other hand, an alternating current has the advantage that both the carbons wear out in the same manner.

For glow-lamps the lighting action of both kinds of currents is perfectly equal.

For motors up to the present time the continuous current has been almost exclusively employed. But thereby it is by no means implied that alternating currents cannot also produce motive work. I even assert, and do not rest upon my own individual views alone, but upon the results of experiments which are not yet terminated, that alternating currents will also be found useful in the working of electro-motors, and will enter into competition with continuous currents.

Continuous currents must, however, be given their due in one particular. Alternating currents are useless for electrolysis, and consequently they are unfit for all metallurgical work. They cannot either be employed with accumulators. This province belongs entirely to continuous currents.

This is, however, the only province wherein alternate currents yield to continuous currents; everywhere else they will dispute the field with them.

SOUTH KENSINGTON EXAMINATIONS.

(Continued from page 158.)

Second Stage or Advanced Examination.

Instructions.—Read the general instructions at the head of the elementary paper. You are not permitted to attempt more than eight questions. You may select only two in Magnetism, three in Frictional Electricity, and three in Voltaic Electricity. The value attached to each question is the same.

Time, three hours.

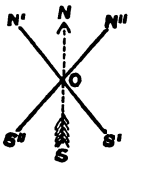
Magnetism.

21. A circular steel disc is magnetised, so that one of its diameters is its magnetic axis. How could you find the magnetic axis by observing the position which the disc takes when it is hung by a silk thread so that it lies horizontally?

A.—When the disc is suspended horizontally, mark some point of its circumference. Invert the disc, again suspend it horizontally with its centre at the same point as before, and mark that point on the circumference which occupies the position previously occupied by the first marked point. The magnetic axis of the disc, being the diameter which occupies the same position before and after the inversion, will be the diameter bisecting the arc intercepted between the two marked points.

22. Two equal and equally magnetised darning needles are thrust through a wooden match at right angles to it; and with the similar poles pointing in opposite directions. If when the match is hung by one end from a silk fibre the needles are not in the same vertical plane, will the combination be astatic? If not, how will it place itself, and why?

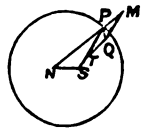
A.—The directing force acting on the combination is that due to the horizontal component of the earth's magnetic intensity at the place of the experiment. We have therefore only to consider the forces acting in a horizontal plane, which we will suppose to be the plane of the paper.



Let the vertical through the point of suspension cut the plane of the paper at O, and let N' S' and N'' S'' be the projections of the two needles on this plane. In order that the system may be in equilibrium, the sum of the moments about O of the force acting upon it must vanish, and, since the needles are equal and equally magnetised, it is clear that this condition will be satisfied when, and only when, the bisector of the vertically opposite angles N' O N'' and S' O S'' lies in the plane of the magnetic meridian.

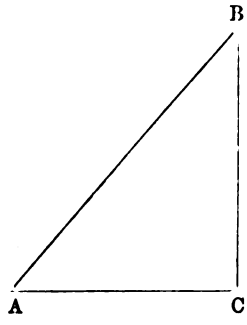
Digitized by Google

23. A bar magnet is laid at the middle of a circle on the floor. Explain a method by which the direction could be found, in which a small compass needle placed at any point on the circumference of the circle would set itself. (The earth's magnetic action may be neglected in comparison with that of the magnet.)



A.—Let N S be the bar magnet, and P the position of the centre of the small compass needle. Since the compass needle is very small in comparison with its distance from N S, we may consider the action of N S on the north pole of the needle to be the same as if the north pole were at the point P. The force exerted on the north pole of the compass needle by the north and south poles of N S respectively will be $\mu/N P^2$ acting in the direction N P, and $\mu/S P^2$ acting in the direction P S, where μ is a constant, its value being the product of the strength of a pole of N S into the strength of a pole of the compass needle. To determine the action of N S on the north pole of the compass needle we must therefore set off from P, along N P produced, a distance P M, representing on any convenient scale the quantity $\mu/N P^2$, and along P S we must set off a distance P T, representing on the same scale, the quantity $\mu/S P^2$. Completing the parallelogram T P M Q, and joining P Q, we find that the effect will be to make the needle set in the direction P Q, with its north pole pointing to Q. If we consider the action of N S upon the south pole of the needle, again assumed to coincide with P, we find in the same way that the effect would be to set the needle in the line P Q, with its south pole directed towards P, the same position as before.

24. Find the total magnetic force of the earth at a place where the horizontal component is 0·223 and the dip 60°.



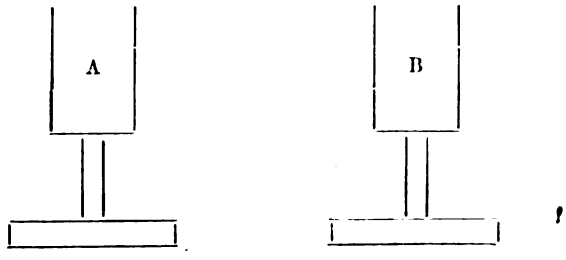
A.—Draw a straight line A C, representing on any scale the horizontal component of the earth's magnetic force; at the point C erect a perpendicular to A C, and through the point A draw the straight line A B, making an angle of 60° with D C, and cutting the perpendicular at B. Then A B represents on the same scale the total magnetic force.

But $$A B = \frac{A C}{\cos 60^\circ} = 2 A C$$

Therefore the total magnetic force is ·446.

Frictional Electricity.

25. You have two metal pots on separate insulating stands; also a metal ball carried by an insulating stem; also a wire connected with the earth. Suppose the ball, or one of the pots, to be slightly electrified. Describe and explain a process by the repetition of which you could electrify the two pots more and more strongly, one positively and the other negatively.



A.—Suppose we begin with a slight positive electrification on the ball.

(1) Hold the ball by its insulating handle within one of the pots, say B, without touching it. While it is there connect B to earth by means of the wire; then remove, first the wire and then the ball. B will thus receive a negative charge nearly equal in amount to the positive charge on the ball.

(2) Bring the ball, held as before by its insulating handle, into contact with the interior of the other pot A, then the charge on the ball will be transferred to A, leaving A positively charged and the ball neutral.

(3) Hold the ball near to the outside of A without touching it, earth-connect the ball, and remove the earth-connection while it is still under the inductive influence of A. The ball will then be charged negatively.

(4) Bring the negatively-charged ball into contact with the interior of B, when it will give the whole of its charge to B, leaving B with a stronger negative electrification.

(5) Hold the ball near to the outside of B without touching it, earth-connect the ball, and remove the earth-connection while it is still under the inductive influence of B. The ball will then be charged positively.

(6) Bring the positively charged ball into contact with the interior of A, when it will give the whole of its charge to A, leaving A with a stronger positive electrification.

By continuing this series of operations it is clear that the positive electrification of A and the negative electrification of B will be continually increased.

26. A large insulated metal ball at a great distance from all other conductors is electrified. And then by touching it with an earth-connected wire it is discharged. It is again electrified to the same degree as before, and then discharged by bringing it into contact with a wall of the room; why does the second discharge produce less heat than the first?

A.—The work done in discharging a conductor charged with a quantity, Q, of electricity, and at the potential V, is $\frac{1}{2}$ Q V.

The capacity of the conductor will have its smallest possible value, and therefore the potential will have its greatest possible value when the charged conductor is at so great a distance from all other conductors of electricity that no inductive action can take place between it and them. The potential of the metal ball will therefore diminish as it approaches the wall, since the latter is a conductor of electricity, while its charge remains unaltered.

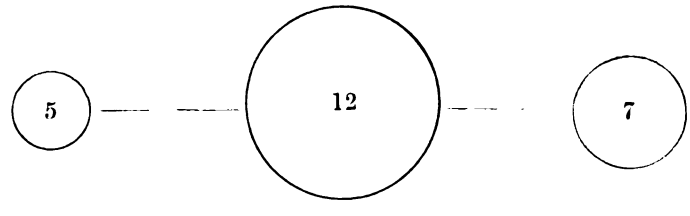
Less work will therefore be done in the direct discharge between the metal ball and the wall of the room than when the ball is kept at a distance from other conductors and discharged by contact with an earth-connected wire, the decrease in the potential of the ball, due to the neighbourhood of the wire, being exceedingly small compared with that due to the neighbourhood of the wall.

The same result may also be obtained directly from considerations of energy, thus:—

The electrified ball, at a great distance from the wall and all other conductors, possesses a certain definite amount of potential energy in virtue of its electrification.

As it is made to approach the wall it induces an opposite charge on the surface of the wall, causing an attraction between them, so that the ball in its approach does a certain amount of work, and, therefore, loses a portion of its stored up energy before the discharge takes place, and, therefore, there will be a smaller amount of potential energy to be transformed into heat during the discharge. The electrification induced on the wire when it is brought near to the ball will be so small that its effect will be practically inappreciable.

27. Three metal balls, the diameters of which are respectively 5, 7, 12in., are all connected together by very fine wires, but are otherwise insulated. If the smallest ball has a charge of 10, what are the charges of the other balls?



A.—If the spheres are so far apart that their inductive action on each other may be neglected, they may be considered as though each were at an infinite distance from all other conductors, as the presence of the fine wire will not increase their capacity by an appreciable amount. In this case, then, their capacities will be measured by their radii; and as they are electrically connected, and therefore at the same potential, their charges will be proportional to their capacities.

Therefore, if the 5in. sphere have a charge of 10, the 7in. sphere will have a change of

$$\frac{10 \times 7}{5} = 14$$

and the 12in. sphere will have a charge of

$$\frac{10 \times 12}{5} = 24.$$

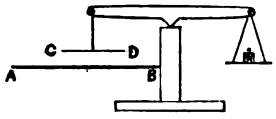
28. Describe and explain the use of any form of "attracted disc electrometer." Show what it measures, and explain the action of the "guard ring."



A.—The attracted disc electrometer consists essentially of a metallic disc A B, insulated and fixed in a horizontal position, and which can be maintained at a constant potential by being connected with the inside coating of a Leyden jar, or it may be kept at zero potential by being connected with the earth. Over the centre of this disc a smaller metallic disc, C D, is suspended horizontally from one end of the beam of a balance, the other end of which carries a weight, W.

The instrument is used to measure the difference between the potential of a conductor placed in metallic connection with C D, and that of the disc A B.

If the disc A B be made large compared with C D it may be treated as though it were an infinite plane; and in that case if V be the difference in the potentials of the discs, and the distance D between them be very small, we may neglect the effect of the electrification on the upper surface of C D, and the density σ on the lower surface will be $V/4\pi D$, and therefore if A be the area of the disc C D, and F the force between the two discs, we shall have

$$F = 2\pi\sigma^2 A = \frac{V^2 A}{8\pi D^2}$$

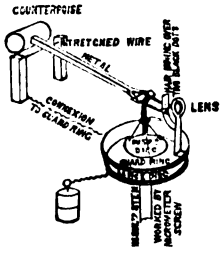
If W be the mass in the scale pan, and g the force of gravity at the place of observation, we shall also have

$$F = W g,$$

and therefore

$$V = D\sqrt{\frac{8\pi W g}{A}}$$

This formula is, however, only exact when D is infinitely small compared with the diameters of the discs, and, therefore, very small distances must be used to get approximately correct results, and it is then very difficult to measure D correctly and also to ensure that this distance should be nearly enough equal between different parts of the plates. Sir William Thomson, therefore, in addition to other improvements, has modified the instrument by the addition of the guard ring, which consists of a metallic disc, at least as large as the fixed disc, and having a central aperture through which the attracted disc can just pass without touching.



(From "Maxwell's Electricity," Vol. I., p. 267, 1st Edition.)

The guard ring has its lower surface truly plane, and is fixed so that it always remains parallel to the lower or fixed disc. The observations are made with the movable disc in the same plane as the guard ring, so that, as they are in electrical communication by means of the fine wire shown in the figure, they may be considered as forming one disc, but the force is only measured on that part of this disc where the distribution is most regular, the want of uniformity being almost entirely near the edge, and, therefore, of no importance, as it occurs on the guard ring and not on the suspended portion. Electrification of the back of the disc is entirely prevented by connecting the guard ring with a metal case surrounding the back of the suspended disc.

The fixed disc is mounted horizontally on an insulating stem, and can be moved vertically through measurable distances by means of a micrometer screw. The suspended disc is delicately balanced in the manner shown in the figure.

To adjust the suspended disc in the plane of the guard ring, the lower disc is screwed up until it comes into contract with the guard ring, and the suspended disc is allowed to rest upon the lower one, so that its under surface is in the same plane as the under surface of the guard ring. Two black dots are then made on an arm attached to the guard ring, and another branch of this arm carries a plano-convex lens, with its convex side next to the dots. A hair is attached to the movable disc in such a position that when it is in the right position with respect to the guard ring, the hair when viewed through the lens appears straight, and bisects the distance between the dots. The horizontality of the suspended disc is tested by comparing the reflection of part of an object from its upper surface with that of the rest of the same object from the upper surface of the guard ring.

The balance is so arranged that when the apparatus is entirely free from electrification (ensured by putting every part in metallic communication), and a certain known weight is placed on the centre of the suspended disc, it is in equilibrium in its normal position, determined as above.

A metal case provided with apertures through which the dots can be seen is placed over the guard ring, and encloses the balance and suspended disc. This case is in metallic communication with the guard ring and suspended disc, but is insulated from the other parts of the apparatus.

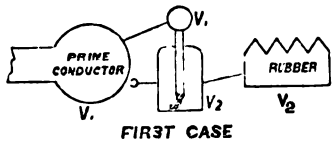
When the difference of potentials of two conductors is to be measured by the instrument, they are connected by means of fine wires to the upper and lower discs respectively, the weight on the suspended disc is removed, and the lower disc is moved up by the micrometer screw until the electrical attraction brings the suspended disc back to the normal position.

A mathematical investigation shows that if the suspended disc and guard ring are accurately in the same plane, and there is only a very small portion of the aperture unoccupied by the suspended disc, the difference of potential will again be given, to a very close approximation, by the formula

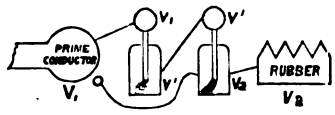
$$V = D\sqrt{\frac{8\pi W g}{A}}$$

where A is now to be taken as the mean between the area of the suspended disc, and that of the aperture in the guard ring.

29. The inside of a Leyden jar is connected with the prime conductor of an electrical machine, and the outside with the rubber of the machine, and also with a brass ball fixed at $\frac{1}{10}$ inch from the prime conductor. If the jar is at first without charge, ten turns of the machine are required to cause a spark to pass between the conductor and the ball. If now (the inside of the jar remaining, as before, connected with the prime conductor) the outside is insulated and connected with the inside of an exactly similar jar, the outside of which is connected with the rubber and the brass ball, show how many turns of the machine would be required to make a spark pass.



FIRST CASE



SECOND CASE.

A.—The same difference of potential must be produced in each case between the prime conductor and the rubber of the machine, and therefore the number of turns required in the two cases will be in the proportion of the capacity of the single jar to the capacity of the two jars arranged in "cascade." Let V_1 be the potential of the prime conductor, and therefore also that of the inner coating of the single jar in the first case, and of the inner coating of the first jar in the second case. Let V_2 be the potential of the rubber, and therefore also that of the outer coating of the single jar in the first case, and of the outer coating of the second jar in the second case. Let V^1 be the potential (in the second case) of the outer coating of the first jar, and therefore also of the inner coating of the second jar.

Then if A be the area of one coating of a jar, d the thickness, and k the specific inductive capacity of the glass, the charge of the single jar will be

$$Q = (V_1 - V_2)\frac{k A}{4\pi d}$$

and in the second case the charge of the first jar will be

$$Q_1 = (V_1 - V^1)\frac{k A}{4\pi d}$$

and the charge of the second jar will be

$$Q_2 = (V^1 - V_2)\frac{k A}{4\pi d}.$$

Hence

$$Q_1 + Q_2 = (V_1 - V_2)\frac{k A}{4\pi d} = Q.$$

So that the capacity of the two jars connected in cascade is $k A/4\pi d$, the same as that of a single jar.

Ten turns of the machine will therefore be required to cause a spark in the second case as in the first.

Voltaic Electricity.

30. Two exactly equal pieces of copper are drawn into wire ; one into a wire 10ft. long, and the other into a wire 20ft. long. If the resistance of the shorter wire is 0·5 ohm, what is the resistance of the longer wire ?

A.—Since the two pieces of wire contain equal amounts of similar metal, therefore the second piece having double the length of the first will have half its sectional area, and therefore, since the resistance of a wire of a given material is proportional to the quotient of its length by its sectional area, the resistance of the second wire will be four times that of the first, or 2 ohms.

31. A thick copper wire and a thin copper wire, of such lengths as to have the same resistances, are joined end to end and used to connect the terminals of a battery, so that the same current flows through them both. Explain why the thin wire becomes hotter than the thick one.

A.—Since the resistances of the two wires are equal, and the same current flows through them, equal quantities of heat are produced in the wires.

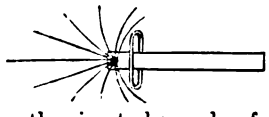
If we consider what happens when the current is first started we see that the thin wire will rise the more rapidly in temperature, for two reasons.

(1) The thin wire, having the same resistance as the thick one, must be shorter, as well as of smaller diameter, and therefore its mass must be less than that of the thick wire.

(2) The thin wire must, for the same reason, have a smaller superficial area than the thick one, and therefore the heat generated in it does not escape so rapidly by radiation.

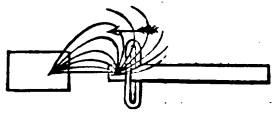
When a permanent state is reached the thick wire will remain at a lower temperature than the thin one, owing to its greater radiating surface.

32. A metal ring is put round the end of a bar magnet. Upon bringing a mass of soft iron near to this end of the magnet, a current is produced in the ring. Show what motions (*a*) of the magnet and (*b*) of the ring will produce a similar current in the absence of the soft iron.



A.—We will suppose the ring to be made of some non-magnetic metal, as the lines of force in that case are not affected by the ring, and therefore the figures will be simpler ; but it will easily be seen that a similar result would be obtained in either case.

Fig. 1 shows the ring surrounding one end of the bar magnet, with the general form and direction of the lines of force due to the pole near the ring. If a piece of soft iron be brought near to this end of the magnet it will be magnetised by the inductive action of the magnet, and will deflect the lines of force, making them cut the ring in the direction shown by the arrow in the second figure, causing a momentary current round the ring.



In order to produce a similar current in the absence of the iron by a motion of the ring relative to the magnet, the motion must be such that the lines of force will cut the ring in the same direction as before, and it is clear from the first figure that this will occur either when the ring is pushed further on to the magnet (towards its centre) or when the magnet is pushed further into the ring.

33. A battery is employed to drive a magneto-electric engine. Does the rate of consumption of zinc increase or decrease (and why) if the speed of the engine is increased by lessening the work it has to do ?

A.—If the speed of the engine be increased by lessening the work it has to do, the back electromotive force will be increased. This will diminish the current through the battery, and therefore the rate of consumption of zinc will decrease.

34. Six Grove cells, connected (*a*) in a single series and (*b*) as two series of three each, are used to decompose water in a voltameter. If there is no local action in the battery, show how much zinc is dissolved in each case (*a*) and (*b*) in the whole battery, while one grain of hydrogen is evolved in the voltameter.

Take sulphate of hydrogen (sulphuric acid) as H_2SO_4 (98) and sulphate of zinc as $ZnSO_4$ (161).

A.—Taking $H=1$ we get

$SO_4=98-2=96.$

And therefore $Zn=161-96=65.$

Now Zn replaces H_2, therefore for each grain of hydrogen evolved in the voltameter $65/2=32·5$ grains of zinc are dissolved in each cell connected in series. Thus

Quantity dissolved in first case $=32·5\times6=195$ grains.

Quantity dissolved in second case $=32·5\times3=97·5$ grains.

COMPANIES' MEETINGS & REPORTS.

Submarine Telegraph Company (Limited).

The half-yearly meeting of the proprietors of this Company was held at the offices, 2, Throgmorton-avenue, London-wall, on the 3rd inst., under the presidency of Sir Julian Goldsmid, Bart, M.P.

The SECRETARY (Mr. S. M. Clare) having read the notice convening the meeting, and the Chairman having affixed the seal to the register of shareholders, the report, which has appeared in *The Electrician*, was taken as read.

The CHAIRMAN, in moving the adoption of the report, said : I have very few observations to make. You will see that the diminution in the length of the messages has continued, and the result has been that we have received considerably less than we did during the corresponding period of 1885, and at the same time, owing to causes mentioned in the report, to which I shall refer a little presently, the expenditure has increased. Now, with regard to the length of the messages, it has been my practice for several years to give you complete information, in addition to what appears in the report, and I think you will immediately see, when I give you the figures to-day, why it is that we have received so much less. The report says that we carried 20,777 more messages in the six months which ended on the 30th June last than we did in the corresponding period of 1885. But we carried in those messages 747,315 words less. Now, of course, as we are paid by words you will understand that by the reduction in their number we have received so much less. In January, 1885, the average length of the messages was 11·80 words, and in the month of January, 1886, the average length was 11·10 words. That shows you a decrease of ·70 words for the month, and each month has gone on much in the same proportion. In February, 1885, the average length was 11·75 ; in February, 1886, it was 11·07 ; in March, 1885, 11·69 ; in March, 1886, 10·95 ; in April, 1885, 11·86 ; in April, 1886, 11 ; in May, 1885, 11·62 ; in May, 1886, 11·11 ; and in June, 1885, 11·57, against 11·08 in 1886. The total gives an average of 11·72 words for the six months ended June 30th, 1885, whereas the average length of the messages sent in the six months which have just ended was 11·05 words, showing a decrease of ·67 words. That decrease, therefore, clearly explains to you the diminution of the income in the half year. The next point is that we have some increase of expenditure. First of all, and most important, and most necessary, has been the increase of expenditure upon the cables. As you will remember, during the previous year or two we had been singularly fortunate as to accidents to the cables. We had very few, and the result was that we spent comparatively little on the cables. But the half year we are now referring to was less satisfactory. We had to put in a considerable amount of new cable in our repairs. We used £1,700 worth more cable in our repairs than we did in the previous half year. The increase altogether was £2,095—that is an increase to carry on our business. No sensible man—and I believe all proprietors in submarine telegraphs are sensible men—will object to that. The other item of increase is the salaries of the clerks. We have several classes of clerks, and the men gradually rise from one class to another. The two highest classes contain a fixed number, and at the present time there are of the second class that can be promoted to the first class only three clerks. The result is that we have, I trust, got nearly to the maximum of expenditure as to salaries. But it is right that the Company should give fair and reasonable salaries. The system adopted has cost the Company a good deal of money, however. The other amount of increased expenditure is the large payment to the French Government on account of the clerks on the other side of the water. At the former meeting I said there was some question raised by the French Government as to the payment on our part for clerks in Paris. We thought the claim on us was unreasonable, and we instructed our legal advisers to resist the claim. We were threatened with considerable law suits, and although we were advised that we should win, no sensible company likes to have a fight with a Government with whom it is carrying on business, and I saw a chance of a satisfactory settlement with the excellent man who is now the Minister of Posts and Telegraphs, and we came to an arrangement by which we have to pay a moderate increase, arriving at the same time at a final settlement of the matter. This arrangement was approved by the directors. It may cost us £1,000 or £1,200 a year more, but it puts us on a satisfactory footing with the French Government. Those are the items of increase, and you will see why they have occurred. Under the circumstances we are only able to pay you a dividend at the rate of 12 per cent. per annum. There are indications of the prospect of more business during the next six months than the last half year, and consequently I hope we shall be able to submit to you a better report. At the same time I have always tried since I was Chairman of the Company to put the exact state of affairs before you, and I think it is right that shareholders should know that as much as Directors. I have told you exactly how we stand, and I think that is all I have to tell you. I now move the adoption of the report and accounts.

The Hon. ASHLEY PONSONBY seconded the motion, which was carried unanimously.

The CHAIRMAN then moved the declaration of the dividend recommended, payable, less income-tax, on and after the 1st proximo.

The Right Hon. ROBT. BOURKE, M.P., seconded the motion, which was carried unanimously.

On the motion of the CHAIRMAN, seconded by Alderman Sir THOMAS DAKIN, the Hon. A. Ponsonby was re-elected to his seat at the Board, as was also the Hon. H. R. Brand, on the motion of the CHAIRMAN, seconded by Mr. HOLDSWORTH (a shareholder).

General HUTCHINSON next moved, and Mr. GIVENS seconded, the re-

Digitized by Google

election as Directors of Mr. Wm. R. Cole and Alderman Sir Thomas Dakin, which was unanimously agreed to.

Mr. HOLDSWORTH proposed a vote of thanks to the Chairman and Directors. The Chairman, he said, had not been able to give them as satisfactory a statement as they could wish; but, on the whole, there were several elements of satisfaction in it. He gathered from what the Chairman had said that the tide had turned as regarded the diminution in the length of the messages. Another very satisfactory feature in the Chairman's statement was the fact that they would come to an amicable arrangement with the French Government as to the payment of the clerks. Nothing, he thought, could be more important than that they should be on thoroughly friendly terms with the French Government, especially taking into consideration what might happen in a very few years' time.

Alderman Sir THOMAS DAKIN seconded the motion, which was carried unanimously.

The CHAIRMAN: We are much obliged to you for the observations which have been made in such a friendly spirit by the mover of this resolution and for your continued confidence in the Board. The Directors, as heretofore, will endeavour heartily to do their best in the interests of the Company.

The proceedings then terminated.

Cuba Submarine Telegraph Company (Limited).

Report of the Directors for the half-year ending 30th June, 1886, to be presented to the shareholders at the thirtieth ordinary general meeting on the 11th inst., at 1 o'clock p.m. :—

From these it will be seen that the gross receipts (including the balance brought from last account) amount to £20,150. 17s. 4d., and the gross expenditure (including the half of the annual payment on account of the 1881 cable, and the expenses in connection with cable repairs), to £10,148. 19s. 8d., leaving a sum of £10,001. 17s. 8d. to the credit of revenue account. After providing for the preference dividend, a balance of £7,001. 17s. 8d. remains out of which the Directors recommend the payment of a dividend on the ordinary shares at the rate of 8 per cent. per annum, free of income-tax, which will absorb £6,400, and leave £601. 17s. 8d. to be carried forward to the current half-year's account. The Batabano-Cienfuegos (original) cable broke down on 28th March, and was repaired on 25th May. This cable not being duplicated, messages were forwarded during the interruption over the land lines of the Government. The repair was effected by Mr. Keith, the Company's engineer, who has also during the half-year laid a new harbour length at Santiago to replace one worn out. With regard to the proposed cable between Halifax (Nova Scotia), Bermuda, and Jamaica, referred to in the last report, the shareholders will be glad to learn that the British Government have decided not to lay a cable from Bermuda to Jamaica, but only from Halifax to Bermuda, thus avoiding the injury which this Company would have sustained had the project being carried out in its entirety. The director who retires from the Board at this time is Mr. Alexander F. Low, who, being eligible, offers himself for re-election. Mr. Thomas Greenwood, the auditor, also retires, and offers himself for re-election.

The National Telephone Company.

Report of the Directors for the year ending 30th June last, to be presented to the shareholders at the sixth annual ordinary general meeting of the Company, to be held at the offices of the Company, 11, Queen Victoria-street, on Friday, August 6th, 1886, at 3 o'clock p.m :—

The capital expenditure for the year, including the purchase of the system of the Dundee and District Telephone Company, Limited, has been £39,930. 7s. 7d., against £53,290. 17s. 1d. in the previous twelve months. The gross revenue allocated to the past year is £75,635. 5s. 8d., against £62,525. 18s. 6d. allocated to the previous year, and the amount carried forward to next year is £43,985. 18s. 6d., against £38,641. 13s. 10d. carried forward last year. The annual rentals on the 30th June reached £80,674. 2s. 8d., against £70,943. 11s. 3d. at the corresponding date of the previous year, showing an increase of £9,730. 11s. 5d. After providing for the accrued interest on the debentures, the dividend of 6 per cent. on the first preference shares, the dividend of 6 per cent. on the amount of second preference capital called up, and after having paid an interim dividend for the first half of the year at the rate of 3 per cent. per annum on the ordinary capital, there remains a balance of profit amounting to £10,822. 15s. 3d. Out of this the directors propose to allot a further sum of £7,875 to the payment of a dividend upon the ordinary capital for the second half of the year, at the rate of 3½ per cent. per annum, and, besides placing 2,000 to the reserve fund, to carry forward £947. 15s 3d. To the reserve fund of £5,000, which was taken last year out of the amount carried forward from the profits of that and previous years, the Directors propose to add, as indicated in the last paragraph, a further sum of £2,000, which will increase the reserve to £7,000. The Company has continued the erection of the trunk wires to connect different towns in various parts of its territory, as well as for the purpose of hereafter substituting those rented from the Postmaster-General in the Glasgow district. The Company has now 363 miles of trunk pole lines carrying 2,216 miles of wire. The revenue from annual renters is growing steadily, whilst that from free messages shows a rapid and regular monthly increase. During the past year the Company has opened telephonic exchanges in nine towns which did not previously possess the advantage of a telephonic system, and further development in the same direction is in progress. The United Telephone Company has again met with decisive success in the defence of its patents against infringers. The retiring directors are Messrs. William Hardwicke Bradbury, London, William Lowson, Dundee, and Samuel de la Grange Williams, Birmingham, who, being eligible, offer themselves for re-election. The auditors, Messrs. Quilter, Ball and Company, also retire, and are eligible for re-election.

South of England Telephone Company.

Report of the Directors for the fifteen months ended 30th April last, to be presented at the second ordinary meeting of shareholders, to be held at Winchester House, Old Broad-street, E.C., on Monday, August 9th, at 1 o'clock :—

Up to the 30th April, 1886, a sum of £11,849. 10s. 6d. has been expended on account of capital expenditure. The revenue account shows a gross revenue of £3,408. 14s. 10d., and a credit balance of £1,051. 5s. 7d., after payment of all charges, including a proportion of the preliminary and formation expenses. The dividends on the 6 per cent. preference shares, due October 31st, 1885, and April 30th, 1886, have been paid. Every effort has been made to push forward the business of this Company since its district was taken over from the United Telephone Company, with a result as shown by the following statement :—

	Exchange Subscribers.	Private Line Renters.
February 1st, 1885	116	123
April 30th, 1886	687	248
Increase	571	125

In addition to the telephone exchanges at Brighton, Norwich, and Ipswich, handed over to this Company by the United Telephone Company, exchanges have since been established at the following places, and further extensions will be made as the business develops :—

Bedford.	Gravesend.	Maidstone.
Cambridge.	Great Yarmouth.	Northampton.
Chatham.	Hastings & St. Leonards.	Oxford.
Eastbourne.	King's Lynn.	Peterborough.
Folkestone.	Luton.	Reading.

It is with extreme regret the Directors have to announce the death of the late Chairman, Mr. Robinson Kendal, on March 13th last. The vacant seat on the Board has been filled by the election of Mr. Alexander M'Gregor, of 3, Collingham-gardens, London, S.W., and Mr. David Owen Bateson has been elected Chairman. In conformity with the Articles of Association the following directors, Messrs. D. O. Bateson, T. F. Campbell, and A. M'Gregor, retire, and, being eligible, offer themselves for re-election. The shareholders' auditor, Mr. J. Weise, retires, and is eligible for re-election.

NOTES.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 6th inst. amounted to £3,167.

WEST AFRICAN CABLE.—The Silvertown Company has received a telegram from West Africa announcing the completion of the Accra-Grand Bassam section on the 28th ultimo.

ELECTRICITY AT THE ECOLE CENTRALE.—The subject of the theme set the pupils of the Ecole Centrale for the end of the scholastic year is "The utilisation of a waterfall equal to 300 horse-power for the public and private lighting of a town."

ADMIRALTY ORDERS.—We are informed that the Admiralty have recently placed a large order for switches, fusible plugs, brackets, and other electrical fittings in the hands of the Woodhouse and Rawson Electric Manufacturing Company.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 6th inst. were £2,476, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ELECTRICAL EXHIBITION AT BERLIN.—The Berlin Edison Company are about to open a private exhibition in Berlin. It is expected that they will display a very interesting collection of apparatus illustrating the employment of electricity for domestic purposes.

THE TELEPHONE FOR RAILWAY SIGNALLING.—The stations upon the Valmordois (Aisne) line of railway have now been placed in communication by telephone. This is the first instance in which the telephone has been employed for railway signalling in France.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for July were £23,000, and the receipts for the period from 1st January to the 31st July, £147,560; for the corresponding months in 1885 and 1884, £168,040 and £155,880 respectively.

CENTRAL STATION LIGHTING IN BRUSSELS.—It is stated that the Brussels Municipality have made a convention empowering a M. Helmer to lay underground wires throughout the city for electric lighting; but no details of the project have yet come to hand.

A CHURCH STRUCK BY LIGHTNING.—During a thunderstorm a few days since the church at Reminemont (Vosges) was struck by lightning, and suffered damage to the extent of 87,000fr. We regret to state that at the same time the relics of St. Romaric were entirely destroyed.

THE RECENT PATENT LAW DECISION.—We have received from Professor Silvanus Thompson a duplicate copy of a letter which he has sent to *The Times* in continuation of the correspondence upon the above subject. We are, of course, unable to insert it until *The Times* has had an opportunity of doing so.

EDISON.—Edison has stated that he is chiefly devoting his attention at present to methods for cheapening the production of electric lamps and carbons. It is to be hoped that he will attain a very complete success in this direction, and that the consumer will be permitted to enjoy a fair share of the benefit.

PROGRESS OF ELECTRIC LIGHTING IN AMERICA.—The American journals continue to record a rapid rate of progress of electric lighting in that country. New companies, new dynamos, new lamps, both arc and incandescent, new installations, both public and private, and the multiplication and enlargement of central lighting stations are continuously recorded.

BELGIAN ELECTRICIANS.—The Belgian Society of Electricians is to be fused with the Belgian Society of Engineers, who meet in the Brussels Bourse. This step will probably lead to a considerable accession of Belgian electricians to the ranks of the International Society of Electricians, whose head-quarters are at Paris. This body has now appointed M. Bandsept, of Brussels, as Belgian delegate.

PUBLIC LIGHTING IN PARIS.—There are at present only three public installations of the electric light in Paris, and neither of these is at all of an extensive character. The Place du Carrousel is lit by the system known in France under the name of Lontin de Mersanne. The Brush system is to be found in the Parc des Buttes-Chaumont, and Jablochkoff candles are still to be seen in the Parc Monceau.

MR. W. E. CASE'S "HEAT CELL."—Since the communication presented to the Royal Society by Mr. W. H. Preece, which we printed in our last issue, Mr. Case has written to the *Electrical World* stating that by the substitution of carbon for platinum as the negative element in his "heat cell," he has succeeded in obtaining an E.M.F. of 0·473 volt. This is very nearly double the value which was given by the former arrangement.

THE TELEPHONE AS A STREET FIRE ALARM.—A new system of public fire alarms has recently been erected in certain districts of Berlin. A telephone is enclosed within a suitable iron box, which is closed in front by a pane of glass. The instrument is connected with the nearest fire station. A notice forbids any one to break the glass in order to use the telephone unless they are able to inform the fire station of the exact locality of the fire.

TELEPHONE TROUBLES IN INDIANA, U.S.—All the poles and wires belonging to the Telephone Company in Evansville (Indiana) have been cut and pulled down by order of the City Council, the whole of the instruments being thereupon taken down and removed to Boston. This strong measure upon the part of the council is stated to be due to a refusal of the company to comply with certain ordinances concerning the working of the instruments issued by the civic authorities.

LODYGUINE'S INCANDESCENT LAMPS.—The lamps constructed by M. Lodyguine are said to be characterised by a remarkable toughness in the quality of the carbon. According to a recent statement the mechanical strength of the filament is "enormous." It is therefore possible to run these lamps at a very low expenditure of watts per candle-power, without unduly shortening their life. At the same time it is claimed that the extreme hardness of the carbon tends to prevent the blackening of the inside of the globes.

KEY WEST.—We are informed that the ss. "International," of the Silvertown Telegraph Company, sailed for Key West and Havannah on 11th inst. to renew the 1868 cable of the International Ocean Telegraph Company. This vessel should arrive at Key West about the 2nd prox., and will be joined there by Mr. M. L. Hellings, the cable manager of the American Company. Mr. Theophilus Smith goes out in charge of the work, and is accompanied by Mr. E. March Webb, the chief electrician of the Silvertown Company.

AN AMERICAN STORY.—A common result of too frequent applications of electricity is the paralysis of the affected parts. A quack in Portland, Oregon, has been professing to be a magnetic healer, and standing on plates connected with a concealed battery, he has been shooting the healing current through his patients by the laying on of hands. This wonderful healer has come to grief, not through the action of

Digitized by Google

the Portland police, but through Nature's own action, for he has been paralysed by the continuous electrical action, and is now paying the penalty of his trickery.

EFFECTS OF LIGHTNING.—From *Nature* we learn that during a severe thunderstorm which passed over Central Norway last week a remarkable example of the power of lightning was witnessed. A fir tree 80ft. in height was struck by lightning, and a piece of the trunk 60ft. in length was torn off and thrown a distance of several yards. Strangely enough, the surface of the detached part is as smooth as if cut with a saw, while the stump remaining in the ground is jagged, charred, and splintered to the root. The ground around was torn up in all directions, one furrow being several feet in width and depth and 30ft. in length.

PORTUGUESE TELEGRAPHS.—Advices from Lisbon report an important reform in the Portuguese Public Works Department, which will have the effect of bringing the postal and telegraph services under the direct supervision of the Public Works Minister. Since the last reform of the telegraph service 64 new stations have been opened, and an increase of the *personnel* is required. It is therefore proposed to superannuate some of the old servants, and increase the total number of *employés*, with a view to improving the service, which is said to be in a very bad condition, and the cause of frequent complaints on the part of the public.

MILL LIGHTING BY ELECTRICITY.—Messrs. Platts are making use of electricity at their Quarry-street Mills, at Ashton-under-Lyne, for lighting purposes. The installation has been effected by the Manchester and District Edison Electric Light Company. The dynamo is of the Edison-Hopkinson type, and is capable of maintaining 400 sixteen candle-power incandescent lamps. It is driven from the main engine, and with the 320 lamps at present fitted absorbs about 36 horse-power. The lamps are Swan's, and are provided with white porcelain shades. The improvement is highly appreciated by the workpeople, and the temperature of the rooms is 15 to 20 degrees lower.

THE "VOLTA" PRIZE COMPETITION.—By a decree dated 11th June, 1882, the Government of France offered a reward of 50,000 francs for the discovery of greatest value relating to the utilisation of electricity for any of the following purposes:—As a source of heat, of light, or of chemical action; as a means of transmission of mechanical power, or of verbal communication in any form; or, finally, as a curative agent. The Minister of Instruction has now announced that June 30th, 1887, will be the latest date for entering the competition, and that the prize will be awarded in the following December. The competition is open to all, without restriction, and *savants* of all nations will be invited to participate in the award.

SERIOUS DAMAGE TO AN AMERICAN INSTALLATION.—From one of the American journals we take the following story:—A few days since a two-storied timber-built house was being moved through the streets of New Jersey City. All day long the Erie street horse cars were blockaded. On Friday night the labourers made their hauling tackle fast to one of the telegraph poles. The strain was so great that the pole leaned over, and several of the wires gave way, and fell upon the Electric Light Company's cables. Forty-one arc lamps in the principal streets were extinguished, and the insulation of the dynamos was seriously injured, besides other damage in the machine room. The owner of the house is threatened with a suit for damages.

TELEPHONIC COMMUNICATION BETWEEN BRISTOL AND BATH.—The Western Counties and South Wales Telephone Company have just completed the laying of a trunk wire between the cities of Bath and Bristol. The distance is only about fourteen miles, and therefore it need hardly be said that the results have proved thoroughly satisfactory. At present there is no telephonic exchange in Bath, although there are a number of private users of the telephone. It is expected that the facilities now offered for communication with Bristol will have the effect of largely increasing the list of subscribers in Bath, so that an exchange will probably be started at an early date. It is also in contemplation to lay down several more trunk wires connecting Bristol with adjacent towns and villages.

A NEW PRIMARY BATTERY DEVICE.—At the recent meeting of the International Society of Electricians a paper was read, describing an arrangement devised by M. Aboilard, by which the zinc plates of a primary battery may be lowered into or removed from the porous pots by mechanism actuated from any distance. The zincs are attached to a frame, which is suspended from a wooden support, and counterbalanced by weights placed upon the arm of a lever. A rod connected with this lever is moved in either direction by a clockwork attachment. The clockwork is released by means of an electro-magnetic catch placed in the circuit of an auxiliary Leclanché cell. By means of two separate pushes at the place from whence the battery is to be controlled, the zincs can be raised or lowered, as may be desired.

SPIRAL LIGHTNING.—During a severe thunderstorm which occurred on the 12th May in the present year, M. Ch. Moussette succeeded in obtaining several photographs of the lightning. In some of these the discharge has assumed the form of an irregular spiral. In the case of two flashes which were taken upon the same plate, the first is a dextrorsal spiral, and the second divides into two branches, for which the direction of rotation is different, one being right-handed and the other left-handed. The distance between the separate turns of these spirals varies greatly in different portions of the same discharge. It has been suggested that flashes of this character are probably due to the discharge of globular lightning having a gyratory motion, similar to the effects obtained upon a smaller scale by M. Planté.

ELECTRIC TRAMWAY AT HAMBURG.—An electric tramway has just been completed at Hamburg. The accumulator system has been adopted. Each car is capable of conveying thirty-three passengers, and weighs when fully loaded about 4,830 kilogrammes, the weight of the accumulators alone being 1,200 kilogrammes. The battery consists of 96 cells, each containing seven positive and eight negative plates. They are charged by means of two "Schwerd" dynamo machines, driven by an engine of 10 horse-power. The motors are of the Siemens type. Their speed is regulated by a switch, which alters the grouping of the battery cells. The cars are able to run about 50 kilometres with a single charge. The normal current on the level is 10 amperes, but it is sometimes as high as 80 amperes when mounting the steepest gradients.

THE ELECTRIC LIGHT AT A SHORTHAND SCHOOL.—Since the beginning of the present year the Metropolitan School of Shorthand has been lit by the electric light. The installation, which consists of fifty-eight incandescent lamps, conveniently distributed throughout the various passages and class rooms, and one arc light in the doorway, was put up by the Pilsen-Joel Company. The dynamo is driven by a 6 horse-power Otto gas engine in the basement of the building. Each pair of lamps in the class rooms is provided with a separate switch. Of course, it is not to be expected that so small an installation, independently worked—the fixed charges being quite as great

Digitized by Google

as those for an installation two or three times the size—will be found to show any economical advantage, but the benefits resulting from its introduction in the matter of coolness and luminosity are highly appreciated by the students, and has undoubtedly led to their more rapid progress in stenography.

THE ELECTRIC LIGHT FROM A SANITARY POINT OF VIEW.—M. Gariel has recently published in the *Revue Scientifique* a paper of considerable length upon the sanitary aspects of artificial lighting in general. He treats the subject in three divisions—the use of (1) solids, (2) of liquids, (3) of gases, as illuminating agents. The first head is again subdivided into (1) those solid bodies which undergo chemical alteration—that is those which are burnt; (2) those which are heated by the combustion of another substance, but do not themselves undergo any chemical change; (3) those which yield a light without the necessity of any chemical action whatever taking place. M. Gariel concludes that the only method of the artificial lighting which can be considered thoroughly satisfactory from a hygienic point of view is one which fulfills the last-named conditions. He concludes his paper by a very strongly-worded commendation of the incandescent electric light.

BLOWING UP A SHARK.—The following sailor's yarn is now in course of circulation :—"We were lying off Natal the other day when a most exciting occurrence happened. We saw two or three monster sharks playing round the ship for some time—the largest of them measuring about 14 feet long—so we baited a line with a small piece of pork and dropped it out to him. He calmly swallowed the bait, hook and all, and cut the line with his teeth, taking no further notice of it. We then had recourse to strategy. The breast of a buck, which had been hanging up some time and was rather high, was weighted, in order to sink it, and a hand-charge of guncotton inserted therein, the whole being connected by wire with a boat's battery. No sooner had the venison reached the water than the shark made straight for it; but just as he opened his mouth to swallow the bait the charge was exploded, his jaws being completely shattered. The monster turned on its back and sank in the bay."

WHITWORTH SCHOLARSHIPS.—Twenty-five of these scholarships are awarded annually, one of £200, eight of £150, and sixteen of £100. The following are the successful competitors for 1886 :—G. C. Humphrey, Nottingham; R. Holt, Liverpool; R. Chorley, Manchester; J. H. A. M'Intyre, Glasgow; W. C. Borrowman, Glasgow; T. R. Murray, Galashiels (formerly Stafford); J. T. Nicholson, Newcastle-on-Tyne; G. M. Wooliscroft, London (formerly Crewe); J. Brown, Glasgow; R. Wallis, Newcastle-on-Tyne; R. M. Ferrier, Ardrossan; R. B. Creah, Crewe; E. Wilson, Leeds; E. S. Padmore, Birmingham; W. H. Watkinson, Glasgow; R. Johnstone, London; J. M. Malcomson, Woolwich; H. Shoosmith, London; E. Codling, Newcastle-on-Tyne; C. Day, Stockport; C. Hyde, Ebbw Vale; A. Etchells, Hyde; W. Berry, Glasgow; D. Kemp, Glasgow; G. H. Follows, Manchester. The students of the College of Science and Arts, Glasgow, have achieved a remarkable success, no fewer than six scholarships having been gained by them.

AURORA.—During the last few weeks many people have been remarking the very beautiful effects which have been visible above the N.W. horizon shortly after sunset. These appearances have taken the form of luminous clouds of a silvery blue lustre, and apparently floating at a very great elevation. Professor Piazzi Smith has written to *Nature* describing the results of a spectroscopic investigation of these clouds which he made upon the evening of the 27th ult. He found that the aurora line was distinctly present at different places upon or near the horizon. At this time there was a faint red glow in the west, at a higher elevation some stars were visible, and passing almost immediately overhead a long white streamer—apparently of cirrus cloud—trailed half across the sky. In the spectroscope this white streamer gave the aurora line with great distinctness, and only a very faint continuous spectrum in addition. Towards one in the morning a very beautiful display of auroral scintillations took place, and after this the whole display died out in a very few minutes.

CUBAN STORMS.—Father Vines, of the Royal College of the Society of Jesus, at Havana, and compiler of the "Meteorological Annual," for 1885, which has only lately been published, gives some interesting particulars as to the characteristics of thunderstorms in Cuba compared with those in the United States, which suggest that this line of inquiry is likely to lead to valuable additions to our knowledge of weather changes. For four days previous to the observation of the highest temperature of the year—July 30, at 4 p.m., 98·8deg. —auroras had been observed in the United States, and the magnetic and electrical conditions showed marked disturbances at Havana. Of eighty recorded thunderstorms sixty-five occurred during the five months from May to September, and only three during the four months from January to March and December. This almost total absence of thunderstorms from the rains of the winter months as compared with the summer months, when lightning or some other electric phenomenon occurs almost daily, is important in its bearing on the theory of the thunderstorm.

AN ABSTRACT ON SECONDARY ELECTROLYSIS.—E. Semmola, in the *Journal* of the Chemical Society, says : "If a small ribbon of platinum is immersed in a voltameter containing acidulated water, in such a way that its ends are opposite the electrodes of the voltameter, and a powerful current is passed through the latter, hydrogen and oxygen are evolved not only from the electrodes, but also from the ribbon. This secondary electrolysis varies greatly with different conditions, and ceases altogether when the current is not strong, but if oxidisable metals are used instead of platinum it becomes much more energetic. The phenomena are well seen with amalgamated zinc, which is not attacked by acidulated water except when the current passes. When the circuit containing the voltameter is closed, hydrogen is given off from one half only (the negative half) of the zinc, whilst oxygen is absorbed by the other half. If several pieces of zinc are immersed in the water in the voltameter, hydrogen is given off from each of them. This secondary electrolysis is due to a current derived from the immersed zinc."

LONG DISTANCE TELEPHONING.—The American Telephone and Telegraph Company of New York has recently been organised for the purpose of establishing direct telephonic communication between the large cities of the country. The first line has been constructed between New York and Philadelphia, the length of the route adopted being about 100 miles. Four years ago a similar attempt was made to connect New York and Boston, but the iron wire erected between the two cities did not prove successful. The present company has employed hard drawn copper wires, and now has seventy-four of them running the whole distance. The line is entirely aërial, except where waters of some width are crossed, in which case submarine cables are employed. Between the two cities there are six series of cables, the longest stretches being under the Hudson and Delaware rivers. The cables terminate at the foot of Vessey-street in New York, and near the foot of Walnut-street in Philadelphia. The line will probably be open

Digitized by Google

for business within a few weeks, and it is expected that it will prove a great convenience.

THE "PARTZ" ACID GRAVITY BATTERY.—This battery has been designed with the intention of applying the principle of gravity for the separation of the solution in cells of the Bunsen type, in the same way as was done by Meidenger, Minotti, and others, for the Daniel cell. The Bunsen battery would, undoubtedly, meet with a much more frequent use at least for laboratory purposes, but for the trouble of having to set up the cell afresh every time it is required. In the "Partz" cell an acidified solution of an alkaline chloride or sulphate, is poured into the cell until it just covers the zinc plate, which is suspended from the rim of the vessel. A plate of carbon lies upon the bottom, and a special "depolarisation salt" is dropped upon its surface through a glass tube. This salt is formed by the action of sulphuric acid upon chromic acid. By this means the carbon plate is soon covered with a saturated layer of the depolarisating solution, which can at any time be renewed by merely dropping fresh pieces of the salt through the glass tube. The electromotive force is said to be 1·95 volt, and the internal resistance is relatively low.

LECLANCHÉ CELLS FOR LARGE CURRENTS.—An American manufacturer has introduced some modifications in the Leclanché cell, which would seem for certain purposes to be valuable improvements. Instead of employing either a porous pot or the "agglomerated" carbon, the inventor constructs the inner vessel of a very porous carbon. It is then filled with manganese and broken carbon in the usual way. The exterior surface of the vessel is rendered as large as possible by a series of projecting ribs. In this way the internal resistance of the cell is so much reduced that a battery of this construction is said to be capable of yielding a current sufficiently large for use in electric lighting. We imagine, however, that the E.M.F. must fall off at the same rate as it does in all other cells of the Leclanché type, and, if so, the electric lighting could only be of an intermittent character. On this point we are disposed to make a suggestion for the benefit of the inventor. Why not take two or more batteries, each capable of supplying the required current, and place in the circuit an automatic switch, which would switch in another set of cells as soon as the E.M.F. of the one in use had fallen below the required standard? We need not enter into details, but the idea may be taken for what it is worth.

ELECTRICITY AT THE WALTHAM POWDER FACTORIES.—A somewhat novel arrangement has recently been adopted for lighting the outlying sheds and warehouses of the Royal Gunpowder Factories at Waltham. The principal part of these works has been lit by electricity for some considerable time, but many of the storehouses, which are situated at a considerable distance from the dynamo room, have not hitherto been lit. But since each of these buildings stands upon the banks of one of the numerous canals by which the works are intersected, the superintendent, Colonel W. H. Noble, R.A., has devised a very simple and effective plan for lighting them when required. A small boat, 25ft. in length, has been built, capable of carrying about 30 of the E.P.S. cells (type 238), and is fitted with an electric motor and screw for its propulsion. When any of the buildings referred to are required to be visited at night, the boat moves up to the spot, and the batteries are then connected to the permanent installation of glow lamps with which each building is fitted. In this way the work of loading or unloading barges at night is very readily carried on. The electrical details were designed by Mr. T. Webb, the chief engineer of the works. The boat has been christened "The Spark," and has, so far, given every satisfaction.

POLARITY OF TADPOLES.—The following letter, by Dr. Leonard, on this subject has appeared in the *Scientific American*:—"In your issue of July 3 I notice a short paragraph on the 'The Polarity of Tadpoles,' which states that when a current was passed into the dish containing them (the poles of the battery being immersed in the water), all of them without exception took up 'one position, that in which the head was turned to the anode and the tail to the cathode.' I see nothing really surprising in this, and certainly nothing that would prove 'polarity' in the tadpole. The 'shock' from the cathode is always a great deal stronger than from the anode; also, the head of the tadpole (as in all animals) is the more sensitive portion of the body, electrically; hence the cathode presented to the head, if the current be strong, becomes quite powerful, whereas, if presented to the feet or tail, the current is much less severely felt. The arrangement of the tadpoles with their tails to the cathode is the position they should assume in order to reduce to a minimum the unpleasant sensation of the passage of the electrical current through their bodies. Confine a man in such a way that the current from a battery must pass through his body from head to foot, and he would very soon arrange himself with his feet to the cathode and his head to the anode, and yet this would be far from proving 'polarity' in the human body. There may be 'polarity' existing in the tadpole, but a different experiment than that made by Prof. Herman is necessary to prove it to me."

ELECTRIC TIMING OF BICYCLE RACES.—E. H. Foote, of the Massachusett's Bicycle Club, has submitted to President Ducker a scheme for obtaining absolutely correct timing of races, and it is so ingenious that the club will put it into practice. Take a strip of rubber 2½ to 3in. wide and 1-16th of an inch thick, long enough to cross the track. Sew or rivet on one side of this two strips of thin sheet brass or copper. Fold the two sides of the strips together. Fasten one end to the ground on the side next the stand. This end to be attached to a block of wood or rubber having binding screws connected with the metal strips. The screws are also connected in circuit with a battery and a loud single stroke bell. The strips are kept apart at the opposite end by a wooden plug if necessary. The riders to be started with their wheels just in contact with the strips. Whenever there is pressure enough put on the rubber to bring the metal strips in contact the bell will sound. The starting time to be taken at the first stroke of the bell when the first man crosses, as there would be a slight variation in the men getting away, and the rear wheels would also cause a stroke. The time of finish to be also taken by stroke of the bell. The time between the strokes of the bell would be absolutely correct, and could probably be taken more accurately than by the eye. This system could be extended by putting in the battery circuit a recording instrument, which would automatically and accurately record on paper each and every time, however many men there might be in the race. This would necessitate additional expense, as the recorder would have to be actuated by an accurate timepiece.

EXPERIENCE WITH A CHLORINE BATTERY.—Mr. J. W. King has written to the *English Mechanic*, giving an account of his experience with an "Upward" battery of his own construction. Everything being ready, and the cells (four in number) fully charged, the current was switched on to a 5 candle-power lamp, which it raised to a bright red heat. "Just then," Mr. King proceeds, "a leakage occurred in the generator, and in

Digitized by Google

endeavouring to stop it up with clay I got nearly choked, and although the whole apparatus was in a shed nearly open, built outside the house, the gas got into the house, and caused great inconvenience. With great difficulty I filled the generator with cold water, thinking to stop the production of the gas, and left the whole concern to itself. Since then, without touching the batteries, I have taken every night a current from them, on the eighth night about one ampere, measured by one of Ayrton and Perry's instruments, which was not available for use before that." Mr. King, notwithstanding this distressing experience, considers the battery to be a first rate one, and that if only sundry objections could be overcome it would be without an equal. The difficulties which he considers require to be removed he summarises as follows:—"The first is some method of discovering any leakage in the apparatus. You can easily tell when there is a leak, but the thing is to find out where, and while you are doing that you are getting choked. The next thing is to be able easily to stop the production of the gas, as in the case of accident to any portion of the apparatus the gas continues to escape as fast as generated; and the third point is to find some easy method of absorbing the gas already generated and rendering it harmless in the case of accident." Mr. King concludes that until this has been done the battery is not adapted for use in the hands of unskilled persons. With regard to Mr. King's second and third points, we may state that a strong solution of hydrogen sulphide poured into the generator would speedily stop the evolution of chloride, and the same solution if heated in the apartment where the chlorine has escaped will render the gas practically innocuous; but hydrogen sulphide itself possesses so objectionable an odour that it is a question whether the remedy is not nearly as bad as the disease.

The Magnetic Survey of France.—M. Mascart has just completed the reduction of the observations which were taken under his supervision during the years 1884-5 for the construction of a new magnetic chart for the whole of France. The observation of the magnetic elements was carried out at 78 different stations in various parts of the country. Each station was carefully selected so as to avoid, as far as possible, any local disturbance which might arise from purely artificial causes, such as the neighbourhood of railways, factories, &c. The apparatus employed was specially constructed for the purpose by MM. Bruner, and consisted simply of carefully mounted declination and inclination magnets. The azimuth of the magnetic meridian was determined by taking the mean value deduced from the readings in several different positions of the compass. The horizontal component was obtained by counting the number of oscillations, after having determined the magnetic moment of the needle by the method of Gauss. The inclination was read directly from the needle when placed in the magnetic meridian. By comparison with the curves of annual and secular variation recorded by the magnetometer at the Observatory of Parc Saint-Maur all the observations have been reduced so as to be correct for the 1st January, 1885. The following are some of the most noteworthy results obtained:—The declination is a minimum at Belfort (13°·59′) and a maximum at Conquet (19°·25′). In the North of France it varies about 30′ for each degree of longitude; in the south the variation is smaller. Since the last survey by Lamonte, in 1854, the declination has diminished 3°·58′ in the north, and only 3°·19′ in the south. The mean annual variation of declination during this period has been 6·5′ at Nice, 7·4′ at Paris, and 7·7′ at Lille. It results from this that the lines of equal declination are at present gradually becoming parallel with those of the geographical meridians. Turning next to the value of the horizontal component, we find that the minimum value (0·18460 absolute units) was observed at Dunkerque, and the maximum (0·22124) at Perpignan. These curves are very nearly perpendicular to those of the magnetic meridian. The decrease of this element per degree of latitude proceeds more rapidly in the south than in the north. Since Lamont's observations in 1848 the mean value of the horizontal component has increased about 0·05. The annual variation is greatest in the west and slightly less in the east. Its mean value is about +0·00025. These lines are approaching the direction of the geographical parallels. The isoclinal lines have sensibly the same orientation. Since 1848 the inclination has diminished by 1°35′ in the north of France, and by 2° in the south. The annual variation is least at Belfort in the north-east (2′·6) and greatest in the extreme south (3′·4). These lines are also approximating to the geographical parallels.

Electric Lighting in a Calico Factory.—The Gülcher Electric Light Company have just completed the lighting of the calico print works of Messrs. J. H. Gartside and Co., Bucktonvale Works, near Stalybridge. The light has, in the first instance, been installed in the printing department, and it will be further extended to the other departments, dye and washing, &c., when the alterations are sufficiently advanced to permit of this being done. The lamps are arranged as follows:—1st, printing room, consisting of twelve printing machines, six 20 candle-power lamps, distributed to each machine; 2nd, printing room or shed, consisting of three machines, eighteen 20 candle-power lamps. The foreman's office and colour room, the manager's office, and the laboratory are also lighted. The 102 lamps used are of the Swan-Edison type, of sixty volts, and are driven from a No. 4 Gülcher dynamo, compound wound or self-regulating, of their latest and improved type. The machine is able to supply more than double the present number of lights. The motive power for drawing the dynamo is taken from the main driving shaft of the engine driving the hot air fans in use for the printing machines. A belt from this shaft drives a counter shaft fitted with fast and loose pulley with striking gear, from which a horizontal belt drives the dynamo. The current from dynamos goes to a circular switch, and is then split into three circuits so arranged that an equal number of lamps are in each circuit. Separate switches are fitted to every six lights, and wherever required to individual lights. Each switch is fitted with cut outs, in addition to the main cut outs at dynamo. The main leads are run in casing suspended by stout iron clips from the existing gas mains, which run over the printing machines. The branch leads are run to a switch-board placed conveniently for use in front of each printing machine, the tapping wires from same being run along the gas pipes to the individual lights. The lamps are all fitted with white opal shades, or reflectors, so that the utmost efficiency is obtained by directing the light on the work. This is found of great advantage in this installation owing to the variety of colours used in the work done. The lamps in the printing sheds are fixed to the existing gas fittings by strong brass clips to which is attached the holder, of Woodhouse and Rawson pattern, to carry the lamps and shades. One lamp to each printing machine is made portable, to allow the printer to set his rollers, &c. This lamp is placed in a circular brass guard, with a mahogany handle through which the flexible wire runs to the lamp. Bronze brackets are used in the offices and laboratory, each fitted with separate switch, with white opal reflectors. Great satisfaction is expressed by all interested in the use of the light, and no doubt in the future it will be extended over the entire premises.

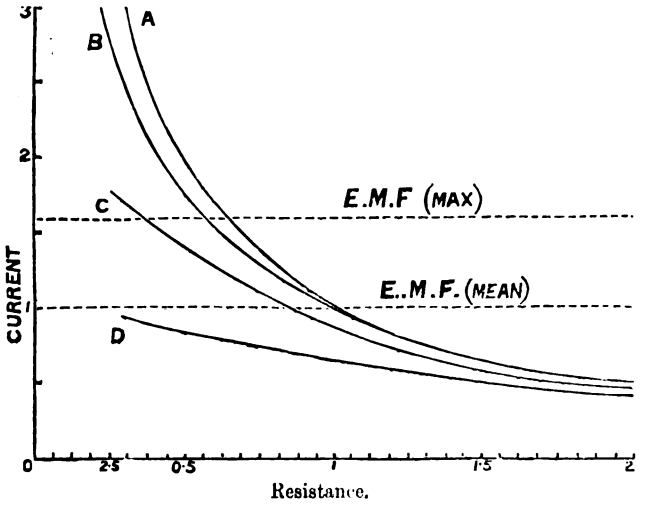
ALTERNATING AND INDUCED ELECTROMOTIVE FORCES.—IV.

BY W. H. SNELL.

In the last paper it was shown that the quantity of electricity conveyed by an alternating current is measured by $I \times 0{\cdot}637$, where I is the maximum periodic value of the current. In Fig. 7 resistance from zero up to 2 ohms is taken upon the axis X and values of current upon the axis Y. If the horizontal line along the unit ordinate be taken to represent the value of a *continuous* electromotive force acting in the circuit, then, as is well known, the current curve becomes a rectangular hyperbola, of which curve A will be the portion within the limits of the figure.

FIG. 7.



Now, let the same horizontal line represent the *true mean value* of an alternating electromotive force acting in the same circuit. Then the maximum periodic value of E will be represented by the horizontal line, which is drawn upon the ordinate $\frac{1}{0{\cdot}637} = 1{\cdot}49$. If, in the first place, these lines refer to *resultant* electromotive force, then the *true mean value* of the alternating current will be represented by the same curve as the continuous current, and the values of I will be at all points equal to 1·49 times the ordinates of curve A.

Next, suppose that the horizontal lines refer to *impressed* instead of to resultant electromotive force. Then, if there were no self-induction, curve A would still represent the current. Now, let us introduce a coefficient of self-induction such that $L = \frac{1}{4} N$; we shall therefore get a smaller resultant current, and this will be represented by curve B. Comparing A and B, it will be noticed that when the resistances are comparatively large the two curves are indistinguishable upon the scale of the diagram. Hence, at this time, the current is almost independent of the coefficient of self-induction if the latter be not very great in comparison with N. But as the resistance is reduced a point is reached when the current begins to diminish rapidly in the circuit containing self-induction, until at length the difference between the two currents becomes almost constant, and this difference is very nearly independent of the resistance.

The effect of increasing the value of L may be traced in curves C and D, for which $L = \frac{1}{2} N$, and $L = N$ respectively.

The case in which R is made constant at unit value, and the periodic time becomes subject to variation, may be illustrated by means of the same figure, R being now made always equal to unity; we may take the scale of abscissæ to represent *relative* values of T. The impressed electromotive force will then be given by the hyperbolic curve A, and if the values of L are made successively equal to 0, $\frac{1}{4}$ N, $\frac{1}{2}$ N, and N, then A, B, C, D will represent the respective currents. The curves will in this case represent either the true mean or the maximum values of the currents, according to whether A has been taken, in the first place, either for the mean or for the maximum periodic value of the electromotive force.

The case in which N varies does not require any special notice, for it is obvious that the result is merely to vary the vertical scale of the curve in direct proportion to the value of N.

There remains one more case which might easily be illustrated in the same way—that, namely, in which the variations of I are plotted with L constant and with successive values of R and T. This corresponds very approximately to the case in which an alternating machine is used upon an electric lighting circuit and the number of lamps is varied, while the machine is also run at different speeds. But in this case we should not be much interested in the current curves; it is the number of watts in the circuit that would be important. In order to save space we shall therefore omit this set of curves.

We will now proceed to consider in detail the rate at which work is done in any given circuit by an alternating current. It has already been shown that the continuous current which will do work at the same rate is equal to $I \times 0{\cdot}707$. The number of watts in the circuit will therefore be given by the equation,

$$W = (0{\cdot}707\, I)^2 R$$
$$= 0{\cdot}5\, I^2 R.$$

Substituting the value of I from (10) we have

$$W = \frac{1}{2}\left(\frac{2\pi N}{T}\right)^2 \left\{\frac{\sin^2(\theta - \phi)}{\left(\frac{2\pi L}{T}\right)^2 + R^2}\right\} \cdot R$$

but as the maximum value of the sine is unity, this reduces to

$$W = \frac{2\pi^2 N^2 R}{4\pi^2 L^2 + R^2 T^2} \qquad (13)$$

It therefore appears that the work done in unit time in a circuit of given resistance is increased either when L is diminished or, as might be expected, when the speed is increased. But if L and T are constant, then there will be a certain value of R, for which the number of watts becomes a maximum. This value of R may be found in the usual way by forming the equation

$$\frac{dW}{dR} = 0$$

and solving for R. We thus obtain

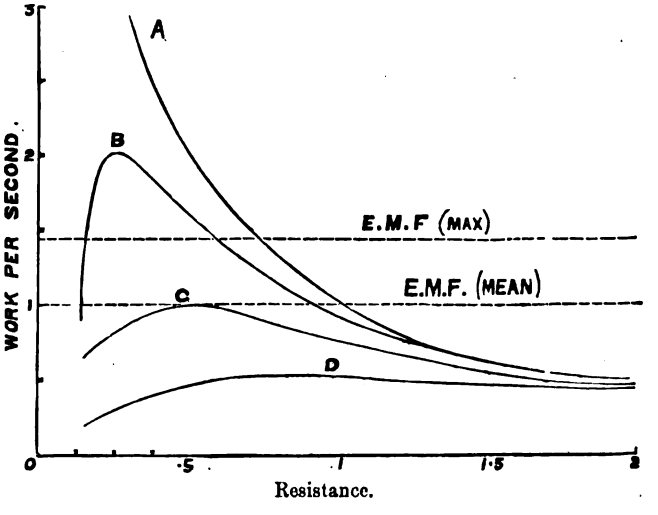
$$R = \frac{2\pi L}{T} \qquad (14)$$

as the condition under which W is a maximum. Now, we already know that the tangent of the angle of retardation is expressed by $\frac{2\pi L}{RT}$. Consequently (14) may be written

$$R = R \tan \phi.$$

Hence $\tan \phi$ must be equal to unity, and therefore ϕ is an angle of 45°. We thus learn that when a given alternating current does work at its maximum possible rate the angle of retardation will always be 45°.

FIG. 8.



In Fig. 8 resistance is taken along axis X and watts upon axis Y. Following the same method as in Fig. 7, we sup-

Digitized by Google

pose, in the first place, that the horizontal line upon the unit ordinate represents a *continuous* electromotive force. The expression for the rate of work will be

$$W = \frac{E^2}{R}.$$

This is the equation to curve A, and as E has been made equal to unity, we obtain the same curve as A in Fig. (7).

Now, let the horizontal lines upon the unit ordinate represent the *mean* value of an alternating electromotive force. If this be taken as a *resultant* E.M.F., such that its maximum periodic value is drawn upon the ordinate $\frac{1}{0\,707} = 1{\cdot}414$, then the same work will be done in the circuit in a given time, either by the continuous or by the alternating electromotive forces, so that curve A again gives the number of watts produced.

Next, let the two horizontal lines refer to *impressed* instead of to resultant electromotive forces. The remaining curves are then drawn to equation (13), under the condition that T is constant, and L has the successive values given below. The column headed R gives the resistance for which the number of watts is a maximum in each case.

Curve	L.	R.
A	0	0
B	0·25 N	0·25
C	0·5 N	0·5
D	0 N	1·0

It is of course apparent that as the resistance increases from zero, the work done in unit time by a continuous electromotive force of constant value continuously *decreases*. And it will also be seen that the same thing holds good when the electromotive force becomes alternating, provided that there is no self-induction to the circuit. If, however, the circuit possess a coefficient of self-induction, then up to the point of inflexion of the curve the watts *increase* with the resistance; and the rate of increase is the more rapid as the value of L is *smaller*.

After passing through what may in this connection be termed the "critical value" of R, the watts decrease when the resistance rises, as they would do if the current were continuous. However large the value of L may be, if R is continuously increased we at length arrive at a point where the number of watts produced when the *impressed* E.M.F. has a constant mean value is practically the same as if the current were continuous, and the effect of self-induction has thus well nigh disappeared.

Fig. 9.

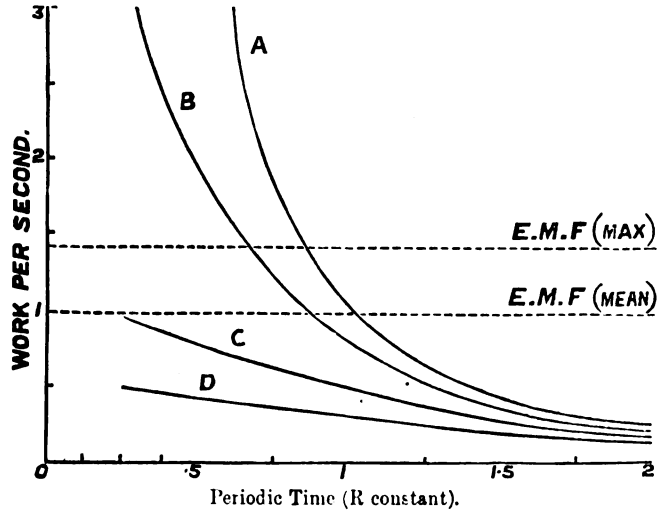


Fig. 9 illustrates the variation of W under the condition that R remains constant at unit value, while the self-induction and the periodic time undergo variation. R being constant there is no critical point in these curves. The relative values of T are taken along axis X, and the values of L are as follows:

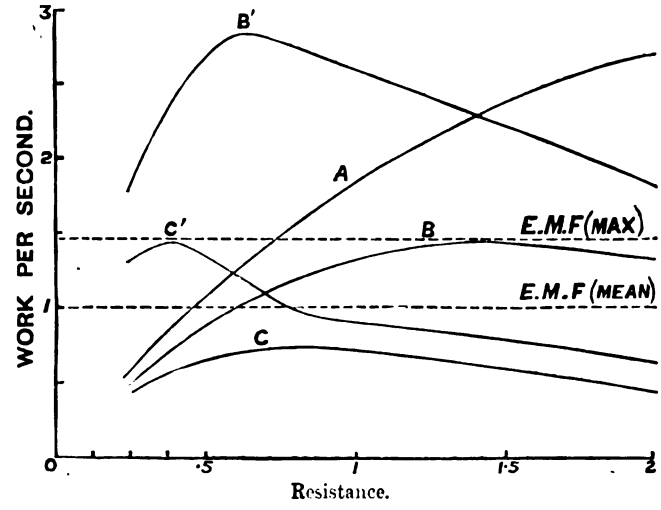
Curve	L	Curve	L
A	0	C	½ N
B	¼ N	D	N

The lines of electromotive force are drawn only for the case when T is put equal to unity; in the other cases they would lie upon the ordinates equal to $\frac{1}{T}$. With this exception the figure may be examined in the same way as in the preceding case; taking the lower line of E.M.F. to refer in the first instance to a *continuous*, next to a *resultant*, and lastly to an impressed electromotive force.

Fig. 10.



Finally, Fig. 10 illustrates the variation of W with the periodic time and the resistance. It thus closely corresponds to the case of an alternating current machine, with a constant field, running at different speeds, upon an electric lighting circuit in which the number of lamps is varied. Two sets of curves are given for different values of L, as shown in the following table. As before, the column headed R gives the resistance which makes W a maximum:—

Curve.	T.	L.	R.
A	¼	½ N	2·83
B	½	½ N	1·414
C	1	½ N	0·707
B′	½	¼ N	0·707
C′	1	¼ N	1·414

The curve for $T = \frac{1}{4}$, $L = \frac{1}{4}$ N, would lie almost entirely beyond the limits of the figure.

In this figure there is no curve corresponding to a continuous current, because we have not plotted the case when L = 0. Also, as in Fig. 9, the lines of E.M.F. refer only to the case when T is put equal to unity.

CORRESPONDENCE.

INCANDESCENT LAMP FILAMENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The accompanying table (*see* next page), which illustrates the effect of varying both the size and form of an incandescent lamp filament, may interest your readers.

On reference to column one of this table it will be seen that the comparisons made are under identical conditions of energy, or, more precisely speaking, the kinetic energy expended per unit of cubical content is the same in each case. This being so, it is reasonable to assume that, with equal quality of carbon and under similar conditions of vacuum, all will have the same life.

The term "efficiency" as applied to incandescent lamps can hardly be considered correct, and for the want of a better I have employed the word "economy," which here simply implies the ratio between the energy expended and light emitted.

It is sometimes stated that an efficient lamp will necessarily have a short life, and that the economy in employing such is as long as it is broad. This would be correct if it went a little

further. As it now stands the impression conveyed is that to work with greater economy as to power, more current must be forced through the filament, with the result of shortening its life, whilst the table, I think, clearly shows that there are other considerations which determine economy of working besides forcing the filament or even improving the quality of the carbon. Filaments marked 2 and 3 throughout have each half the areas of those marked 1, and give, as shown in Column K, an improved economy of about 40 per cent. over that of No. 1, a result that is due to the fact that in the forms given the radiating surfaces are, for equal lengths of filament, proportional to the square roots of their areas, so that reduction of area does not mean a correspondingly large reduction of radiating surface.

It would hardly be safe to assert that the whole interior of the filament is idle as regards emission of light, and probably the high percentages given would require some correction.

The quality of a good carbon should evidently be such as to resist to the highest degree the disintegrating action of the current and its resulting forces, but, assuming we have reached perfection in this direction, the next most important conditions are that it should have sufficient structural strength to withstand ordinary usage or vibration, and as large a radiating surface as possible.

As regards the structural strength of the filament, a recent improvement in this direction has been to support the loop by a separate piece of idle filament projecting from the bottom of the lamp globe. It might also be expected that the annular filament now constructed by some makers would possess greater structural strength, area for area, than the ordinary round or rectangular forms.

Perhaps the most important advantage obtained by diminishing the sectional area of the filament is its improved relation to the external circuit. For example, if it be assumed that the round carbon No. 1 gives 20 candles, then No. 2 would only give 14·2, and to make this equivalent to No. 1 it would be necessary to increase its length by about 41 per cent., which would increase its resistance by the same amount, so that No. 2, although now of the same candle-power as No. 1, would have a considerably higher resistance, and a smaller conductor could be employed whilst still maintaining the same percentage of loss therein.

The table also shows the relative values of different sections of filaments, and on comparing the results it is evident that a riband form of filament, with infinitesimal thickness, having a rectangular form of section, would be best. The illustration given has a thickness half of its breadth, and even with this reasonable proportion between thickness and width, it gives by far the best result. The annular of same solid sectional area comes next; in this the solid sectional area is equal to half that of its total sectional area, and therefore the thickness of its shell is about one-tenth of its mean solid circumference, so that it is considerably thinner than the preceding riband filament.

It will be observed that the riband form of filament has about 80 per cent. more radiating surface than the round, although of equal area. No doubt a riband filament would be more liable to break, and it would be interesting to know if any attempt has been made to construct it in a spiral form for greater structural strength.

It is a common custom with electric light engineers to calculate all formulæ relating to incandescent lamps by aid of a constant, generally given by the manufacturers. This constant expresses the relation between the candle-power given and number of watts required, and in value represents the reciprocal of the figures given in Column K of the table.

The process, though good enough for many purposes, is by no means correct when dealing with lamps of the same electromotive force.

In considering and comparing the relative properties of incandescent lamps it is necessary to determine what functions shall remain constant whilst making such comparisons. It is evidently desirable that the degree of energy to which the filament is subjected should be the same in each case, as well as the quality of the carbon and degree of vacuum; the lamps will then be comparable on a reasonable prospect of equivalent lives. Assuming, then, the above to be the basis for comparison, there will be two distinct methods of constructing lamps of different candle-power, either by altering the length of the filament and keeping the sectional area constant, as illustrated in filaments 2 and 3, which means a constant current and varying E.M.F., or by altering the area and keeping the length constant, which means a constant E.M.F. and varying current. It would be quite possible to construct lamps of different candle-power and same E.M.F. by making variations in both the length and area of the filament, but this could not be done under the same standard of energy.

Now, on referring again to the table, Column K, it will be

Digitized by Google

seen that filaments 2 and 3, constructed according to the first of the above methods, have the same factor of economy, so that the figure given by the manufacturers would in this case be a constant for comparing lamps of this class; but a comparison between filaments 1 and 2, which are constructed in accordance with the second method, will show a considerable difference in this respect, which is due, as before stated, to the ratio existing between the area and radiating surface. Now, as the length of the filaments in these lamps will always remain the same, the radiating surface will vary as the square root of the sectional area, and if it be assumed that the radiating surface is proportional to the candle-power, then the candle-power will vary directly as the square root of sectional area; but as the factor of economy given in Column K varies inversely as the square root of the sectional area, it may be stated that the above factor will vary inversely as the candle-power, or that the constant given by the manufacturers will vary directly as the candle-power. For example, take a Swan lamp 20 candle-power, requiring 3·5 watts per candle, then a 10 candle-power lamp of same E.M.F., and working under similar conditions of energy, would take $\frac{10 \times 3{\cdot}5}{20} = 1{\cdot}75$ watt per candle.

This is not to be taken as absolutely correct, but until more accurate data can be given regarding the relation between radiating surface and candle-power under equivalent conditions of energy, it serves to show how erroneous may be the calculations referred to.—Yours, &c.,

N. G. THOMPSON.

4, Queen Victoria street, London, E.C., August 11th, 1886.

INCANDESCENT LAMP PATENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to the reports which have appeared in the daily papers of the proceedings in the Chancery Division of the High Court of Justice, on Friday, the 6th inst., in the matter of the Edison and Swan United Electric Light Company *v.* Holland and the Jablochkoff and General Electricity Company, it is to be feared that the condensed reports referred to of what took place in court may give the public an erroneous impression of the real facts of the case, and in justice to the industry I ask that you will be good enough to afford me space to briefly state the position of the matter.

Notwithstanding that the decision of Mr. Justice Butt against Messrs. Woodhouse and Rawson is now under appeal, the Edison and Swan Company have been threatening the users of lamps not manufactured by themselves with proceedings for infringement, and among others the customers of the Anglo-American Brush Corporation.

My corporation therefore advertised their readiness to indemnify their customers against any proceedings for alleged infringements of patents by the use of the Brush Victoria incandescent lamp, and did, among others, indemnify the Jablochkoff and General Electricity Company, and their customer, Mr. Holland, of the Albert Palace.

My corporation also called upon the Edison and Swan Company, under the provisions of the Patent Act, to justify their threats by commencing proceedings against the Brush Corporation in respect of the lamps in question; but the Edison and Swan Company instituted proceedings against the Jablochkoff Company and Mr. Holland, instead of against the Brush Corporation, who are the manufacturers of the lamps.

Meanwhile the Brush Corporation have been compelled to protect their interests by instituting proceedings against the Edison and Swan Company for infringement of their lamp patents, which cover their manufacture of incandescent lamps, and which action is still pending.

The proceedings in court yesterday were:—Firstly, to confirm an arrangement made out of court between the parties, under which Mr. Holland will remain in undisturbed possession of the lamps already purchased, but will not purchase any more such lamps pending the hearing of the action, or unless Mr. Justice Butt's decision be reversed; and, secondly, to hear an application made by Mr. Holland and the Jablochkoff Company, with the consent of the Anglo-American Brush Corporation, to admit the Brush Corporation as third parties, so that they may defend the action of the Edison and Swan Company *v.* Holland and Jablochkoff. This application was granted by Vice-Chancellor Bacon, with costs against the Edison and Swan Company.

The Anglo-American Brush Corporation are fully determined to contest anew the validity of the patents owned by the Edison and Swan Company, and they have every reason to think that they will do so successfully.—Yours, &c.,

E. GARCKE, Secretary,

Anglo-American Brush Electric Light Corporation (Limited).
112, Belvedere-road, Lambeth, S E.,
7th August, 1886.

AMPERE'S RULE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If your correspondent thought that I used the words "absolute negative charge" in the sense of a negative charge which has no corresponding positive charge bound to it anywhere, he is quite mistaken. I used the word "absolute" in much the same sense as "actual," and meant thereby that the negative electricity was not merely induced in particular spots, but that the earth, on the whole, had more negative electricity than positive in it or on it.

The potential of any conductor depends both on its own charge and on the charges of neighbouring bodies. If the conductor is infinitely distant from all other charged bodies, its potential will depend on its own charge alone. If it has no charge its potential will be zero. This is true zero potential. We call the potential of the earth zero, but probably it seldom is so, accurately. If the conductor in this case (*i.e.*, when infinitely distant from all charged bodies) has a positive or negative charge, its potential will be of the same sign as its charge.

What I mean by the earth's having an absolute negative charge is that its potential would be negative if it were infinitely distant from all charged bodies; it would attract a particle of positive electricity and repel one of negative (supposing this latter not close enough to cause induction). In the case of a charged body infinitely distant from all other bodies the corresponding charge of opposite sign must still exist according to the ordinary theory of statical electricity, but it will be infinitely distant. When a body is near charged bodies it does not follow that its charge is of the same sign as its potential. The potential of the earth is sometimes positive instead of negative, and possibly its electrification is continually varying.

But generally potential increases as we pass outward from the earth; hence force lines proceed from somewhere to the earth, though it is doubtful where the positive electricity lies whence they proceed. Many seem to hold the opinion that the positive charge lies in the upper regions of the atmosphere, and this is sometimes partially brought down to the earth by the thunder clouds and discharged in the lightning.

In one of Rowland's two experiments the rotating disc had a negative charge. This charge was bound to the positive charges on two gilt glass discs connected with the earth. On Maxwell's theory the electrostatic action between the rotating and stationary discs in Rowland's experiment should cease when the rotating one has reached a certain velocity. I do not know whether other observations than those on the magnet were made at the time, but if not it would have been a curious thing to observe whether there was any flow from the stationary discs as the velocity increased, owing to the diminution of the statical action of the electricity on the rotating one.—Yours, &c.,

J. M. CHAMBERS.

NOTE.—In my last letter I said statical electricity had no effect on a magnet. I should have said "no magnetic effect." A magnet would be affected by statical induction when a charged body was brought up to it, like any other conducting body.

THE HOUSE OF LORDS' COMMITTEE ON ELECTRIC LIGHTING.

A Blue Book has just been published containing the evidence given before a Select Committee of the House of Lords last May on the three Bills then under consideration for amending the original Electric Lighting Act of 1882. Besides a full report of the evidence this volume includes some useful appendices of statistics furnished by several expert witnesses with regard to the comparative progress of the Electric Light in the principal countries of Europe and in the United States; the manufacture and distribution of gas by local authorities who have taken up that line of business; and the actual cost of supplying Electric Light to such places as the House of Commons and the Museums at Bethnal Green and South Kensington. No report is given of the discussions which took place in Committee, but judging by the brief minutes of the resolutions submitted, and the names which appear on either side on the divisions, the Government, as we conjectured at the time, had secured a preponderance of votes for its own Bill, which, except on one point of detail, was fully endorsed in the teeth not only of the friends of the two rival Bills, but of the evidence in support of them.

It will be remembered that the late Government, the members of which had been the framers of the original Act, were at length convinced by the unmistakable facts of the case that a large extension was needed of the period assigned for electric lighting operations before they became liable to be absorbed by the local authorities; and in the end Lord HOUGHTON proposed to double the time of grace, thereby condemning the obstructive legislation of 1882. But the terms of purchase remained the same—that is to say, any Electric Lighting Company at the end of forty-two years could be compelled to part with its business to the parish or town Board for the price of the old plant. Lord BURY, with more good nature than some people consider prudent, accepted the amendment, extending the period to forty-two years, but introduced in his Bill a clause providing that in case of purchase the terms should be such as are usually stipulated for "a going concern." The other Bill, that of Lord RAYLEIGH, made no provision whatever for compulsory sale, but left the Electric Lighting industry to work on precisely those lines which the Gas and Water Companies have enjoyed, subject only to the conditions which Parliament has in recent years deemed it right to impose upon those great monopolies. The difference between Lord BURY'S and Lord RAYLEIGH'S Bills is, perhaps, not very material. Whether a monopoly may be held in perpetuity or only certainly for forty or fifty years is, comparatively, a small matter, seeing that the State can extinguish any monopoly by legislative enactment whenever it is so minded. The really important question is, on what terms shall this be done? for it makes all the difference to the prospects of a business operation if it is only liable to be purchased as a going concern, or, on the other hand, is pretty sure to be confiscated as an extinct concern.

This was the essential point of divergence between the two Bills promoted in the interests of Electric Lighting and the Government Bill framed in the supposed interests of the public. As we have already stated, the evidence was conclusively against Bill No. 3. Men of authority on matters of business were unanimous in declaring that compulsory sale without regard to the value of the business to be sold would be an effectual hindrance to that business being embarked upon, whatever might be the fixed period of exemption; moreover, that in the interests of the public such a provision was inexpedient, for in view of certain loss on the ultimate sale the proprietors would make the public pay for it while they had the chance. "If," as one witness observed, "it is necessary to provide a return of, say, 12 per cent. per annum on the capital that comprises a sinking fund for the return of the capital within a short period, the light must cost a great deal more than if it were only necessary to provide a return of 8 or 6 per cent. per annum." The same witness emphatically declared his belief with reference to the Government Bill that "nobody would look at it," because the majority of prudent people would not dream of going into an investment where, within a measureable distance of time, the thing is absorbed for the value of the material." Another eminent man of business put the whole case very neatly as follows:—"It seems to me that they (the Electric Lighting Companies) would be between Scylla and Charybdis; that they would either have to charge so high a price that nobody would desert gas for them, or that they would charge so low a price that it would not pay them at the end of the time for their risk, and give them a reasonable profit on their investment."

These and other witnesses who spoke to the same effect were men who had no interest in the business of electric lighting; and where there was a leaning to compulsory purchase it was on purely political grounds, or on grounds which are obviously traceable to political prejudices of modern growth, and for which no better reasons could be assigned than that it is desirable the State should reserve the power of compulsory purchase—a power which, as we have already pointed out, the State will always possess without any antecedent reservation. What is really contemplated is a preliminary bargain for a prospective con-

Digitized by Google

fication, which the State would not have the face to suggest either now or forty years hence. Nobody denies that State reasons, or even parochial need, may justify the compulsory transfer of private undertakings into public hands; but hitherto one indispensable condition has been complied with, namely, that owners shall be fairly compensated. Any departure from this rule is made none the less odious by postponing it for two-and-forty years, as Bill No. 3 proposes; either the State will rob the company or the company will rob the public—so true is it that you cannot play tricks with the political conscience without disorganising social morality.

Some highly instructive evidence was tendered the Committee on the subject of corporation trading, Sir FREDERICK BRAMWELL, who was under examination during a whole sitting, speaking strongly against it, and giving excellent reasons for his opinion; and Mr. E. O. SMITH, the town clerk of Birmingham, testifying in the opposite sense, with reasons not so excellent. Mr. SMITH betrayed a strong prejudice against the Electric Light, chiefly, it would appear, because a great many corporations have invested in gas manufacture and are afraid of competition. Pressed to explain why he came to advocate terms of purchase for Electric Lighting undertakings vastly less advantageous than those which Birmingham had agreed to in respect to gas, he had nothing to urge except that *at present* investors had sunk no money in the undertakings which had not yet been started. To this his interrogator rejoined, "That is to say, you would like them to risk their money upon terms that if the undertaking is a failure it shall be at their risk, but if it is a success it shall be at your profit?" To which the witness could only reply that that was "a very broad way of putting it," and that a sinking fund would, he thought, adequately meet the contingency—a device which we have already characterised as injurious to all the parties concerned. We have often suspected that the terms of the Act of 1882 were framed with an eye to Birmingham and its imitators; and the glance we have been able to take at the Leeds and Birmingham Town Clerks' revelations under sharp cross-examination have rather confirmed our suspicions. Fortunately the Amendment Act of the late Government has not yet passed; the information now made public by the issue of this Blue Book can hardly fail to influence advantageously the shape of that measure when it comes on for discussion again.

THE MACKAY-BENNETT CABLES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I see from the reports of the half-yearly meeting of the Anglo-American Telegraph Company, held at the Cannon-street Hotel on Thursday, the 29th ult., it was stated by the chairman, Viscount Monck, that "their rivals the Mackay-Bennett cables were giving exceptional advantages to individuals."

This statement was repeated by Mr. Thomas Smith, a shareholder, who, also addressing the meeting, added that these advantages were obtained by allowing rebates to their clients.

I beg to say that this is not the case, as no rebates or discounts have ever been allowed by the Commercial Cable Company to their clients.

I have written to his lordship and also to Mr. Thomas Smith, requesting them to contradict the above-mentioned statements, as they are entirely without foundation and calculated to injure the Commercial Cable Company.

As considerable publicity has been given to the statements above referred to I shall be obliged if you will kindly publish this letter in an early issue of your journal.—Yours, &c.,

CH. A. DILLON, JUN., Managing Director.

96, Gresham House, Old Broad-street,
London, Aug. 10, 1886.

THE LALANDE BATTERY.

We recently had an opportunity of inspecting an installation at 11, Copthall-court, where the electricity necessary for the lamps was generated by means of a Lalande battery. It is well known that very great efforts are being made to obtain a satisfactory primary battery for electric lighting purposes. Not long ago we mentioned the Upward battery, a battery which has received considerable attention lately. The Lalande battery, however, is not of so recent a date, and, according to its proprietors, has passed through the experimental stages, and is now satisfactorily used in practice. The installation in

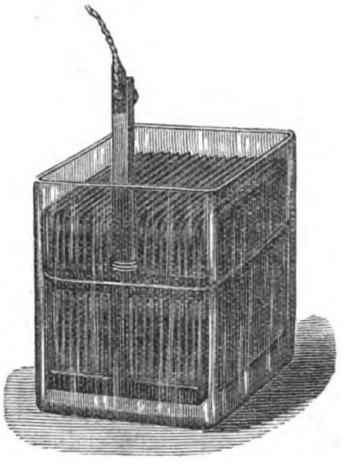
the City is by no means an experimental one. It has been, we believe, purchased of the company as a practical means of obtaining the electric light in the offices of Messrs. Borthwick. We believe that the confidence in its action is so great that gas has been entirely abolished so far as those offices are concerned. The battery is placed in one of the cellars of the



Secondary Battery Cell.

building, as shown by our illustration. Upon either side of the cellar 12 iron troughs are placed, six of which form a battery holding some 90 gallons of liquid. Down the centre of the cellar is placed the secondary battery, which is being continually charged by means of the primary, and from which the current is drawn off, so to speak, for use in the lamps as required. So far as the battery itself is concerned, we shall leave the reports of Prof. Tait, Dr. Squire, and others to speak, and devote our attention more immediately to the method adopted by the company in this installation. It will be seen from the report of Dr. Squire that the idea of the company is to obtain a saleable article from the residues of the battery after they

Digitized by Google

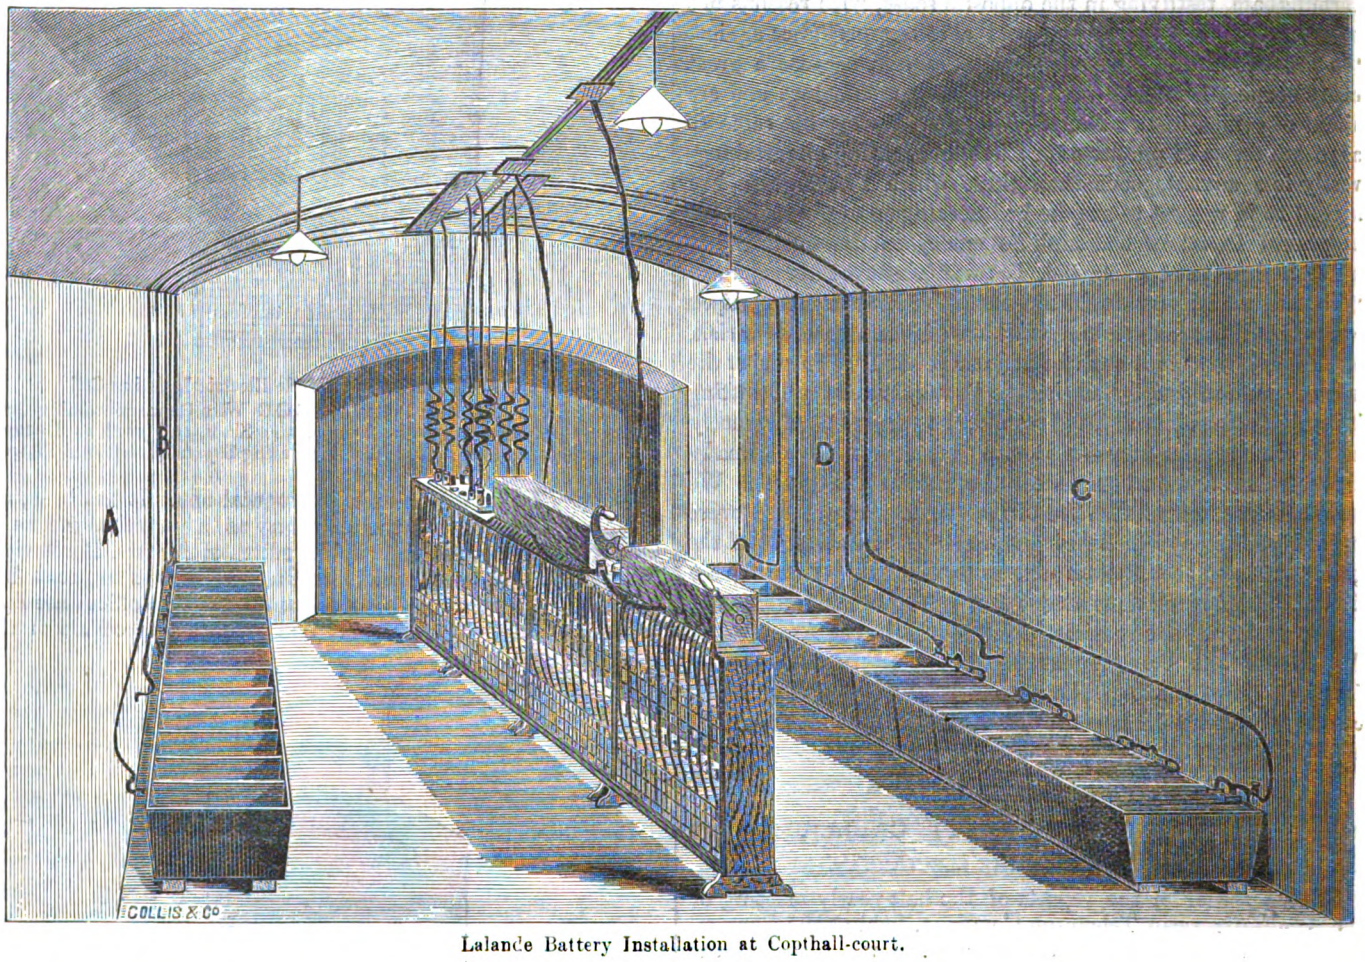
are run down from lighting. In order to do this—as every reader will understand—the work must be performed on a large scale. No one individual user would ever take the trouble to save the residue or to manufacture it into saleable product. The company, however, proposes to collect periodically all the used-up material, to open chemical works, and to obtain what may be termed a saleable by-product, and from this, in reality, to get its profits. If this can be carried out, the users of the electric light upon this system will be placed very much on the footing of the users of gas; in fact, they will be in a better position, in that the use of the electric light is far less dangerous than the use of gas. They will have absolutely nothing to do with the battery, as will be seen; duplicate sets of cells are kept, so that the company can at convenient times and seasons send carts containing the liquid, and by means of a tube, run it from the street into the spare batteries. The residual liquid is placed in large galvanised iron tanks, and periodically carts, supplied with the necessary apparatus of pumps and tubing, pump up this residual liquid and convey it to the factory, where it is treated for the by-products. Of course the whole question comes to be one of pounds, shillings, and pence. Can any company pay a dividend upon its capital under the circumstances here shadowed forth? If they can, the use of this and similar batteries will no doubt gradually extend in many places where the dynamo, steam engine, and gas engine are not applicable. There is absolutely no doubt but that satisfactory installations can be carried out by the means adopted in this instance, so that the only question is one of cost. The following are the reports to which we have referred, and we give them fully, in order that readers may derive their own conclusions.

Principal Jamieson, in his report, among other things, says:—

> The light derived in this manner is absolutely steady, and in every respect equal to that obtainable from accumulators charged by dynamos and driven by steam engines, gas engines, or water power. I find that if the instructions you gave me are attended to, there is no difficulty in putting in and taking out the daily required supply of electricity; in fact, the manipulation of these operations is so simple that they could be performed by any ordinary female servant, as it is only necessary to turn the handle of the commutator to the right or to the left at stated times. For an ordinary house or office requiring ten lamps of 10 candle-power each, for an average of five hours' lighting every day, I find it would be necessary to have *two* separate sets (six cells each) of your Lalande batteries, with from ten to twelve storage cells of sufficient size to accumulate electric energy for two days' lighting. As may be observed from my tests and calculations, the two sets of Lalande batteries would require to be completely refilled about once a fortnight. . . . If it can be satisfactorily proved, upon a commercial scale, that you can produce and find a ready market for the sulphide of zinc white paint (arising from the decomposed zinc plates, with the caustic potash liquid returned to you perfectly pure) without any loss, or at a small profit to cover the expenses of refitting the batteries, then, undoubtedly, you get your electricity for nothing, and you can charge householders whatever amount you find it necessary or advisable in order to suitably remunerate you for simply supplying them with Electric Lighting instead of gas lighting.

The report of Dr. Squire is as follows:—

> At your request I have studied the action of the Lalande battery, and have worked out a process for the recovery and the utilisation of the waste products. Before describing this process in detail, it may be well to explain the construction and action of the battery itself. A primary battery consists of a solution of some substance capable of conducting electricity, into which are plunged two different substances, both conductors, one of which is chemically acted upon by the liquid, while the other is either not at all, or at all events less easily, attacked by the solution employed. When the two substances are united by a conductor exterior to the battery, a current of electricity is set up. The substance most easily attacked (the positive element) is acted upon, while hydrogen gas is liberated on the surface of the other (the negative element). A battery is (other things being equal) more powerful in proportion to the electrical difference in the two substances employed. The more positive the one, and the more negative the other, the more powerful will the battery be. I have just said that, during the action of the battery, hydrogen gas is liberated on the surface of the negative element, but hydrogen is itself powerfully positive, and, as it accumulates on the surface of the negative element, the battery becomes weaker and weaker, until it ultimately comes to a standstill. It is then said to be polarised. In order to obviate this polarisation some means must be employed to get rid of the hydrogen as fast as it accumulates.
>
> With this object in view, it is customary to surround the negative element with some oxidising (depolarising) substance, such as chromic or nitric acids, contained in porous pots, or pieces of black oxide of manganese. These completely effect their object, but they are attended with



Lalande Battery Installation at Copthall-court.

Digitized by Google

many inconveniences, such as porous pots, which are soon destroyed, poisonous fumes, &c. The batteries are difficult and inconvenient to charge and discharge, and above all they are expensive, for the depolarising substances are decomposed by the action, and they cannot be regenerated, or, at any rate, the cost of regeneration is so great as to be absolutely prohibitive.

It is the distinguishing feature of the Lalande battery that the depolarising substance can be regenerated with the utmost facility. The battery consists of a plate of zinc immersed in a strong solution of caustic potash opposite the negative element. Unless the circuit is completed, nothing happens; but when this is done, and the battery is in action, the water of the solution is decomposed, the oxygen goes to the zinc, converting it into oxide of zinc, which dissolves in the caustic potash, while the hydrogen is liberated on the negative element. This negative and depolarising element consists of oxide of copper cemented together by means of a cement not acted upon by the solution. As the hydrogen arrives on the negative element, it unites with the oxygen of the oxide of copper, which is thereby reduced to the metallic condition, and the action goes on as long as there is any oxide of copper left. In order to regenerate the negative and depolarising element, nothing is necessary but to withdraw it from the cell, dry it, and heat it to a dull red heat in air. Under these circumstances the oxygen of the air combines with the copper, reproducing the oxide of copper from which we set out. This simple regeneration is most perfect, and I have examined the elements which have been repeatedly regenerated without the slightest deterioration.

The copper being thus disposed of, I turn to the solution of the oxide of zinc in caustic potash, which must either be regenerated for use in the battery, or obtained in the form of a valuable commercial product. Of the compounds of zinc, the sulphide is undoubtedly the most valuable. It is a white body, already largely used as a substitute for white lead, over which it possesses the great advantages of being much less poisonous, and of retaining its colour unchanged under conditions which speedily blacken objects painted with white lead. It is distinguished by great body, or covering power, in which respect it is vastly superior to oxide of zinc, which is also largely used as a pigment. An extremely simple way of regenerating the potash would be to add to the solution of oxide of zinc in potash (spent liquor) a concentrated solution of pure sulphide of potassium. Under these circumstances the whole of the zinc is precipitated as a mixture of sulphide and oxide, while not only is the original potash regenerated, but the potash produced by the decomposition of the added sulphide of potassium is obtained in the free form as well.

Simple and easy as this process looks at first sight, there are serious objections to it.

Firstly, commercial sulphide of potassium is far too impure for the purpose, and the cost of preparing a pure sulphide is prohibitory. Secondly, the mixture of sulphide and oxide of zinc produced in this way is not suitable for use as a pigment. The process which I have devised, and now recommend as yielding excellent results, is the following:—I take any convenient quantity (say 100 gallons) of spent liquor. Into this I pass a stream of sulphuretted hydrogen gas, until the whole of the zinc is precipitated (in the form of impure sulphide), and the potash is regenerated. The precipitate is separated and dissolved in sulphuric or hydrochloric acid. This process of solution is accompanied by the evolution of the whole of the sulphuretted hydrogen used to precipitate the zinc. The gas thus evolved is passed through a second 100 gallons of spent liquor, whereby a second quantity of zinc is precipitated and a second quantity of potash regenerated. The precipitate is dissolved in acid as before, and the gas led into a third quantity of spent liquor regenerating the potash and precipitating, and so on, the same quantity of sulphuretted hydrogen serving indefinitely for the operation of regeneration. The potash being regenerated, it remains to deal with zinc which is now in solution in the condition of chloride or sulphate. The solution is brought to a state of neutrality, and a small quantity of bleaching powder is added to precipitate any traces of iron which may be present. Lastly, the clear solution is precipitated by sulphide of barium, a substance which can be obtained commercially in a state of great purity, at a low price. If the zinc is present in a state of chloride, a perfectly pure suphide of zinc is precipitated, while chloride of barium remains in solution, and can be recovered as a by-product. If the zinc is present in the state of sulphate, not only is the sulphide of zinc thrown down, but the whole of the sulphuric acid, and of the barium present, accompanies it, precipitated in the form of sulphate of baryta This mixture of sulphide of zinc and sulphate of baryta is the ordinary commercial article known as "sulphide of zinc white." The more expensive pure sulphide of zinc is used only when great body is required. The ordinary process for the manufacture of sulphide of zinc consists in dissolving metallic zinc in hydrochloric or sulphuric acids, and precipitating the solution with sulphide of barium. Beyond the metallic zinc, the only raw materials used are hydrochloric or sulphuric acids and sulphide of barium. These are the only materials used in the regenerative process, and in precisely the same quantities, neither less nor more. It follows, then, that starting from the metallic zinc, the sulphide of zinc white can be obtained as cheaply in the one case as in the other. But, in the regenerative process, the zinc, before it becomes sulphide, has given out all the electricity it is capable of developing, the other elements of the battery being regenerated for use again. In other words, a company working the Lalande battery with the regenerative process would obtain, on the "sulphide of zinc white," the same profit as the other manufacturers of the article, while they would get their electricity for nothing.

I estimate that the expenses of manufacture of the "sulphide of zinc white" would not exceed (and will probably be less than) £4 per ton. The "sulphide of zinc white" is, I understand, quoted in the market now at 20s. per cwt. I propose to take it at 15s. per cwt. On this basis, and making proper allowances for loss, the profit on the sulphide of zinc white obtained from each charge of the battery would appear to be:—

Cr.				
230lb. caustic potash	at 22s. cwt.	£2	5	2
60lb. scrap zinc	at 14s. ,,	0	7	6
700lb. sulphide zinc white	at 15s. ,,	4	13	3

		£5	16	10
Showing a profit on each charge of...		£0	9	1

while the electricity is obtained for nothing. I am not aware what is the quantity of sulphide of zinc white manufactured at the present time, but I believe it to be considerable, and I understand that its use is rapidly extending, as its advantages become known. There is also, I understand, a considerable demand for sulphate and chloride of zinc, especially the latter. Both these salts are obtained in the course of the process, and it is obvious that they may be sold in this state, to supply any demand that may exist, instead of converting them into sulphide.

In a postscript to his report Mr. Squire adds:—"Since writing the above, I have made inquiries as to the probable amount of sulphide of zinc white which could be disposed of. One paint manufacturer informed me that, from experiments he had made, the covering power of sulphide of zinc is greater than that of white lead, and that he had one customer who would take about 750 tons per annum. A foreign importer of colouring matters told me that he had imported sulphide zinc white, which he sold in parcels of sixty or seventy tons. He had no doubt he could dispose of very considerable quantities. Generally, it appears that the trade in this article has, up to the present time, been very insufficiently pushed. There appears, also, to be a considerable demand for india rubber manufacturers."

Mr. Stanley C. Currie thus writes:—

In my explanatory pamphlet for a system of electric lighting by means of the Lalande battery, in conjunction with the accumulators, I have stated (page 16) that a set of six cells, the same size as those supplied to Profs. Jamieson and Tait for the purpose of being tested, gives on an average 6,000 ampere hours (useful), and that the proportional consumption of zinc for this amount is 120lbs. Now, in calculating the useful energy to be obtained, we must of course multiply the ampere hours by the average electromotive force at which the battery works during its run. On page 6 in my pamphlet, I have stated that E.M.F., through high resistance, is slightly under 1 volt. Prof. Tait gives it as ranging between ·83 to ·94 volt. Now, the working E.M.F. varies according to rate of discharge, and the state of exhaustion of liquid. For useful work, where the primary battery is not being used in conjunction with accumulators, the limit of fall, according to my experiments, should be not less than ·6 volt. That is to say, one can get 6,000 ampere hours out of above cells at a useful rate of discharge, say 35 amperes, without the E.M.F. falling below ·6 volt. Taking these figures, a set of six cells should give $6{,}000 \times 6 \times 6 = 21{,}600$ watt hours. The rate of discharge, as I stated (page 8) in my pamphlet, depends upon various causes, but any particular sized cell can be arranged to give a larger or smaller discharge rate according to surface of plates.

Prof. Tait does not mention the average rate at which his battery was discharged, but I presume it was less than 40 amperes, for he states that the E.M.F. never fell as low as ·6 volt, and was on an average ·7 volt. The useful energy, according to Prof. Tait, is thus

$$6{,}000 \times \cdot 7 \times 6 = 25{,}200 \text{ watt hours.}$$

Whereas, I never allow in practical work for more than 21,600 watt hours, Professor Tait only obtained 5,556 ampere hours out of his battery, still

$$5{,}556 \times 6 \times \cdot 7 = 23{,}335 \text{ watt hours,}$$

which is 8 per cent. above what I allow.

The consumption of zinc, however, in Professor Tait's battery was 123lb., whereas I put it at 120lb., which thus brings the total result of his experiments to—1lb. of zinc gives 189·71 watt hours, or putting one electrical horse-power hours = 746 watt hours.

3·93lb. of zinc = one electrical horse-power hour.

Now, Professor Jamieson, in his report upon these batteries, *which were charging accumulators*, gives

4·28lb. of zinc as yielding one horse-power hour.

Taking my figures, viz., ·6 volt per cell of 6 cells, giving 6,000 ampere hours and consuming 120lb. of zinc—

4·19lb. of zinc = one horse-power hour.

Thus Prof. Tait, notwithstanding the fact of his battery consuming 3lb. more zinc than it should have done, and getting 5,556 ampere hours instead of 6,000, gave on the whole better results than Prof. Jamieson's, and also better than I allow for. Thus my figures represent a very fair mean between the two independent results. Prof. Tait found there was local action in his battery. This is sometimes the case, especially when the battery is first charged, from impurities in the zinc. It is for this reason I only allow for 6,000 ampere hours per 20lb. of zinc in each cell, or 300 ampere hours per pound of zinc consumed, whereas, in many cases, it is considerably above 300 ampere hours. In some instances I have known it as high as 350 ampere hours per pound, which is very little less than

Digitized by Google

the theoretical amount. The zinc which has hitherto been used is the ordinary commercial article, and I may mention the fact that arrangements are now being made by the Standard Company for obtaining zinc specially rolled for the use of these batteries, by which means a purer article will be used. The potash also frequently contains impurities, which will not be the case after the first treating by Dr. Squire's process. Thus, when in regular work, each battery may be relied upon to give over 6,000 ampere hours per 120lbs. of zinc, which in the case of charging accumulators, is equivalent to 12,000 watt hours (useful) per 120lbs. of zinc consumed, or 100 watt hours per lb. of zinc, or 7·46lbs. of zinc per horse-power hour. Prof. Jamieson obtained from the three batteries he tested an average of 10,725 watt hours, and in one 14,474 watt hours, the consumption of zinc being in proportion.

It will thus be seen that taking the two reports upon four different batteries, Profs. Jamieson and Tait's experiments fully corroborate the figures I have given as representing the fair average work of the battery, and the weights and quantities upon which Dr. Squire's estimate is based.

Prof. P. G. Tait has written the following report upon the examination of the battery by Mr. Peddie:—

I enclose the report of the examination which Mr. Peddie has made for you of the electrical qualities of the Lalande battery. He is a careful and accurate experimenter, and has used instruments of precision, so that his results may be fully relied on. He describes the precautions taken to obtain a set of cells fairly representing an average, and he confirms the statements which have been already made to the effect that

1. The average electromotive force of a cell is always above 0·6 volt.
2. Each cell, when freshly charged, is capable of furnishing in all as much electricity as would correspond to that which passes when a current of one ampere is maintained for about 6,000 hours, *i.e.*, in the new-fangled nomenclature somewhat over 20,000,000 (twenty million) coulombs.

I hope that this independent confirmation of the statements made will be satisfactory to you.

Report on the Lalande Battery by MR. W. PEDDIE.

The battery to which this report refers consisted of six cells, selected at random from a large number prepared by Mr. Boothby. The zinc plates and the liquid were supplied by the company without selection. The report deals with two points only; first, the *electromotive force of the battery;* and second, the *total quantity of electricity* obtained from it. The company guaranteed the E.M.F. of each cell to be not less than 0·6 volt when the battery was in efficient working order. They stated also that the six cells should supply, before they ceased working, a quantity of electricity not less than that given by a current of intensity one ampere continued for 6,000 hours. The battery might cease working properly for various reasons. For example, the E.M.F. might fall too low, or the current might become very feeble for other reasons. But, in any case, I was requested to stop the battery whenever the specific gravity of the cell liquid became so high as to give a reading of 90 divisions on a Twaddle hydrometer, which the company furnished. It must be distinctly understood, then, that this report deals *only* with the questions of *E.M.F.* and *whole quantity of electricity* furnished. No account is taken of intensity of current through a given resistance, or of the efficiency of the battery, or of any other questions beside the two specified, except in so far as they have a bearing on these two. As regards intensity, for example, the condition required by the company was not satisfied as tested by their own instruments when the battery was used to charge ten of their accumulators. This may or may not have been due to imperfection in the accumulators, not in the battery.

Local Action.—The average weight of each zinc plate was 23lb. 7oz. when the battery was first set up. To test the cells for local action, which seemed to be considerable, they were left on open circuit for a fortnight. In that time the average loss of weight of each plate was 2lb. This action continued during the whole time of testing the battery.

E.M.F.—The instrument used to measure the E.M.F. of the cells was a Thomson quadrant electrometer. It was sufficiently sensitive to indicate a difference of potential equal to 0·01 volt. The E.M.F. of each cell was tested against a standard Latimer Clark cell, and also against a standard Daniell. The correctness of the standards was further tested by means of absolute measurements with a Helmholtz tangent galvanometer. There could be no error greater than 1 per cent. At starting the E.M.F. of the cells ranged from 0·83 to 0·94 volt. It fell slowly as the cells were more and more worked out; but in no case did it fall to the value 0·6 volt.

Quantity of Electricity.—The battery was at first used to charge ten accumulators in multiple arc. This was done for about 20 hours in all. Afterwards, the battery was simply run down through a metallic resistance. The current was in all cases measured by a Helmholtz tangent galvanometer. In this instrument any error due to variation in the horizontal intensity of the earth's magnetic force could be neglected in comparison with possible error in reading the scale. This error might be the 10th part of a degree. As the deflection was about 40 degrees, this involved only an error of 1 in 250 in the estimation of the current strength. The time for which the current was allowed to run at a stretch, varied from rather less than two hours to slightly over 47. The deflection varied from over 40 degrees to about 32 degrees as the battery was getting worked out. There was only a single exception to this statement when the deflection averaged only 25 degrees. This, however, was due to heating of one of the battery connections. The cells stopped working while the liquid was such specific gravity as to give a reading of 83 divisions on the hydrometer. At this stage, the deflection of the galvanometer fell to one-fourth of its value at starting, within a quarter of an hour, and diminished still farther until it indicated a current of only one-tenth its original amount. This recurred every time the experiment was repeated, although all the battery connections were taken down and polished to make certain of good contact. Some of the zinc plates were nearly worn through, so that the increase of resistance due to this probably caused the stoppage. The total quantity of electricity obtained was equal to that given by a current of intensity one ampère, continued for 5,556 hours. The possible error in this number cannot be more than ±20. The weight of zinc left was 158lb. So the above quantity of electricity was obtained from the consumption of 123lb. of zinc. The average E.M.F. of each cell would be about 0·7 volt. Hence a rough estimate of the energy in the circuit can be got.

Conclusions.—As regards E.M.F., the battery tested has satisfied the condition that the E.M.F. of each cell shall not be under 0·6 volt. As regards quantity of electricity, the required amount was very nearly, but not quite obtained. But it is probable that had the battery been used during the first fortnight, instead of being left on open circuit for the purpose of testing local action, the required amount would have been exceeded.

THE "KROTOPHONE"—A NEW FORM OF TELEPHONE.

Many variations have already been devised upon the telephone receiver in every-day use, and few possess such decided novelty as to attract more than a passing notice; but a form of receiver which has recently been devised merits some attention, as the inventor does away with the use of all magnets, diaphragms, helices, secondary currents or induction coils. The principle upon which Mr. Edward S. Spaulding, of this city, the inventor of this novel instrument, bases its operation, consists in reproducing the human voice through the medium of crepitations or minute crackling sounds or detonations. He accomplishes this by causing the original disturbances in the transmitter to be sent over the line so as to affect the receiver and cause it to give forth a series of crepitations or intermitting detonating sounds.

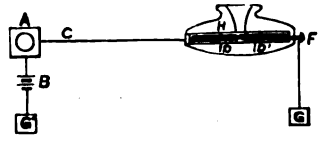

FIG. 1.—The Krotophone.

The illustration, Fig. 1, shows the original form of instrument employed, and Fig. 2 the modified and improved apparatus. As in the ordinary system, any form of microphone transmitter shown at A may be employed. Within the case H, Fig. 1, there are two carbon points D D', which form part of the circuit C, one of the points D being rigidly secured in the receiver H, and the other

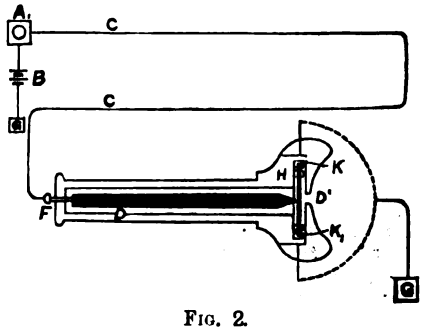

FIG. 2.

point D' being adjustable with reference to the other point by means of the screw F.

This constitutes the entire receiver. The theory upon which the instrument operates is so novel that we prefer to give it in Mr. Spaulding's own language, as set forth in the patent recently granted to him.

"For the sake of illustration we will assume that the circuit consists of a battery, line, and the receiver shown in Fig. 1 be used as a transmitter, and a similar instrument be used as a receiver proper. Assuming that the current passes through the carbon pencils in parallel lines, any disturbance of the point of contact of these pencils in the transmitter will produce a series of crepitations, which cause a series of corresponding electrical impulses to be transmitted over the circuit. Referring to the receiver, this circuit, passing in parallel lines through the pencil D, causes its points of contact with the opposite pencil D' to vary by reason of the elongation and contraction of the pencil D, due, for want of a better term, to the polarisation of the molecules or atoms of the pencil. Now, assuming that through the pencil the current passes in a series of many parallel lines, then the movement of the atoms

Digitized by Google

in each of these lines would be uniformly similar and in parallel lines, and thus a disturbance created in the receiver corresponding to the impulses affecting it, which impulses in turn correspond with and depend on the primal disturbances in the transmitter. Now, then, it being shown that the polarisation or disturbance of the atoms in the pencil D in the receiver is produced, I have noted that this result is accompanied by a series of crepitations or crackling sounds, which are clearly distinguishable from even the faintest sounds when produced by vibrations or other cause, and from this distinction I infer that the said crepitations are strictly 'neutral,' and so denominate them. Therefore, as such crepitations are individually neutral when they are arranged in constantly-varying groups, corresponding exactly to the primal disturbances which cause them, and thus if articulate sounds be the primal cause of the disturbance in the transmitter, articulate sounds will be the effect in the receiver."

Mr. Spaulding has found that when two pencils of carbon are used as the receiver the sounds will be audible and distinct, but faint; and to overcome this objection, he replaces one of the pencils by a plate of carbon of such size and quality as to be non-sonorous and non-vibrating, as shown in Fig. 2. This plate is provided with a circumferential ring K, and the plate D′ has a suitable elastic packing-ring to prevent fracture when rigidly secured in place in the holder H. In this form of receiver the current passing as before in parallel lines through the pencil D, and thence to the plate D′ from the point of contact of the pencil, the current then rapidly diverges in every direction toward the metallic ring, and thence to the ground, as before. This construction gives an amplied sound, and this effect Mr. Spaulding attributes to the radial or diverging paths the current takes. In the first form of receiver described the current passes in parallel lines, and the movement of the atoms on each of these lines is uniform, and consequently the crepitations are faint; but in the second instance these several lines are not parallel but divergent, and increased crepitating effect is produced.

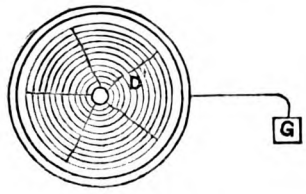

Fig. 3.

The illustration Fig. 3 shows the circumferential connection of one of the carbon points.—*Electrical World.*

THE "CHALLENGE" MOTOR.

At a recent meeting of the Electrical Section of the American Institute, Mr. John M. Pendleton exhibited to the society a small electric motor of his own design which embodies several novel features. Mr. Pendleton remarked that the general introduction of

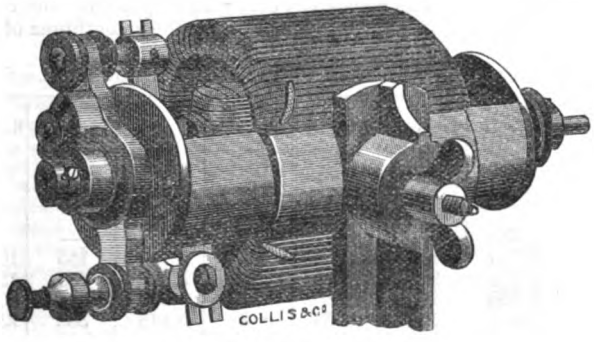

Fig. 1.—Challenge Motor.

electricity had drawn considerable attention to electric motors lately from the recognised fact that power is not only more readily transmitted by electricity, but also on account of the facility with which it may be subdivided and distributed without loss—a point in which neither steam nor gas engines can compete with it.

The motor, which is shown in perspective in Fig. 1, weighs forty ounces, and is capable of developing power sufficient to run a sewing machine or other light running apparatus, such as a dental drill, mallet, or a fan.

The armature of the motor, which is shown detached in Fig. 2, is of the three-pole type, and each of the three segments of the commutator is consecutively cut out in such a manner as to reverse the polarity of the pole of the armature so that for one-half the distance of the pole piece attraction takes place, and during the other half repulsion.

This construction obviates any dead point, and the motor starts instantly at any position of the commutator. This is evidently an indispensable quality in a motor designed to operate intermittently, stopping and starting at frequent intervals. Such work also frequently requires a change in speed, so as to run fast or slow, and this has also been provided for, by making the brush holder adjustable. The latter is controlled by a spring which normally maintains it at the position of maximum speed. By rotating the brush

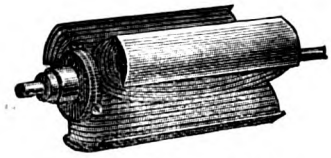

Fig. 2.—Armature of Motor.

holder, however, the position of contact, and hence the speed, can be varied at will from the maximum down. This shifting of the brushes doos not require any manipulation by hand, but is accomplished by a cord attached to a treadle, thus leaving the operator's hands free to guide the work.

THE HEATING OF AERIAL CONDUCTORS BY ELECTRIC CURRENTS.*

BY J. GILBERT WHITE, PH.D.

Introduction.

While engaged on some tests for the Franklin Institute at the Electrical Exhibition, in the fall of 1884, the writer found it necessary to consider the effect of heating and consequent change of resistance of aerial conductors carrying electric currents, and was unable to find any data by which the change of temperature due to the passage of a given current under different conditions of exposure could be determined. It had been noted that, in some cases, covered wires were less heated than naked by the same current, and Sir W. Thomson had shown by mathematical analysis that such should be the case for certain values of emissive and conducting powers. But to what extent these conditions obtained in practice, whether covered wires in general kept cooler than naked, or did so only in exceptional cases, had not been determined, and nothing, so far as the writer knew, was known of the relation that existed between the heating of covered and naked wires for any particular case.

It seemed, therefore, desirable that such experiments should be instituted, and in the winter of 1884-5, the writer proposed to Mr. J. G. White, then pursuing a course of graduate study at the Cornell University, to make a thorough study of the subject both theoretically and experimentally. The method adopted for the experimental investigation made it necessary to have continuous wires partly covered and partly naked. These were obtained through the courtesy of the Electrical Supply Company, of New York, who induced manufacturers to prepare for the purpose samples of wire in lengths of about 100ft., half covered and half uncovered, of a great variety of styles of covering. The investigation proved a much more extended one than was anticipated, and Mr. White having accepted a position in the University of Nebraska, was obliged to leave it before completing all that had been planned. It is believed, however, that the results so far obtained are of sufficient value to warrant their publication, and it is expected that the investigation will be continued. WM. A. ANTHONY.

Physical Laboratory, Cornell University,
Ithaca, N.Y., May 10, 1886.

The heating of conductors by electric currents is a subject of great practical as well as theoretical interest. It constitutes a leading factor in many of the electrical engineering problems of the day, especially in those of electric lighting and transmission of power. All electricians are familiar with the heating of wires by currents, and know that overheating is not economical, injures the insulation, and may even lead to firing of buildings or ordinary combustibles.

Yet very little has been written in this country on the subject; and, so far as we can learn, no experiments have been made.

* From the *Electrician and Electrical Engineer* (New York).

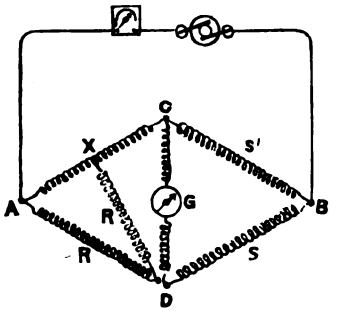
Digitized by Google

Letters from several of the leading electricians of the country show that quite diverse opinions are held on the most important and practical problems connected with the subject. Furthermore, many of the practical electrical engineers compute the size of wire to be used for any purpose by the rule (prescribed by the Board of Underwriters) of allowing a certain number of amperes current per square inch cross section of the conductor. This rule, as we shall show later, is proven to be wrong by theory and by experiment, and might lead to serious consequences if the computations were for large currents.

In Europe a number of articles have appeared in the scientific periodicals which have discussed the various questions connected with electric conductors ; but the results arrived at have been quite unlike, and very few have gone into any experimental verification of their theoretical deductions. It has therefore seemed wise to undertake some experiments which might verify the results of the theoretical solutions which might be found in other articles or which might be deduced. A description of the method of conducting the experiments and a synopsis of the results will now be given in order that these results may be referred to from the theoretical discussions given later in this paper, and the results reached by the two methods compared.

The currents used in the experiments were obtained from a Gramme generator, independently excited by a small Weston generator. By having a proper set of resistance coils in the "field" of the Weston machine and also between the Weston and the "field" of the Gramme machine, the amount of the current could be varied at will. The temperature of the wire experimented upon was determined by its resistance, which was measured by means of a Wheatstone bridge.

An idea of the connections may be obtained from an inspection of the following figure :—x consists of the wire under consideration. When two wires were to be compared they were joined and the current sent through them in series. By means of a temporarily devised mercury key the connections could be made so as to give R the position shown full or dotted. By determining R and R′ alternately, we get the values for the resistance of one wire and of both. By subtracting the average



value of R′ from the average value of R, the value of the resistance of the other wire could be obtained. R and R′ were readings on one of Elliott Brothers' four dial resistance boxes ; and since they were always thousands of ohms, any slight difference in the resistance of the connecting wires in the two positions would be entirely inappreciable. s was a length of No. 00 insulated wire very loosely coiled so as to be well ventilated. x was in most of the experiments a No. 16, No. 18, or No. 20 wire, and hence s, being so much larger than x in diameter, would not be appreciably heated by the currents which were used to heat x.

At all events, all the experiments of practical significance consisted in the comparisons of two wires ; and, since any slight alteration of s would make the same percentage of difference in R and R′, such a change would not vitiate the results. A little study of the experiments in the results of which this slight change in s would introduce *any* error, shows that, at most, this error would be only a fraction of one per cent. Owing to the variable factors which enter into these results, this is considered as within the limits of attainable accuracy for these particular experiments. s was a part of the resistance of an ordinary resistance box, and remained constant during any set of experiments ; but was varied when a new wire was placed at x so as to have R as large as possible in all instances. Connections were so made that by keys on the resistance box containing R the circuit A R D S B could be closed, and, immediately afterwards, the galvanometer circuit. As x and s were only fractions of an ohm, and as (R+S) was always thousands of ohms, the current which flowed through R and S for the short time during which the circuit A R D S B was closed was very small ; and R and S were not appreciably heated. G was a delicate galvanometer.

The above description shows that the bridge was so arranged that the results obtained from its readings can be relied on. In each of the experiments the resistance of the wire x was obtained, when the wire was cold, by means of one or two gravity cells. Then as only x and R changed during the experiment, the increase in R would enable the per cent. of increase in x to be computed. The temperature of x was then computed, on the assumption that the resistance of x increased 0·388 per cent. for each rise of one degree centigrade. This assumption is not exact; since $R' = R(1 + at + bt^2)$, in which equation R′ is the resistance at any temperature t, R the resistance at zero, and a and b are constants determined experimentally. Now b is so small in comparison with a, that it is only when t becomes of considerable magnitude, that the second term becomes worthy of attention. The calculations have therefore been made as indicated above.

To determine the current flowing at any time one of Thompson's ammeters with sliding magnet and needle was connected in the main circuit. The constant of this instrument was determined by means of the copper voltameter, and found to be 5·2608, or with instrument set

at 32	current	=	·1644 × deflection
,, 16	,,	=	·3288 × ,,
,, 8	,,	=	·6576 × ,,
,, 4	,,	=	1·3152 × ,,

Other determinations by other persons, during the progress of the experiments given below, gave almost exactly the same result. The experiments are given below not in the order in which they were made ; but in what seems to be the logical sequence.

Experiments, Set 1.

To determine the law of variation of the temperature of a conductor after starting through it a current of constant intensity. To determine this law the main circuit was so arranged that it could be closed by means of a mercury key at any instant. Several of the students in the laboratory kindly assisted in this experiment ; so that the following arrangement could be made. One person observed and took frequent readings on the ammeter, to see that the current remained steady. Another closed the circuit at the beginning of a minute ; at the expiration of each half minute thereafter he called out a signal, having given a warning signal five seconds before.

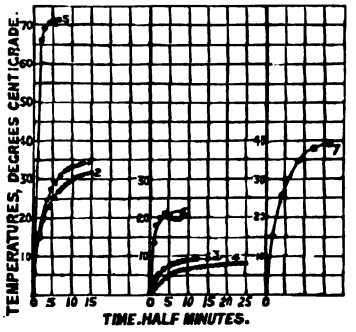


Plate I.

The writer was stationed at the "bridge," and maintained, by changing R, as nearly as possible a balance, calling out the reading of R to another person at the end of each half minute. Of course the exact values of R at the precise instant could not be determined, owing to its constantly changing magnitude ; but fairly accurate results were obtained as is shown by the smoothness of the curves on the cross section paper. In laying out these curves, the rise in temperature of x in degrees calculated as explained above,

LEGAL INTELLIGENCE.

Field v. Bennett.

On Monday, in the Court of Queen's Bench, before the Lord Chief Justice and Mr. Justice Denman, Sir Charles Russell, Q.C. (with whom was Mr. Danckwerts), moved on behalf of the defendant in this case to set aside the judgment given in it for the plaintiff for £5,000, and all subsequent proceedings, on several grounds. The plaintiff, Mr. Cyrus Field, is an American, and well known from his connection with the telegraph companies of the United States, and the defendant is Mr. James Gordon Bennett, the proprietor of the *New York Herald*, which paper has an office in London. His general representative in this country is Mr. Oakey Hall. The action was one brought to recover damages for libel in which the plaintiff was charged with being an unfit person to be the director of a commercial undertaking. On February 26, 1885, the writ was served upon Mr. Hall. On April 1, 1885, the Court of Appeal, consisting of Lord Justice Baggallay and Lord Justice Lindley, made an order for substituted service on Mr. Bennett by service of the writ personally on the defendant, Oakey Hall, the plaintiff undertaking to accept short notice of motion to set the writ aside, and the defendant being entitled to serve such notice without submitting to the jurisdiction. By the order the plaintiff was also to undertake not to sign judgment against the defendant Bennett without leave of the Court at the trial or otherwise. A previous application for an order for substituted service had in fact been unsuccessfully made to the Divisional Court (1 *The Times* "Law Reports," 374). The substituted service had been effected on Hall on April 2, 1885, and on April 28 the statement of claim had been delivered as against Hall, and filed as against Bennett in accordance with Order XIX. On July 12, 1886, the learned counsel for the plaintiff had applied *ex parte* to the Divisional Court and had obtained leave to sign interlocutory judgment against Bennett. On July 26 the damages had been assessed before Mr. Under-Sheriff Burchell at £5,000. The present application was one made on the part of Mr. Bennett to set aside the judgment and the substituted service on three grounds—(1) that the case was not one in which substituted service could be effected; (2) that the signing of the judgment had been wrong, as there had been delay and no proceedings had been taken for more than a year after the issuing of the writ; and (3) that the damages were excessive. As to the first point, it was contended that substituted service could only be allowed where it would have been but for particular circumstances possible to have effected personal service, which was not the present case, the defendant being a foreigner, residing out of the jurisdiction, and having never been within the jurisdiction. Formerly there had been service out of the jurisdiction in cases of tort, but now it was only allowed in the cases enumerated in Order XI., and the present one was not one of them.

Sir HENRY JAMES, Q.C. (with whom was Mr. Pollard for the plaintiff), said that in the present case there had been no application for service of the writ out of the jurisdiction.

Sir CHARLES RUSSELL said that no doubt that was the case. He should, however, contend that if the order made in the case had been right there could be substituted service on a man who could not be served personally. The learned counsel cited "Sloman *v.* Government of New Zealand" (1 C. P. D., 563), "Flower *v.* Allen" (33 *L. J.*, Ex., 83), and "Hesketh *v.* Fleming" (24 *L. J.*, Q. B. D., 255). As to the signing of the judgment that had been wrong, because there had been delay and no proceedings for more than a year after the issuing of the writ, and therefore notice ought to have been given (Order LXIV., Rule 13, and "Webster *v.* Myer," 14 Q. B. D., 564). On the point as to the damages having been excessive, the learned counsel said that the statement of claim had never been brought to the notice of the defendant Bennett, and the endorsement on the writ had simply been "The plaintiff's claim is for damages for libel." The case had been treated before the Under-Sheriff as if it had been one of judgment in default of plea, while it really had been one of judgment in default of appearance. The jury ought not to have been allowed to take into consideration the damage alleged by the plaintiff to have been done to him in America as well as in this country.

Mr. POLLARD said that the point which he had made as to this in the Under-Sheriff's Court had been that the plaintiff sought redress for the injury done to him by the defendant by having sent over false intelligence by his own cable to be published in his newspaper at New York.

At the hour of adjournment the arguments of the learned counsel for the defendant had not been brought to a conclusion, and the further hearing of the case was postponed until Wednesday.

Wednesday and some part of Thursday were occupied with the discussion whether the judgment should be set aside on the ground of irregularity, the defendant not being a British subject. After lengthened arguments on either side, Lord Chancellor Coleridge decided that the Court must have time to consider their judgment.—Judgment accordingly postponed.

Edison and Swan United Electric Light Co. (Limited) v. Holland and the Jablochkoff and General Electricity Co. (Limited).

This was an action brought before Vice-Chancellor Bacon to restrain an alleged infringement of the plaintiffs' patents of incandescent lamps by an electric installation at the Albert Palace, Battersea, of which the defendant, Mr. Wm. Holland, is the manager. The action now came on upon a motion by the plaintiffs for an injunction until the trial. In consequence of the recent judgment of Mr. Justice Butt (already reported in *The Electrician*) pronouncing in favour of the validity of the plaintiffs' patents, the defendants now submitted to an interim injunction restraining them from buying any more lamps except from the plaintiffs, and to keep an account until the trial, with liberty to apply, in case of Mr. Justice Butt's decision being reversed on appeal. It was stated that the plaintiffs had arranged to take the injunction in this form to obviate any inconvenience to the public visiting the Albert Palace. The Vice-Chancellor also made an order, upon the application of the defendants, the Jablochkoff Company, adding the Anglo-American Brush Electric Light Corporation (Limited) as defendants, they being the manufacturers of the lamps supplied by the Jablochkoff Company to the defendant Holland, and having entered into an agreement with the Jablochkoff Company to indemnify them against the litigation. The Attorney-General (Sir R. Webster, Q.C.), Mr. Aston, Q.C., Mr. Moulton, Q.C., and Mr. Bremner appeared for the plaintiffs; Sir H. Davey, Q.C., Mr. Marten, Q.C., Mr. Renshaw, and Mr. Graham for the defendants.

COMPANIES' MEETINGS.

The Cuba Submarine Telegraph Company (Limited).

The thirtieth ordinary general meeting of the Cuba Submarine Telegraph Company (Limited) was held at the Company's offices, No. 61, Old Broad-street, on Wednesday, the 11th August, 1886, under the presidency of Mr. Joaquin de Mancha.

The SECRETARY (Mr. James Scott) read the notice convening the meeting, and the report of the Directors and statement of accounts were taken as read.

The CHAIRMAN then said: Gentlemen, before asking you to pass the report and balance sheet, perhaps you would like to hear a few words from me. During the last six months we have had rather an anxious time, as you will remember when we last had the pleasure of meeting you we were threatened with the laying of a new cable between Halifax and Jamaica.

Digitized by Google

That, as you see by the report, has now been abandoned, and the Government only intend to lay it as far as Bermuda. That being so we shall not be at all injured. That, therefore, is a circumstance off our mind, and I need not say that we were very pleased that the Government came to such a resolution. We then heard of a new cable that it was proposed at one time to lay between the Canaries and Cuba. That also caused us some little anxiety, and we wrote our agent in Madrid asking him to make inquiries, and I am glad to inform you that the Government has not sanctioned this cable, which was another anxiety removed from our minds. Then it came about that our receipts were being diminished. As you will have seen by the report, unfortunately our earnings, compared with those of the same period of last year, have diminished by about £1,700. But, as you are all aware, in every branch of business there has been great depression, and we unfortunately have suffered somewhat, though not to the extent that might have been anticipated. Notwithstanding all these difficulties, which, I am glad to say, have been overcome, and after repairing the cable from Batabano to Cienfuegos, which, unfortunately, has cost us nearly £3,400, we are able to propose to you a dividend at the rate of 8 per cent. per annum on the ordinary shares. Taking into consideration all the difficulties that we have had to go through during the last six months, I hope that that will be considered satisfactory by the shareholders. In paying this we have not trenched at all upon our reserve fund. You will find by the accounts that it is exactly the same as it was before. The only thing that we have had to do has been to trench a little upon the interest. You will see that we have passed the balance of interest account, £1,670, to revenue, and by that means we are able to keep up our dividend, and carry forward £600 to the next half year. I think, taking everything into consideration, that our shareholders must be satisfied with the result. I am glad to inform you that the prospects for the present six months are a little better. I think our increase in July has been about £300 more than there was at the same period last year. We hope that the improvement may continue, and that when we meet you six months hence we shall be able to give you a more favourable report than that now placed before you. With these remarks I beg to move, "That the report and accounts now submitted be received and adopted."

Mr. ALEXANDER F. LOW seconded the motion.

Mr. GRIFFITH: It is generally a pleasant thing to meet the Directors of this Company, for the report that they present is usually one that is very satisfactory and gratifying. While other companies are complaining I think we have cause to rejoice. While the dividend of other companies has been falling off, and notwithstanding that our own business has fallen off a little, I think a dividend of 8 per cent. will satisfy most of us. Had it not been for that unfortunate accident on the Batabano-Cienfuegos cable, I have no doubt that the dividend would have been much larger. We reciprocate the sentiments that you have uttered, and think that we are indebted to you for your able management of this Company. We all take an interest in everything that can promote its success, and looking at the balance-sheet from a mere legal point of view, I think I can possibly make a suggestion. I see we pay a large sum by way of income-tax. I have to inquire whether that income-tax is paid on preference as well as on ordinary shares?

The CHAIRMAN: We deduct it from the preference shareholders, but we do not deduct it from the ordinary shareholders.

Mr. GRIFFITH: I was going to make the remark that in some companies it has been usual to pay the income-tax on preference shares. I am speaking now as the auditor of one of our large companies. They have been taking legal advice on the subject, and have found that they are not bound to pay the income-tax for the preference shareholders. The preference shareholders have merely a preferential claim to their dividend, but any money beyond that is not to be paid at the expense of the ordinary shareholders, but is to be paid at the expense of the preference shareholders themselves. This may possibly vary in particular companies, owing to the particular terms of their constitution. But I think it is pretty clear that the ordinary shareholders should not bear the expense of the income-tax for the preference shareholders.

The CHAIRMAN: If you had read the accounts you would see that we deduct the income-tax from all gentlemen who are preference shareholders, but on the ordinary shares we pay it ourselves. Not only so, but I think I may add that we are so conscientious that the Directors themselves pay income-tax on their remuneration, which I do not think is usual in other companies.

Mr. LOW: And the auditor's as well.

The resolution was then put and carried unanimously.

The CHAIRMAN next moved "That the following dividends for the half year be now declared on the shares of the Company, namely, at the rate of 10 per cent. per annum subject to income-tax on the preference shares, and 8 per cent. per annum free of income-tax on the ordinary shares payable on and after to-morrow."

Mr. LOW seconded the resolution, which was carried unanimously.

The CHAIRMAN: Mr. Low goes out of office by rotation. He is one of the original Directors of the Company. I have had the pleasure of serving with him for many years, and I have great pleasure in recommending his re-election.

Mr. COCHRAN seconded the resolution, which was agreed to *nem con.*

On the motion of Mr. COCHRAN, seconded by Mr. SQUIRE, the auditor of the Company, Mr. Thomas Greenwood, was also unanimously reappointed.

A SHAREHOLDER asked how the new commercial treaty with Spain was likely to affect the Company.

The CHAIRMAN: Anything that takes off the trammels from commerce is sure to be good for commerce generally. I think that with this new treaty with Spain there will be more interchange between Cuba and Spain, which ought to bring us a little business.

Mr. COCHRAN: I know something of Cuba, unfortunately, and I do not think Spain can do much worse for Cuba than she has done in the past. The only difficulty that I anticipate will be this movement in regard to the manumission of slaves. This labour question has really been a substantial difficulty because of the reckless way in which Spain has managed that colony by sending out officials and keeping a large staff who were not administering the affairs honestly and fairly.

The CHAIRMAN: I think before we part I should wish you kindly to second me in giving our thanks to Mr. Keith for the very efficient manner in which he carried out our repairs. In a company of this description we are so liable to have breakages that it is very essential that we should have a good man to call upon at any time. The moment we knew that the cable was interrupted we telegraphed to Mr. Keith to hire a steamer and to repair it himself. He did so very efficiently; and not only that, but he recovered at the same time a great portion of original cable that was laid down, which according to our estimate is worth about £1,000, so that we have repaired the cable without encroaching upon our reserve fund. In this vote I should like also to include Mr. Scott and the other members of the staff. Those who have any intercourse with Mr. Scott know how ready he is to give every information in regard to the Company, and how zealous and assiduous he and the other gentlemen who support him are in performing their duties.

Mr. LOW having seconded the motion, it was carried unanimously.

The SECRETARY briefly acknowledged the compliment.

A SHAREHOLDER then proposed a vote of thanks to the Chairman and the other Directors, which was cordially passed.

The CHAIRMAN: I have, on behalf of my colleagues and myself, to thank you for the honour you have done us in according to us your thanks for our management of the Company. I can only repeat what I said before, that we are always ready to do what is required in the interests of the Company, and it encourages us to be more diligent, if possible, to know that we have your approval.

The proceedings then terminated.

The National Telephone Company.

The sixth annual ordinary general meeting of the shareholders of this Company was held at the Company's offices, 11, Queen Victoria-street, on August 6, under the presidency of Colonel R. Raynsford Jackson.

The SECRETARY (Mr. Wm. B. Campbell) read the notice convening the meeting.

The report, which appeared in *The Electrician* of last week, was taken as read.

The CHAIRMAN: Gentlemen, in moving the adoption of the report I shall have but few remarks to address to you. I will recall to your recollection, in the first instance, that on the 11th of August last year you authorised the Directors to issue £150,000 in Second Preference shares. I have now to announce that all those shares have been taken up by the public. Then I wish to call attention to one paragraph in the report which gives the annual rental at £80,674. 2s. 8d., and I want to explain that that is not the whole of the revenue of the Company, because another revenue outside the rental revenue has been rapidly developed in the last eighteen months. It is that derived from fee messages. On the 1st of January, 1885, the amount received from fee messages was £4. 18s. 2d; in June in the same year it had risen to £39 7s. 11d.; in January this year it amounted to £49. 1s. 10d., and in June to £68. 11s., so that there is a revenue which has not been shown in the report to an amount between £800 and £900. Therefore the total revenue, including rentals and fee messages, was on June 30th £81,500. I will next call your attention to the trunk wires. We have extended our trunk wire system considerably. Glasgow, for example, is in communication with a large number of other towns, and the inhabitants of Glasgow and those towns can communicate with each other either by paying annual rental or the small fee of 6d. per conversation lasting three minutes. I have before me a little sketch of our Glasgow trunk wire system, which it may interest some of you to glance at. It is from a plan that is issued to our subscribers in Glasgow, that they may know how to take advantage of our trunk line system. I may mention, however, that the connection between Glasgow and Edinburgh is not shown there. At present we are depending upon the Post Office for the trunk wire between those two cities. We have also from the Post Office trunk wires between Glasgow and Greenock, and Glasgow and Paisley. We have an engagement with the Post Office, which lasts to the 30th September next year, when we shall be entirely rid of our trunk wire contract with the Post Office, and shall depend upon our own trunk wires exclusively for giving the service to Glasgow, Edinburgh, and the whole of the wealthy industrial parts of Scotland embraced in the district between those great towns. While I am on the subject of trunk wires, I am happy to be able to state that our Company has made an arrangement with the Lancashire and Cheshire Company, by which the industrial towns of Yorkshire are in communication with the large manufacturing and other important centres in Lancashire. The connections are completed, conversations have taken place over the wires, and in the course of a few days the public will have the free use of the advantages which we are able to give as the result of the arrangements between the two companies. Another advantage we have given to the public is that of call boxes. In Glasgow we have as many as twenty-two of them, and our subscribers use them free of charge. Those who are not exchange subscribers use them on a payment of a fee of 3d. That is found to be a great advantage, both to our subscribers and the general public in the centres where the call box is introduced. In many cases we use an automatic call box. The person using it just drops in 3d. and puts himself

Digitized by Google

automatically in communication with the exchange. He is then connected with the subscribers with whom he wishes to hold a conversation. We have, during the year, opened nine new exchanges, and we are now busily at work starting several others, besides examining the country with the view of obtaining the necessary way-leaves to still further extend our system. That extension is giving to those who have hitherto not had the advantage of the telephone the power of using it, and our aim will be as far as possible to connect all the smaller towns with such important centres of industry as it may be desirable for their inhabitants to hold communication with. It has been the custom of the Directors to make some reference in the report to the relations between the Company and the Post Office. We hold the licence under which we work from the Postmaster-General, and we have had various subjects under discussion with that department from time to time, but we have arrived at such a state of chronic amicability in our relations with the Post Office that it is now no longer necessary to introduce a special heading into our report bearing upon that subject. I am happy to be able to inform the shareholders that our relations with the Post Office are about as satisfactory as they well could be. Whilst dealing with this subject there is one point which I wish to remark upon, and it is this—that I think very great additional advantages might be given to the public with benefit to the Post Office, and without grave disadvantage—perhaps it would be somewhat of an advantage to the telephone companies—if the telegraph and the telephone in all parts of the country were connected with each other, and if the subscribers to the telephone companies were enabled through the telephone to communicate with the Post Office, in order to send messages to all parts of the world, receiving their replies through the same double instrumentality, the telegraph and the telephone. As far as the National Telephone Company is concerned, it would be quite prepared to give to its subscribers the benefit of this connection without charge, if the Post Office would allow the Company to connect the postal telegraph with the various exchanges without making any charge to us. I think they might do this, because I am quite convinced that a great increase of telegraph revenue would follow an arrangement of this kind. Gentlemen, I do not think it necessary to dwell upon any other features in the report, or to occupy your attention any longer. I make it a rule never to indulge in prophecy with reference to the prospects of the Company. I think it is sufficient that at the end of each year events should speak for themselves. I will, therefore, content myself with proposing the adoption of the report and accounts.

Mr. JOHN BRUCE seconded the motion, which was carried unanimously.

The CHAIRMAN: As you see by the last paragraph but one in the report, three of our directors retire and offer themselves for re-election. The first in the list is Mr. W. Hardwicke Bradbury, and I have great pleasure in proposing that he be re-elected a Director of the Company. It is not necessary for me to say anything in eulogy of Mr. Bradbury, for I think I may say that it is a source of satisfaction and advantage to the shareholders that the Directors of the Company have paid persistent, valuable, and steady attention to the affairs of the Company.

Mr. CARGILL seconded the resolution, which was carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. BRUCE, Mr. W. Lowson was re-elected to his seat at the Board, as was also Mr. Samuel de la Grange Williams, on the motion of the CHAIRMAN, seconded by Mr. W. A. SMITH.

Mr. CARGILL next moved, and Mr. TIMBERLAKE seconded, the re-appointment of the Company's auditors, Messrs. Quilter, Ball, and Co., which was agreed to.

The CHAIRMAN: I beg to move—"That Article 62 of the Articles of Association be amended by omitting the words 'fifty preference shares of the original capital of the Company,' and substituting for the same the following words: 'fifty first preference, or one hundred second preference shares, or five hundred ordinary shares of the Company.'"

Mr. CARGILL: What is the object of that?

The CHAIRMAN: The object is this: The United Telephone Company is entitled to have two Directors upon our Board, and it is a very large holder of ordinary shares. It is the wish of the United Telephone Company that its Directors should be entitled to qualify with ordinary shares instead of preference shares. I thought it would be better to give a wider range of qualification to all our shareholders, and to enable the first preference, and second preference, and the ordinary shareholders to act as Directors if selected for the purpose.

Mr. BRUCE seconded the motion, which was agreed to *nem. con.*

The CHAIRMAN: You will recollect that at our last meeting there was some difference of opinion as to whether the dividend resolutions ought to be passed by the shareholders. It has never been the custom of this Company to propose such resolutions, and we were advised by our legal advisers that it is not necessary. The Directors have power under their articles to declare the dividend, and the shareholders, by passing the report, approve of the policy indicated in the report with reference to the dividends, so that by implication, at all events, the shareholders, by passing the report, approve of the dividends. But if it is the wish of the shareholders that we should adopt the plan, that is common in some companies, of proposing resolutions on the subject, I have no objection to doing so. I propose, therefore, "That a dividend at the rate of 6 per cent. per annum, less income tax, be paid on the first preference for the six months ended June 30th."

Mr. BRUCE seconded the resolution, which was agreed to unanimously.

On the motion of the CHAIRMAN, seconded by Mr. SMITH, it was further resolved, "That a dividend at the rate of 6 per cent., less income tax, be paid upon the amount called up on the second preference shares for the six months ended June 30th," and, "That a dividend at the rate of 3½ per cent., free of income-tax, be paid on the ordinary shares for the six months ended June 30th.

Mr. SMITH then proposed a vote of thanks to the Chairman. They had, he said, heard from Col. Jackson how the Company had progressed during the last year, and perhaps it would not be amiss for him (the speaker) to say that a very large proportion—in fact, he might say the entire prosperity of the Company was due to Colonel Jackson's personal efforts. It was astonishing to find that a Company which only four years ago had a surplus revenue of £144, should now have £17,500 to dispose of, and he might say at once that, in his opinion, and in that of most of his colleagues, the great bulk of the credit for the condition of their affairs was due to their Chairman. He therefore asked the shareholders to join him in giving a hearty vote of thanks to that gentleman for his unwearied efforts on behalf of the Company. The Chairman had referred to one or two important features of the Company, but he (Mr. Smith) thought it was also encouraging to know at the end of the half-year that in addition to their larger revenue they had more orders in hand.

Mr. CARGILL seconded the motion, endorsing the remarks of the previous speaker.

The resolution having been cordially passed,

The CHAIRMAN said: I must necessarily feel greatly gratified by the manner in which you have passed the resolution proposed by Mr. Smith, as I also am by the language in which he introduced it to the meeting. But, for my part, I cannot take so large a share of the credit for our prosperity as Mr. Smith and Mr. Cargill are willing to give me. When I was called upon to organise this Company an important question for consideration was whether the Directors were to be gentlemen resident in London, or whether they were to be elected on account of the influence they possessed in the various centres in which we were going to work. I thought the latter the right plan, and the Company has got invaluable aid from the various Directors of the Company in the different districts where they happen to reside, and especially has that been so in the Glasgow district, which is largely indebted to Mr. Smith for the great development that has been made in revenue there. It is now close upon £25,000 a year in Glasgow, and its immediate dependencies. I recollect when, at an early meeting of the organisers and promoters of this Company and of a number of gentlemen connected with the United Telephone Company, having resorted to the usual custom of Englishmen when they want anything to be successfully carried out of dining together, and the question being mooted what would probably be the extent of the development of the revenue of the Company in Glasgow—then at a very small figure—Mr. Smith created a great deal of amusement by saying that Glasgow would be good for from £20,000 to £30,000 a year. Mr. Smith's prophecy has been realised in five years from the time when he made it. I see no reason to doubt that another prophecy, which I shall not divulge to-day, but which was made to me lately, may also be justified by eventual circumstances. I have also, as I have said, the assistance of other directors in important centres. One of my colleagues who resides in Yorkshire, for example, gives very great attention to the interests of the Company in that district. Mr. Bruce has done a great deal in Edinburgh, Mr. Lowson in Dundee, Mr. Williams in Birmingham, and Mr. Sands in Nottingham, so that the Company is largely indebted to Directors, who are willing to give me a much greater share of the credit for the progress of the Company than I can properly and conscientiously take to myself.

The proceedings then terminated.

South of England Telephone Company (Limited).

The second ordinary general meeting of this Company was held on Monday, the 9th inst., at Winchester House, Old Broad-street, under the presidency of Mr. David Owen Bateson, the Chairman of the Company.

The SECRETARY (Mr. Fred. L. Robinson) read the notice convening the meeting.

The CHAIRMAN: I am very sorry that our meeting has been so long delayed; but there are several reasons why this has occurred this year. Our books and papers—it being a new Company—required a great deal of consideration before we could decide as to how they could best be kept. Again, we did not have sufficient accommodation for our staff, and we could not get on with our business so fast as was wished. But I see no reason why in future years we should not have our meetings six weeks after each year has expired, and we shall, at all events, do our best to promote that end. I have to apologise for the absence of my good friend, Mr. Campbell, one of the directors, who has been obliged to go to Paris on family matters, and Mr. Morgan is also absent. It is unfortunate that the meetings of the Northern District Telephone Company and of our Company were fixed for the same day. Mr. Morgan has been obliged to go to Sunderland to attend the former meeting, which, I suppose, more required his attendance than our own, and is, so far, complimentary to us.

I hope, gentlemen, you will make every allowance for me, placed, as I was, so suddenly and unexpectedly by the death of Mr. Kendal, in the chair of the Company. You know what an exceedingly difficult man Mr. Kendal was to succeed. He was a man of very great intelligence, wonderful business aptitude, and enormous energy, so far as his health would admit. He also possessed the talent for expressing himself clearly in vigorous and idiomatic English—a qualification in which I much fear your new Chairman is lamentably deficient. We all regret his death exceedingly, and I assure you no one more than I, who am obliged very unworthily to fill his place. I hope you will bear with me while I explain, as far as I can, the position in which the Company is placed, and I trust that you will not institute any invidious comparisons between your two Chairmen, which I know will not redound very much to my advantage.

It is fortunate for me that I have nothing to apologise for or explain away. The success of our Company has been as great as we had any reason to anticipate. Some of our more sanguine share-

Digitized by Google

holders seem to have had visions of a dividend upon the ordinary shares this year, but I think that is extremely unreasonable. They apparently forget that it is the first year of our existence, that we commenced with nothing or next to nothing—with a capital of only £6,433. The figures show that we began with three exchanges, and that we end with 18. We began with 116 exchange subscribers and 123 private lines, and at the end of the year we had 687 exchange subscribers and 248 private lines, and I am happy to say that though, considering our youth, we have attained a pretty fair size, yet like the celebrated Irish giant, we are still growing. Since the close of our financial year our exchange subscribers have reached 820, and our private lines 276, while our new orders for the past three months have been £1,500. I think you will agree with me that we have not been absolutely idle. We have progressed gradually, and we fancy we can discern in the not dim or distant future a dividend on the ordinary shares. We have paid two half-yearly dividends on the preference shares, and have transferred £3,700, the unearned increment of our rentals, to the present year, and we carry forward a balance of £727. These two items are almost 1½ per cent. on the ordinary capital. Of course we could not divide these sums, but they stand to the credit of the Company, and they are a nice little nest egg to begin the new year with.

These results, however, have not been brought about without a great deal of hard work and constant attention. When the reins fell from the dead hand of Mr. Kendal, I was somewhat nervous at taking them up, but it is one of the advantages of a small Board that each and every member is fully aware of all that has been going on, and in our case the transfer of authority was effected without any pause in the business, and without the slightest friction. I say I was somewhat nervous, and hardly think I would have undertaken the office had I not known that I should have the loyal assistance of my good friend Mr. Campbell, who would have made a far better Chairman than I can pretend to be. His other avocations, however, would not admit of this. I knew also that Mr. Morgan, with his extensive experience of telephonic business, was always at my command in case of any serious difficulty, which, however, happily, has not arisen. I may add, too, that our new Director, Mr. Alex. Macgregor, brings an amount of technical knowledge to the service of the Board which is extremely valuable. The short time he has been with us has been long enough to show that he will be a most useful and intelligent member of the Board. I beg also to add a word of thanks to our indefatigable and hard-working secretary (Mr. Robinson). He has all the routine of the business at his fingers' ends, and without his knowledge the Directors would many a time have been very much at a loss. But, gentlemen, there is a great deal of the management of a concern such as ours which only the Chairman or Managing Director can undertake. There is an immense mass of detail which he has to master, and a great variety of minutiæ which he has to get into his head, and which can only be put there and kept there by day-by-day attendance at the office and constant supervision of the work going on. Since I have had charge I have made it my business to be at my post every day. I have hardly been away at all, except when I have been visiting our stations seeing that all was being done there in a satisfactory manner. In all my efforts I have had the countenance and support of the other members of the Board. We all resign our seats to-day in accordance with the Articles of Association. If you see fit to re-elect us, we are willing to continue to do our duty to the shareholders, or if you decide otherwise, we shall hand over our offices to our successors, who will find, I think, the affairs of the Company in perfect working order.

Now, with regard to finance, it was the opinion apparently of our late Chairman that the business of the Company could be satisfactorily carried on with a very small capital indeed. In this the other members of the Board, myself included, rather differed from him, but as he took such an immense interest in the well being of the concern, and held such a large proportion of the ordinary shares, we deferred to his opinion, being pretty well assured that the time would come when he would be compelled by circumstances to alter his views. But we regret to say he did not live to see this time come. Our business has increased so rapidly that it has already absorbed all our originally called-up capital, viz., £6,433, and we have been compelled to borrow £2,000 and to call up 10s. per share on our first issue in order to keep ourselves going. It is somewhat unfortunate, as we now see, that we only issued so small a portion of our preference shares, and it is now our wish to float the balance, say, 13,567 shares, calling up £1 per share in conformity with the original prospectus. Of course you are aware that one ordinary share is by that prospectus attached to each preference share, and the late Mr. Kendal bound himself by a formal agreement to furnish the Company with one ordinary share to be allotted to every person who should subscribe for each preference share. A difficulty, however, has arisen with the representatives of the late Mr. Kendal as to handing over these shares, they contending that they are absolved from this agreement in consequence of the whole of the shares not having been allotted immediately on the issue of the prospectus. I do not think they have a leg to stand on in this contention; but the result is that our way is in a measure stopped, and the extension of our business may be retarded until such time as the matter can come before the legal tribunals, which now cannot be until November. This is very unfortunate; and, unless we make some financial arrangement, I do not see how we can get on. I trust, however, we shall be enabled to do this, as it would be a monstrous pity to have such a very promising business as ours jeopardised. We trust that the Messrs. Kendal will come to a better frame of mind ere long, so as to enable us to offer the preference shares, together with the ordinary share attached, as set out in the prospectus. When the time arrives due notice shall be given. I may add that we have already had application for a large number of our preference shares, which we have been unable to allot for the reasons before stated.

I have now to move that the report and accounts for the fifteen months ending 30th April, 1886, now presented, be adopted and passed.

Mr. A. MACGREGOR seconded the motion.

Mr. TAYLOR observed that the progress to which the Chairman had referred—£1,500 for the past three months—was at the rate of £6,000 a year.

The CHAIRMAN: Yes, but we hope it will be more I do not, however, think that that rate of progress is altogether unsatisfactory.

Mr. PARRISH said that the Company had started in a very fair and prosperous manner, particularly as they are working on comparatively barren ground—that is, ground where there are no large commercial centres, as in Lancashire or in the metropolis. He therefore thought the report and accounts very favourable indeed. As he noted that there was nothing in the accounts to represent the remuneration of the Directors for the past fifteen months, he had great pleasure in proposing that their remuneration should be £250 for that period.

Mr. TAYLOR seconded the motion, which was unanimously passed.

The CHAIRMAN: On behalf of the Board, I beg to thank you for this vote. The amount is more as a recognition of our services than as a reward for our labours. We will hope in future years, when we pay you a dividend on the ordinary shares, you may see fit to review this amount; but we shall do our duty to the Company whatever is voted to us.

Resolutions were afterwards passed re-electing the following gentlemen to their seats at the Board—Messrs. D. O. Bateson, T. F. Campbell, and A. Macgregor,

The CHAIRMAN, in answer to a question, stated that Mr. Morgan was nominated by the United Telephone Company.

Mr. J. WEISE, of the firm of Messrs. Turquand, Youngs, and Co., was re-elected auditor, with a remuneration of 40 guineas.

Mr. GRIFFITHS then proposed a vote of thanks to the Chairman and Directors. He warmly acknowledged the services of the Chairman, whose kind remarks respecting the late Mr. Kendal would be appreciated by the deceased gentleman's relatives, whom he (Mr. Griffiths) was representing at the meeting.

The motion was carried unanimously.

The CHAIRMAN having briefly acknowledged the compliment, the proceedings terminated.

NOTES.

NIAGARA FALLS INSTALLATION.—The Niagara Falls are now furnishing power for about 100 arc lights. The number will shortly be largely increased.

THE VAN RYSSELBERGHE SYSTEM.—It is announced that the employment of the Van Rysselberghe system is to be still further extended in Germany.

DOMFRONT.—The town of Domfront is shortly to be the scene of a magnificent *fête*, on the occasion of the introduction of a permanent street lighting installation by electric light.

THE BELL TELEPHONE COMPANY.—This company has entered two more actions for infringement; one against the "Cushman" Company, the other against the "Inter-State" Telephone Company.

AMERICAN ELECTRICIANS.—The National Electric Light Association of America will hold its next meeting at Detroit, at the end of the present month. Some very interesting papers are expected to be forthcoming.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th Aug. are £1,669, as compared with £2,191 in the corresponding period of 1885.

EDINBURGH TELEPHONE EXCHANGE.—We have received a copy of the Edinburgh Telephone Exchange list of subscribers; the total number of connections is now about 500. We notice that the number of subscribers to the Glasgow trunk line remains very small.

CELLULOSE.—The usual solvent employed in the treatment of cellulose is an ammoniacal solution of sulphate of copper. It is now stated that when cellulose is employed for the filaments of incandescent lamps it is preferable to employ as a solvent a neutral solution of zinc chloride.

JUMPING TO A CONCLUSION.—On the basis of a note which we recently published as to the lighting of a church in Durham, we are informed by a French contemporary that "electric lighting is making *très grande progrès* in the churches of England." We wish that this were a little nearer the truth.

MONTREAL.—The gas company in this city refuses to make way for the electric light. The main thoroughfares are now illuminated by both arc lamps and gas; but the municipality refuses to pay for the latter, which was ordered to be discontinued some time since. The gas company has therefore commenced a law-suit against the corporation.

THE EDISON-SWAN COMPANY.—The *employés* of the Edison-Swan Company had their annual excursion on Saturday last. The company proceeded by an early train to Dover, where a very pleasant day was spent, substantial fare being provided at the Royal Oak Hotel. The weather being favourable the outing was much enjoyed by all who took part in it.

COREA.—The King of Corea is an enlightened monarch. He not only takes an interest in the progress of physical science, but his æsthetic taste is also highly cultivated. He has recently ordered from the Edison Company of New York an incandescent plant, including a very beautiful vase of Bohemian glass filled with artificial flowers and illuminated by a number of small lamps.

ANOTHER CITY INSTALLATION.—We are informed that an office in No. 16, Austin Friars has been for the last fortnight lighted by means of six Edison-Swan lamps of 20, 10, and 5 candle-power. The current is furnished from a Regent primary battery. The installation was carried out by Messrs. Swete and Main, 11, Queen Victoria-street, City, and has so far given entire satisfaction.

SOME NEW INSTALLATIONS.—We understand that Messrs. Faraday and Son, of Berners-street, have lately furnished the designs and fittings for the following amongst other recent installations:—At the residence of Sir Arthur Sullivan; at a chateau in Belgium; for a new theatre at Algiers; for extension of existing installations at Messrs. Shoolbred and Co.'s; and at the British Museum.

PHILADELPHIA. — Wherever the electric light is most familiarly known it may safely be said that it is there most highly appreciated. An illustration of this fact comes from Philadelphia, where the inhabitants of Susquehana Avenue have petitioned the municipality to supply them with arc lights, and have volunteered to pay the first cost of the installation if the maintenance is thrown upon the rates.

A HIGHLY REMARKABLE RESULT.—One of our French contemporaries, whose name we forbear to mention, in the course of an elaborate article upon a new form of a very old battery, states that "the great advantage possessed by the cell is that by suitably varying its shape and size the strength of the current can also be varied at will." We trust that the inventor will not succeed in obtaining a patent for this "peculiarity."

TEMESVAR.—It will be remembered that the town of Temesvar in Hungary was provided rather more than twelve months ago with a very large installation consisting of glow lamps arranged in multiple series and supplied by high tension machines driven by water-power. Since then, although the light has been in successful operation, the total consumption of gas has undergone no diminution—a striking result which is, however, the rule rather than the exception.

MAGNETIC FORCE LINES.—A bowl is filled with water and lycopodium strewn on its surface, the superfluous powder being afterwards blown away. The bowl is then placed in the spot whose magnetic field it is wished to investigate, for example, at the pole of a magnet. Very fine iron powder is then allowed to fall into the bowl from some height. On slightly shaking, the forms of the force lines form on the surface of the water by means of the iron powder borne by the lycopodium.

POLICE TELEPHONE SERVICE.—In Brooklyn, Chicago, and some other American towns there is now being introduced a system of street telegraph and telephones for the use of the police. The instruments are erected in suitable iron boxes placed at convenient intervals, and each policeman possesses a key. The telephone is in direct communication with the nearest police station, and there are also special signals provided for summoning assistance in cases of riot, accidents, fires, &c.

ELECTRIC LIGHT AT TEHERAN.—Mr. Stevens, the bicyclist, who is attempting to ride round the world, has written to a contemporary from Teheran giving an amusing account of the effect produced upon the native mind by the arc lights which the Shah has recently had placed in the square of the palace. It is the lighting up that astounds them most of all. The general conclusion is that nothing but the direct instrumentality of Sheitan could produce an instantaneous illumination of such dazzling brightness.

VULCANISED FIBRE.—Vulcanised fibre is pure cellulose freed from all elements which are soluble in ordinary solvents, and from all volatile matters which are capable of ignition. It is absolutely uninflammable, and is not attacked by oils, benzine, fatty acids, alcohol, &c. Vulcanised fibre is made out of finely ground wood pulp, which is sub-

Digitized by Google

jected in a closed vessel to a pressure of from 350 to 500 atmospheres, the lower pressure being employed in the manufacture of flexible, and the higher pressure in that of hard fibre.

THE PRESERVATION OF TELEGRAPH POLES.—It is stated that in Government contracts the only timber now employed for telegraph poles is the Baltic red-wood, well seasoned and then creosoted. To obtain the specified quantity of 10lb. of creosote injected per square foot the fine skin which grows underneath the bark must be carefully removed by planing. The processes which require the employment of salts of zinc, copper, or mercury have fallen into disuse, mainly on account of the solubility of these salts, and also owing to the rapid corrosion which they caused in the reservoir and apparatus used for injection.

DOMESTIC LIGHTING.—"Impney House," the residence of Mr. John Corbett, M.P., has recently been fitted with the incandescent light. Motive power is obtained from a turbine supplied with water from the River Salwarte under a fall of only 13ft. The machines are situated at a distance of about 250 yards from the house. Accumulators are employed, so that the current is always available. Full advantage has been taken of the æsthetic and artistic possibilities of the glow light, and some very fine specimens of venetian glass chandeliers are placed in the dining room, drawing room, and conservatories. The work has been carried out by Messrs. Nicholson and Jennings, of 759, Old Kent-road.

MEDICAL ELECTRICAL APPLIANCES.—At the meeting of the British Medical Association, held last week at Brighton, the "Electric Apparatus Company" displayed in the museum section an attractive exhibit of instruments showing the application of electricity to medicine and surgery. Among the apparatus which attracted most attention was an electric opthalmoscope, which is used for examining the eye by the aid of a small glow lamp, and is supplied with current from a specially designed "Victoria" battery. Several eye specialists spoke in praise of the arrangement. The company also exhibited a collection of "photophores," bullseye and head lamps, an electric cautery, together with induction coils and constant batteries.

TELEPHONES IN FRANCE.—The *Bulletin du Crédit* commits itself to the opinion that the greatest success of the scientific year is the domestic telephone, introduced by the Société Générale des Téléphones, under the name of "Téléphones et Microphones Domestiques Indéréglables." These telephones, we are informed, are now much used in place of the acoustic speaking tubes. From the *Paris Bourse* we learn that the Société Générale des Téléphones reports a considerable increase in the number of subscribers as compared with this time last year. On the 10th inst. the number of subscribers in Paris was 4,443, and in the Departments 2,199, making together 6,642, as compared with an aggregate of 5,834 on the corresponding date of 1885.

A SERIOUS BLUNDER.—The arrangements for giving an alarm of fire in the large towns of America, and for despatching the fire brigade with the utmost promptitude by the aid of various electrical contrivances, are usually supposed to have reached an almost phenomenal degree of perfection. At Boston, however, there has recently been afforded a melancholy illustration of the ease with which the most elaborate precautions may be frustrated by a little carelessness or stupidity. A fire having broken out in a large factory, the alarm was promptly signalled to the fire stations. Numerous engines and escapes immediately set out for the opposite end of the city, and in the meantime an unfortunate human being, who had climbed upon the roof of the factory, fell a victim to the flames. On an investigation it turned out that two distinct annunciators had each been labelled with the same number.

LIGHTING OF HARROGATE HYDROPATHIC ESTABLISHMENT. Harrogate is one of the very few towns where a certain local distrust of the electric light has lingered, owing to recollections connected with an installation of some years ago which was not altogether a success. Electric lighting has now got well beyond the stage where there can be any possible question whether a simple house lighting installation is or is not to be a success—at least, when the work is undertaken by properly qualified men. The Harrogate Hydropathic Establishment is now lit by incandescent light. The work has been carried out by the firm of Thompson, Dowsing, and Rew, and has given perfect satisfaction. The only special features of the installation are the ceiling plate holders, which are of novel design, and the special switches which have been introduced by the above firm, and which we described some time since.

THE TELEPHONE IN SUNDERLAND.—It appears, from what has fallen from Mr. T. Wilkinson, the chairman of the Telephone Company, that the extension of the system, which was at the outset of the operations of the company slow and tentative, has now become rapid and permanent. Within the last year trunk lines have been run from Newcastle to North and South Shields, and, in fact, the whole of Tyneside is now in communication with Sunderland, the Hartlepools, Stockton, Middlesbrough, and Darlington. It is easy to imagine the convenience this must be to business men, who at so small a cost are able to hold conversation with one another over such distances. In a three minutes' "talk" as much can be done as by a dozen telegrams, and, what is still more satisfactory, it is effected in a clear and rapid manner. The payment of a six per cent. dividend must be as gratifying to the shareholders as to the board of directors.

THE HOTEL DE VILLE, PARIS.—The Fine Arts Committee of the Municipality of Paris have just made a report with regard to the arrangements they recommend for providing the electric light at the Hotel de Ville. About 2,000 lamps are to be installed. The engine power at present provided only amounts to 130 horse-power, and this will be sufficient to do the work upon ordinary occasions. It is therefore proposed to provide dynamo machinery capable of supplying the whole of the lamps, and when on any special *fête* or reception they are all required at once it is arranged to obtain the additional power from one or more portable engines brought in for the occasion. For some reason not given, the Grande Salle Saint-Jeane is not included in this arrangement, but will continue to be lit with gas. In the interests of electric lighting nothing could be better devised than the contrast which will thus be afforded on the occasion of a "crush."

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—The thirty-fifth meeting of the American Association for the Advancement of Science is now being held at Buffalo, New York, and will continue until Tuesday evening next. This is the third time that the Association has accepted an invitation to hold a meeting in Buffalo, the previous occasions having been at intervals of ten years. The city offers such excellent facilities for a gathering of this kind, both in its spacious auditoriums and hotels and its general accessibility from either the east or the west, that it has grown to be a favourite locality with the members, and a large assemblage has been assured. Special attention will be given by the section on geology and geography to the problems connected with Niagara Falls and its gorge. The retiring president, Prof. H. A. Newton, of New Haven, will deliver his address on the

Digitized by Google

first evening of the meeting. The president is Prof. E. S. Morse, of Salem, Mass.

TURNBULL'S TELEPHONE TRANSMITTER.—This transmitter is now attracting some attention in the United States. It is put forward as being equally well adapted for short or long distance telephony, and that for the latter purpose it may be worked wi h a more powerful current, and will therefore speak more distinctly, than any other instrument at present in the field. The construction is sufficiently simple. A number of carbon rods of square section have a circular hole bored through them near one end. They are then strung upon a round carbon rod, which is placed at the back of the diaphragm so that the top ends of the square blocks stand in a row across its central part, where the amplitude of vibration of the diaphragm is greatest. The lower ends of the blocks of square section rest loosely upon a second round rod of carbon. The instrument is therefore merely a multiple microphone, but the construction certainly seems to be well adapted for use with comparatively large currents as claimed.

THE TELEPHONE IN ITALY.—The Commission nominated by the Italian Government to inquire into the question of telephonic communication has addressed the following circular to the Chambers of Commerce, the municipalities, and the proprietors of the telephone lines already in operation:—"The Minister of Commerce has nominated a Commission authorised to inquire into the telephonic service, and the relation of this service to other public departments, and especially to the telegraphs, and also to propose such legislative, administrative, and judicial precautions as may be necessary for the definite regulation of all future concessions for the establishment of telephonic communication. In order to render the work of the commission the more complete, you are requested to be good enough to inform us what are the principal difficulties which have arisen in connection with the telephonic services already established, and what steps you would propose to take in order to safe-guard the interests of the State, municipalities, the general public, and the proprietors of the system."

OZONE BY ELECTROLYSIS.—Prof. H. M'Leod has recently brought before the Chemical Society some results which he has obtained in a series of experiments upon the electrolysis of aqueous solutions of sulphuric acid. These experiments were undertaken in order to determine the quantity of ozone which can be obtained by electrolysis. The positive electrode consisted of a tube containing mercury, with several fine platinum wires of 0·45mm. diameter fused into the glass. The negative electrode consisted of a small plate of platinum. The electrolysis was carried out in a U-tube, surrounded by ice and water; the hydrogen was collected over water, and the ozonised oxygen passed through a tube containing a solution of potassic iodide, by which the ozone was absorbed. The quantity of ozone was determined by acidifying the potassic iodide solution and decolorising by a solution of thio-sulphate. It was found that the maximum quantity of ozone was obtained with solutions about 1·075 or 1·1 in density, the electrolytic oxygen then containing about 16 or 17 per cent. of its weight of ozone.

THE LIGHTNING CONDUCTOR IN ACTION.—The *St. James's Gazette* says:—"On the 27th of July a party of engineers and workmen had an excellent opportunity of observing the way in which a thunder-cloud discharges its electricity. They had just completed the fitting of a lightning conductor at the shelter hut on the Mythen, in Schwyz. A heavy storm was seen approaching from three different points, and they took refuge in the hut. Through a hole in the wall they could see the conductor. From time to time small bluish flames appeared hovering on it; then the lightning flash would be seen descending along the conductor into the earth, followed almost instantaneously by the thunder crash. More than twenty times they watched the phenomena regularly succeeding each other; then there was an electrical discharge of such violence that there seemed to be a recoil, and two of the party felt the shock from below up to their hips, and one fancied that both his legs were shot off. The men were so terrified that they quitted the hut and descended the mountain amid blinding snow, as well as thunder and lightning."

ADVANCEMENT IN ELECTRICITY AND PHOTOGRAPHY.—The following story has been going the round of the Press:—"A wealthy ironmaster in the North of England, whose house and works are dazzlingly illuminated by the electric light, has adopted an ingenious contrivance, by which he may glean some information as to what goes on during his not unfrequent absences from home. In several of his rooms, and in his offices, there is a concealed apparatus in the walls, consisting of a roll of Eastman paper and a train of clockwork. Every hour a shutter is silently opened by the machinery, and an instantaneous photograph is taken of all that is going on in the room. On the great man's return, he delights to develop these pictures, and it is said that they have furnished some very strange information indeed. One clerk, who received his dismissal somewhat unexpectedly, and boldly wanted to know the reason why, was horrified when shown a photograph, in which he was depicted lolling in an easy chair, with his feet upon the office desk, while the clock on the mantelpiece pointed to an hour at which he ought to have been at his busiest. The servants' party in the dining room furnished another thrilling scene!"

ELECTRIC LIGHTING BYE-LAWS IN FRANCE.—The conditions under which an authorisation has recently been granted for the establishment of a central lighting station and the laying of underground conductors in the town of St. Etienne are of a somewhat rigorous character. The articles of the agreement are two in number. The first stipulates the time within which the work is to be completed, and the second simply asserts that the Commissioners may at any time and (practically) for any reason whatever, withdraw the authorisation. They are determined that there shall be no monopoly of supply at St. Etienne. In other parts of the country they are less cautious in this matter; in fact, to sign a contract for the supply of electricity *at a fixed price* for the next *fifty years* is decidedly a rash proceeding on the part of the consumer. Yet this has just been done at Espalion, where (if we may rely upon a recent statement) a local company has undertaken to furnish electricity under the condition of an exclusive monopoly for the above period. The price mentioned is 1,500 francs per annum, for 45 lamps of 10 candles, burning from dusk to dawn all the year round. The effect of a 10 candle-power lamp for street illumination will scarcely be brilliant. In fact, all the figures are so strange than we are disposed to doubt the accuracy of our information.

GLOBULAR "LIGHTNING."—A very detailed account of a discharge of globular lightning comes from Pera. During a violent storm a family seated at dinner saw a "globe of fire the size of a small apple," which entered the open window, sailed slowly across the room, passed between two persons without touching either, and leaving the room by the way which it entered, fell into the street with a tremendous detonation, but without inflicting any injury or damage. Many years ago the writer of this note himself witnessed an almost precisely similar phenomenon, and although only seven years old at the time he has a most vivid recollection of

Digitized by Google

the circumstances. A tremendous storm was raging; suddenly, but quite noiselessly, there issued *from the fireplace* a dark red ball, fully 12in. in diameter. It moved slowly and erratically about the room, passing close beside him more than once. The writer well remembers his grandmother taking him by the sleeve and drawing him aside to let it pass. Perhaps the most remarkable thing in this case was that it also retired by the way it had come—that is, *up the chimney.* Shortly afterwards we heard that our neighbour's house had been set on fire by lightning. It seems reasonable to suppose that the appearance may owe its origin to a drop of water in a highly electrified condition. If so, it is scarcely correct to classify the phenomena as lightning; we had better, perhaps, go back to the old word "thunderbolt."

Electrical Train-Lighting on the Glasgow Underground Railway.—The *Scotsman* says: For some time back there has been a good deal of grumbling among the passengers on this line owing to the carriages not being lighted in passing through the tunnels. Several schemes for lighting the carriages by gas and electricity have been submitted to the North British Railway Company, and on Monday the directors and Mr. Walker, general manager, made trial of a carriage fitted with the electric light in the tunnel between Queen-street and College Stations. There was a sixteen candle-power incandescent lamp in each compartment, and by the system tried the lamps light themselves on entering the tunnel, and go out on leaving it. It is proposed to use the electric light in the tunnels during the day time only, and for this purpose the ordinary gas or oil fittings have not been interfered with, so that they can be used at night. We understand the company intend lighting the trains between College and Charing Cross Stations in the meantime, which should be of great benefit to the public, as at present the carriages are dark at some of the stations too. At the trial the lighting was very successful, both when the train was running at full speed and also when standing in the tunnel, while the light was quite as good as gas, and the cost, it is understood, is considerably less. The carriage was fitted up at the Cowlairs Works, and the trial carried out by the railway company themselves. Mr. H. S. P. Carswell, one of the assistant engineers, is the patentee.

A Novel American Installation.—The American confraternity of engineers and electricians are bent on maintaining their reputation for being first in the field when any new line is to be "prospected." For some months past, as we have already taken occasion to mention, the electric lighting station at Lowell, Mass., has been "operated" by an engine deriving its energy from the expansion of bisulphide of carbon vapour. Another American installation possessing points of novelty is now at work at "Cottage City." This consists of a plant which provides both heat and light to the whole town. The lighting is attended to by several of those heterodox machines, the Ball "unipolar" dynamo. It is a decidedly perplexing fact that these machines should continue to find favour in the States, but in this case, as well as in several others of which we have recently heard, their performance is spoken of in terms of satisfaction. However this may be, it is not so much the dynamo machinery which is the strong point of the Cottage City installation. Its distinction lies in the method of utilising the boilers for the double purpose of supplying steam for driving the engines, and also for the manufacture of "water gas" by which the town is provided with all the heat which is required. It is not our intention to go into details as to the methods adopted, although these are of considerable interest on their own account. With a plant of this description the boilers may be profitably employed in continuous working, and it seems not unlikely that under certain conditions the system would find a successful application in this country.

New Cable Proposals.—We take the following extract from the *Sydney Daily Telegraph* for July 3rd:—"The Minister for Education has received a cablegram from Mr. John Pender, chairman of the Eastern Extension Telegraph Company, making proposals on an entirely new basis. They read as follows:—'The proposals for extending the cable subsidy having been declined, the company, as further evidence of their desire to meet the colonies' wishes, and in response to a frequently-expressed opinion that a large reduction of the tariff would result in a large growth of traffic, submit the following proposition for your consideration—namely, the company would be prepared to lower the tariff between Europe and Port Darwin to any figure the colonies might fix down to the limit of out payment on consideration of the colonies guaranteeing the average receipts over the cables for the last three years. If the guarantee extended to the Eastern Company and their partners, the amount the colonies would have to make up at a 5s. tariff—if no increase took place—would be about £107,000; with an increase of 25 per cent., £89,000; 50 per cent., £70,000; 75 per cent., £51,000; 100 per cent., £32,000. At a 4s. tariff without increase, £119,000; with increase 25 per cent., £103,000; 50 per cent., £87,000; 75 per cent., £71,000; 100 per cent., £55,000. The above figures are based on the assumption that South Australia would reduce her transit to 10d. and 5d. per word respectively. This would be a fair way of testing the effects of the cheap tariff, and might be tried as an experiment for five or ten years, at the end of which period, if the results were not considered satisfactory, either party would be at liberty to revert to the existing arrangement. I believe the guarantee principle would prove the best solution for the colonies, as it would give them full control over the tariff and enable them greatly to benefit the telegraphing public.' These proposals are altogether apart from the reductions which came into effect on July 1, and they are now being considered."

An Abstract on Chemical Behaviour of Iron in the Magnetic Field.—E. L. Nichols, in the *Journal* of the Chemical Society, describes a set of experiments with aqua regia, nitric acid, hydrochloric acid, and sulphuric acid, to illustrate the phenomenon that when finely-divided iron is placed in a magnetic field of considerable intensity and exposed to the action of the acid, the chemical reaction differs in several respects from that which occurs under ordinary circumstances. With aqua regia, it was found that the speed of reaction is greater in the magnetic field than without, and that the heat of chemical union is much greater. The production of nitrous fumes under the influence of the magnet, and the yellow colour of the resulting solution, show that the reaction was modified in chemical character. With nitric acid, the effect of the magnet was to greatly increase the speed, reducing the average time from eight minutes to less than one minute. Red fumes always resulted from the action within the field. With hydrochloric acid, the rise of temperature was much smaller than in the experiments with aqua regia and nitric acid; the speed of reaction within the magnetic field differed very little from that occurring under ordinary circumstances; and the character of the reaction in the two cases was almost identical. The rise of temperature under the influence of the magnet, however, was found to be slightly in excess of that produced when the magnet was not in action. With sulphuric acid the reaction was uniform and complete, and apparently of the same chemical character within and without the fluid

Digitized by Google

The magnet was found, however, to increase the speed of reaction, and to decrease the amount of heat produced. A series of measurements was made with nitric acid, in which powdered copper was substituted for iron. The reaction in the field was found to be identical with that which occurred when the magnet was not in action. The results arrived at by the author are shown in a series of curves; the ordinates denoting temperature in degrees centigrade, and the abscissæ time in minutes. The experiments are preliminary to a more complete investigation of the novel series of effects developed.

THE UTILISATION OF NATURAL FORCES.—Under this heading the *Bulletin International de L'Electricité* has the following observations, which seem to us to be of a very sensible character :—"If there is any country upon the face of the earth where the forces of nature are most abundantly placed at the disposal of man, surely it is the northern region of the United States. Not only do we here find numberless rivers and streams, but their flow is beneficently regulated by numerous lakes which play the part of so many natural reservoirs. Here, then, above all other places, should we expect to find a field for the employment of electricity in the transmission of power to the centres of industry, and if the schemes of M. Marcel Deprez offered such industrial advantages as are claimed, they should long since have been put into practice in this region. Yet up to the present nothing has been done. The American engineers have preferred to utilise these natural forces upon the spot where they are to be found, and for ourselves we do not believe that they have been wrong in so doing. They are a set of men too well informed, and too expert to neglect an industrial development of this character if it in reality possessed a definite value. The River Blackstone, for instance, passes through the State of Massachusetts, and drives more than 60 mills; the River Merrimac, of which the mean fall is about 0·75m. per kilometre, furnishes motive force to the towns of Laconia, Tilton, Hooksett, Manchester, Lowell, and Lawrence; the rapids in the State of Maine, which fall 1·50m. to 1·75m. per kilometre in some parts of their course, are made to do mechanical work upon their banks; but no one in America has ever dreamt of attempting to transmit their energy to a distance of 50 or 60 kilometres. Can it be otherwise in France? We believe not. We believe that the utilisation of the forces of nature in the particular manner which at present so much engrosses the attention of the daily journals will always remain a scientific possibility rather than an industrial process. The transmission of power by electricity for shorter distances rests altogether upon a different footing, and we believe that this application will before long become of the utmost importance and receive great and continuous development."

GAS V. ELECTRICITY.—Mr. H. G. Massingham has written the following interesting letter to the *Taunton Courier*:—"Dear Sir: In a leading article on the annual meeting of the Taunton Gas Company you say 'Both the general public and the shareholders in the Taunton Gas Company must feel some considerable amount of pleasure in the roseate state of affairs which Dr. Kelly was enabled to present at the recent annual meeting.' As one of the 'general public' it certainly did afford me considerable pleasure to read your congratulatory article. It is now nearly twelve months since I first suggested the desirability of introducing the electric light into Taunton, owing to the numerous complaints of the insufficient lighting of the town, and I at once met the very natural fears of the gas shareholders by stating it would create a demand for more light, and tend to increase rather than decrease the consumption of gas. In addition to which, gas would in the future be more used for cooking, heating, &c., for which it is better adapted than for lighting purposes. I am pleased, therefore, to see that my prediction has been more than realised. I can add my testimony to the great convenience of gas cooking stoves, and also the undoubted economy of using these during the summer months, when fires are not required. I feel the more pleasure in doing this owing to the fact that some of the gentlemen connected with the local gas company cannot forgive me for introducing the electric light into Taunton, but I hope that before long they will realise that while I have tried to benefit the town I have in no way injured their particular interests. Unlike the gas shareholders, I cannot congratulate myself upon any return for my capital, but I have the satisfaction of knowing that I am doing a useful work, and I am pleased to say that were I not giving away the light from the seven parade lamps (which will cease in December) I should be covering all expenses, which is highly satisfactory to me, as I purposely decided to supply the light at the cost of production, directly the local syndicate declined the risk, and I undertook the sole responsibility. Had a local company been formed, as they would have been receiving 10 per cent. more than I am charging, they would have paid a dividend of from 6 to 8 per cent. by the end of the first year."

THE ELECTROLYTIC SEPARATION OF FLUORINE.—The element known as fluorine is chiefly remarkable from the fact that it is the only known element which forms no compound with oxygen. It has an intense affinity for hydrogen, and is extremely difficult to obtain in a separate condition. This difficulty arises in part from the fact that fluorine in the presence of moisture strongly attacks silica; hence it is impossible to treat it in glass or porcelain vessels. The French chemists, Knox and Lonyet, acting upon a suggestion originally due to Sir Humphrey Davy, attempted to prepare this element by treating argentic fluoride with chlorine in a vessel constructed of fluor spar. The experiment did not, however, lead to any very definite results. Since them M. Fremy, by means of the action of dry iodine upon dry silver fluoride, obtained a colourless gas which did not attack glass. Recent researches undertaken by M. Moissau have, however, thrown some slight doubt upon the question whether the gas so obtained is actually free fluorine. M. Moissau having prepared anydrous hydrofluoric acid (HF) by a method due to M. Fremy, submitted it to electrolysis in a platinum U tube under the action of 50 Bunsen elements. Hydrogen was given off at the negative pole, and at the positive pole a gas was obtained which had the following characteristics:—In the presence of mercury it was rapidly absorbed with the formation of proto-fluoride of mercury of a clear yellow colour. In contact with water the latter was decomposed with the formation of ozone. Phosphorous was inflamed with the formation of two fluorides of phosphorous, sulphur was melted with rapidity, carbon seemed to be unaffected, melted potassic chloride cools with disengagement of chlorine; and, lastly, crystallised silicon takes fire and burns with great brilliancy upon contact with the gas, forming silicic fluoride. The platinum iridium electrode forming the positive pole was much corroded, the negative electrode was not attacked. M. Moissau prefers for the present to reserve his opinion as to the exact nature of the gas he has obtained, pointing out that although the most obvious supposition would be that it consists of pure fluorine, yet at present the evidence is not conclusive. It may, for instance, turn out to be a perfluoride of hydrogen, or some mixture of ozone and hydrofluoric acid. It will be noted that the gas differs from that previously taken for fluorine in its action upon silicon.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XXXI.

BY OLIVER HEAVISIDE.

(Continued from page 253.)

The Influence of Electrostatic Capacity.—Impedance Formulæ.

Let us now return to the more general case of section XXIX., the amplitude of the current due to a simple harmonic impressed force at one end of a line. Although the formula (41*b*) for the amplitude at the distant end is very compact, yet the exponential form of the functions does not allow us to readily perceive the nature of the change made by lengthening the line, or making any other alteration that will cause the effect of the electrostatic charge to be no longer negligible, by causing the electromagnetic formula to be sensibly departed from. Let us, therefore, put (41*b*) in the form $V_0/C_0 = \&c.$, and then expand the right member in an infinite series of which the first term shall be the electromagnetic impedance itself, whilst the others depend on the electrostatic capacity as well as on the resistance and inductance.

On expanding the exponentials and the cosine in (41*b*), we obtain a series in which the quantities $P^4 - Q^4$, $P^6 - Q^6$, &c., occur, all divided by $P^2 + Q^2$.

To put these in terms of the resistance, &c., we have, by (37*b*),

$$P^2 + Q^2 = SnI, \quad 2PQ = SnR', \quad Q^2 - P^2 = Sn^2L', \quad . \quad (58b)$$

where

$$I = (R'^2 + L'^2n^2)^{\frac{1}{2}}, \quad . \quad . \quad . \quad . \quad . \quad (59b)$$

I being the short-line impedance per unit length. Using these, we convert (41*b*) to the following form,

$$V_0/C_0 = Il\left[1 - \frac{l^2}{3}Sn^2L' + \frac{2l^4}{45}(Sn)^2(\tfrac{1}{4}R'^2 + L'^2n^2) - \ . \ . \ .\right]^{\frac{1}{2}} \quad (60b)$$

Here we may repeat that V_0 and C_0 are the amplitudes of the impressed force at one end and of the current in the wire at the other end of the double wire of length l, whose "constants" are R', L' and S, the resistance, inductance, and electrostatic capacity per unit length, R' and L' being functions of the frequency already given. I do not give more terms than are above expressed, owing to the complexity of the coefficients of the subsequent powers of S. To go further, it will be desirable to modify the notation, and also to entirely separate the terms depending upon resistance in the [ ] from the others. Let

$$SL' = v^{-2}, \qquad f = (R'/L'n)^2, \qquad h = nl/v. \quad . \quad (61b)$$

Here v is a velocity, f and h numerics. The least value of the velocity is $(SL)^{-\frac{1}{2}}$, at zero frequency, L being the full steady-flow inductance per unit length, as before. As the frequency increases, so does v. Its limiting value is $(SL_0)^{-\frac{1}{2}}$ or $(\mu_2\epsilon_2)^{-\frac{1}{2}}$, the speed of undissipated waves through the dielectric. The ratio f falls from infinity at zero frequency, to zero at infinite frequency. See equations (43*b*) to (46*b*). The ratio h is such that $h/2\pi$ is the ratio of the time a wave travelling at speed v takes to traverse the line, to the wave period.

In terms of I, f, and h, our formula (41*b*), or rather (60*b*), when extended, becomes

$$V_0/C_0 = Il\left[\left(\frac{\sin h}{h}\right)^2 + \frac{fh^4}{90}\left\{1 - \frac{1}{7}h^2 + \frac{1}{105}h^4\left(1 + \frac{1}{12}f\right)\right.\right.$$
$$\left.\left. - \frac{4}{105.99}h^6\left(1 + \frac{3}{16}f\right) + \frac{10}{105.99.91}h^8\left(1 + \frac{3}{10}f + \frac{1}{80}f^2\right) - \ . \ . \ .\right\}\right]^{\frac{1}{2}} \quad . \quad . \quad . \quad (62b)$$

From this, seeing that in the [ ] resistance appears in f only, we see that the corresponding no-resistance formula is simply

$$V_0/C_0 = Il\frac{\sin h}{h} = L_0v\sin\frac{nl}{v}, \quad . \quad . \quad . \quad (63b)$$

where, of course, v is the speed corresponding to L_0, or the speed of undissipated waves. The sine must be reckoned positive always. To check (63*b*) derive it immediately from (41*b*) by taking R = 0. We shall find the following form of (41*b*) in terms of f and h useful later.

$$V_0/C_0 = \tfrac{1}{2}L'v(1+f)^{\frac{1}{4}}\{\epsilon^{2Pl} + \epsilon^{-2Pl} - 2\cos 2Ql\}^{\frac{1}{2}}, \quad . \quad . \quad (64b)$$

where

$$\left.\begin{aligned} Pl &= h(\tfrac{1}{2})^{\frac{1}{2}}\{(1+f)^{\frac{1}{2}} - 1\}^{\frac{1}{2}} \\ Ql &= h(\tfrac{1}{2})^{\frac{1}{2}}\{(1+f)^{\frac{1}{2}} + 1\}^{\frac{1}{2}} \end{aligned}\right\} \quad . \quad . \quad . \quad (65b)$$

Let us now dig something out of the above formulæ. This arithmetical digging is dreadful work, only suited for very robust intellects. I shall therefore be glad to receive any corrections the following may require, if they are of any importance.

It will be as well to commence with the unreal, but easily imaginable case of no resistance. Let the wire and return be of infinite conductivity. We have then merely wave propagation through the dielectric, without any dissipation of energy, at the wave speed $v = (\mu_2\epsilon_2)^{-\frac{1}{2}}$, which is, in air, that of light waves. Any disturbances originating at one end travel unchanged in form; but owing to reflection at the other end, and then again at the first end, and the consequent coexistence of oppositely travelling waves, the result is rather complex in general. Now, if we introduce a simple harmonic impressed force at one end, and adjust its frequency until the wave period is nearly equal to the time taken by a wave to travel to the other end and back again at the speed v, it is clear that the amplitude of the disturbance will be enormously augmented by the to and fro reflections nearly timing with the impressed force. This will explain (63*b*), according to which the distant-end impedance falls to zero when

$$nl/v = \pi, \quad \text{or } 2\pi, \quad \text{or } 3\pi, \quad \&c.;$$

here $2\pi/n$ is the wave period, and $2l/v$ the time of a to-and-fro journey. The current amplitude goes up to infinity.

If, next, we introduce only a very small amount of resistance, we may easily conclude that, although the impedance can never fall to zero, yet, at particular frequencies, it will fall to a minimum, and, at others, go up to a maximum; and that the range between the consecutive maximum and minimum impedance will be very large, if only the resistance be low enough.

Increasing the resistance will tend to reduce the range between the maximum and minimum, but cannot altogether obliterate the fluctuations in the value of the impedance as the frequency continuously increases. In practical cases, starting from frequency zero, and raising it continuously, the impedance, which is simply Rl, the resistance of the line, in the first place, rises to a maximum, then falls to a minimum, then rises to a second maximum greater than the first, and falls to a second minimum greater than the first, and so on, there being a regular increase in the impedance on the whole, if we disregard the fluctuations, whilst the fluctuations themselves get smaller and smaller, so that the real maxima and minima ultimately become false, or only tendencies towards maxima and minima at certain frequencies.

By this to-and-fro reflection, or electrical reverberation or resonance, the amplitude of the received current may be made far greater than the strength of the steady-flow current from the same impressed force, even when the electrical data are not remote from, but coincide with, or resemble, what may occur in practice. To show this, let us work out some results numerically.

As this matter has no particular concern with variations of current density in the conductors, ignore them altogether; or, what comes to the same thing, let the conductors be sheets, so that R' = R, the steady flow value, and $L' = L_0$ very nearly, the dielectric inductance, both per unit length. Then, in (64*b*), let

$$f = 1, \qquad Ql = \pi, \qquad v = 30 \text{ ohms}. \quad . \quad . \quad . \quad (66b)$$

Then, by the second of (65*b*), we find that

$$h = 2{\cdot}85;$$

and, by (64*b*), that

$$V_0/C_0 = \tfrac{1}{2}L_0v.2^{\frac{1}{4}}[\epsilon^{-8284\pi} + \epsilon^{-8284\pi} - 2]^{\frac{1}{2}}$$
$$= 60{\cdot}6L_0 \text{ ohms}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (67b)$$

The ratio of the distant-end impedance to the resistance is therefore

$$\frac{60{\cdot}6 \times 10^9L_0}{Rl} = \frac{60{\cdot}6 \times 10^9}{nl} = \frac{20{\cdot}2}{10h} = \frac{202}{285} \quad . \quad (68b)$$

Digitized by Google

by making use of the data (66*b*). That is, the amplitude of the received current is 42 per cent. greater than the steady flow current, when (66*b*) is enforced.

But let $Ql = \frac{1}{4}\pi$, then

$$V_0/C_0 = \tfrac{1}{2} L_0 v . 2^{\frac{1}{2}} [\epsilon^{\cdot 2071\pi} + \epsilon^{-\cdot 2071\pi}]^{\frac{1}{2}}$$
$$= 28 L_0 \text{ ohms};$$

and the ratio of impedance to resistance is

$$\frac{28}{60 \cdot 6} \times \frac{202}{285} \times 4 = \frac{4}{3} \text{ nearly,}$$

or the amplitude of current is only 3/4 of the steady flow current.

And if $Ql = \frac{1}{2}\pi$, we shall find

$$V_0/C_0 = 43 \cdot 5 \text{ ohms,}$$

and that the impedance is slightly greater than the resistance. Whilst, if $Ql = \frac{3}{4}\pi$, we shall have

$$V_0/C_0 = 47 \cdot 8 \text{ ohms,}$$

and find the ratio of impedance to resistance to be $\frac{63}{85}$, making the received current 35 per cent. stronger than the steady flow current.

The above data of $f = 1$, and $Ql = \frac{1}{4}\pi$, $\frac{1}{2}\pi$, $\frac{3}{4}\pi$, and π, have been chosen in order to get near the first maximum and minimum of impedance. The range, it will be seen, is very great. Let us next see how these data resemble practical data in respect to resistance, &c. Remember that 1 ohm per kilom. makes $R = 10^4$ (resistance per cm. of double conductor). Also, that $f = 1$ means $R = nl = 10^5 nl_1$, if l_1 is in kilometres. Then, in the case to which (66*b*) to (68*b*) refer, we shall have, first assuming a given value of R, then varying L_0, and deducing the values of n and l_1, the following results :—

	$L_0 = 1$	$L_0 = 10$,
$R = 10^3$,	$n = 10^3$,	$n = 10^2$,
	$l_1 = 856$,	$l_1 = 8568$.

This is an excessively low resistance, $\frac{1}{10}$ ohm per kilom.; the speeds are rather low, and the lengths great. Next, 1 ohm per kilom.

	$L_0 = 1$,	$L_0 = 10$,	$L_0 = 100$,
$R = 10^4$,	$n = 10^4$,	$n = 10^3$	$n = 10^2$,
	$l_1 = 85$.	$l_1 = 856$.	$l_1 = 8568$.

The $L_0 = 100$ case is extravagant, requiring such a very distant return current (therefore very low electrostatic capacity). Next 10 ohms per kilom.

	$L_0 = 1$,	$L_0 = 10$,	$L_0 = 100$,
$R = 10^5$,	$n = 10^5$,	$n = 10^4$,	$n = 10^3$,
	$l_1 = 8 \cdot 5$,	$l_1 = 85$.	$l_1 = 856$.

Lastly, very high resistance of 100 ohms per kilom.

$$R = 10^6, \quad L_0 = 10, \quad n = 10^5, \quad l_1 = 8 \cdot 5.$$

In all these cases the amplitude of received current is 42 per cent. greater than the steady flow current.

In the next case, $Ql = \frac{1}{4}\pi$, the quantity nl/v has a value one fourth of that assumed in the above; hence, with the same R and L_0, and same frequency, the above values of l_1 require to be quartered. Then, in all cases, the current amplitude will be three-fourths of the steady flow current. Similarly, to meet the $Ql = \frac{1}{2}\pi$ case, use the above figures, with the l_1's halved; and in the $Ql = \frac{3}{4}\pi$ case, with the l_1's multiplied by $\frac{3}{4}$.

A consideration of the above figures will show that there must be, in telephony, a good deal of this reinforcement of current strength sometimes; not merely that the electrostatic influence tends to increase the amplitude all round, from what it would be were only electromagnetic induction concerned, but that there must be special reinforcement of certain tones, and weakening of others. It will be remembered that *good* reproduction of human speech is not a mere question of getting the lower tones transmitted well, but also the upper tones, through a long range; the preservation of the latter is required for good articulation. The ultimate effect of electrostatic retardation, when the line is long enough, is to kill the upper tones, and convert human speech into mere murmuring.

The formula (62*b*) is the most useful if we wish to readily see to what extent the electromagnetic formula is departed from. In this two quantities only are concerned, f and h, or $(R'/L'n)^2$ and nl/v, and if both f and h are small, it is readily seen that the *first* form of (63*b*) applies, the factor by which the electromagnetic impedance is multiplied being $(\sin h)/h$. Even when h is not small the f terms in (63*b*) may be negligible, and the first form of (63*b*) apply. For example, suppose $h = \frac{1}{3}$, and f small, then $(\sin h)/h = 3 \times \cdot 3272 = \cdot 9816$, showing a reduction of 2 per cent. from the electromagnetic impedance.

Now, this $h = \frac{1}{3}$ means $nl_1 = 10^5$, or the high frequency of $10^5/2\pi$ on a line of one kilom., $10^4/2\pi$ on 10 kilom., and so on, down to $10/2\pi$ on 10,000 kilom., always provided the f terms are still negligible. This may easily be the case when the line is short, but will cease to be true as the line is lengthened, owing to the n in f getting smaller and smaller. Thus, in the just used example, if the resistance is 10 ohms per kilom., and $L = 10$, we shall have $f = \frac{1}{100}$ on the line of 1 kilom., and $f = 1$ on 10 kiloms. So far, the f terms are negligible, and the first form of (63*b*) applies. But f becomes 100 on 100 kiloms., which will make an appreciable, though not large, difference; and $f = 10{,}000$ on 1,000 kilom. will make a large difference and cause the first (63*b*) formula to fail. It is remarkable, however, that this formula should have so wide a range of validity.

In the above we have always referred to the distant end impedance. But at the seat of impressed force there is a large increase of current on account of the "charge." Thus, at $x = 0$, by the formula preceding (41*b*) we have

$$\frac{V_0}{C_0} = L'v(1+f)^{\frac{1}{2}} \left[\frac{\epsilon^{2Pl} + \epsilon^{-2Pl} - 2\cos 2Ql}{\cdot\ \cdot\ \cdot\ + \cdot\ \cdot\ \cdot} \right]^{\frac{1}{2}} \quad . \quad (69b).$$

The term impedance is of course strictly applicable at the seat of impressed force. As the speed is raised, this impedance tends to be represented by

$$V_0/C_0 = L'v(1+f)^{\frac{1}{2}},$$

and, ultimately, by

$$V_0/C_0 = L_0 v = 30\, L_0 \text{ ohms.} \quad . \quad . \quad . \quad (70b).$$

if the dielectric be air. L_0 is usually a small number.

(To be continued.)

CORRESPONDENCE.

ELECTRIC BELLS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Could any of your numerous readers kindly inform me about what date electric bells were introduced for house purposes?

In the summer of 1851, while on a visit to a farm house about four miles from this town, I was shown as a curiosity an electric bell in use.

It was also connected with the gate leading to the house to give notice of the approach of visitors.—Yours, &c.,

Dumfries. K.

THE HOTEL SCHWEIZERHOF INSTALLATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to a notice in the last issue (6th August) of your esteemed journal regarding the electric lighting of the Hotel Schweizerhof, of Lucerne, we beg to inform you that the said hotel is not lighted by 600 Edison lamps, but by a total of 800 Swan lamps.

The central station is situated at Dorenberg, at a distance of about 5 kilometres from Lucerne. There is available at Dorenberg water-power up to 600 horse-power, which is utilised by two turbines for supplying electric light and power to long distances. We have installed there two self-exciting alternate current dynamos, which, running at a speed of 250 revolutions per minute, yield a current of 35 amperes at a tension of 1,800 volts. The primary conductors are four naked copper wires of 6mm. gauge, carried by telegraph poles. The central station is lit by 15 Swan lamps fed by a special small transformer. At 2·4 kilometres from Dorenberg a second transformer will be derived for 1,500 watts to supply current

Digitized by Google

to 40 lamps in the "Fluhmuhle," the property of Messrs. Gebruder Troller and Co., who are also the owners of the central station in Dorenberg and contractors for the supply of the electric light to the consumers. The next secondary stations are at a distance of 2·2 kilometres from the "Fluhmuhle," and consequently a total distance of 4·6 kilometres from the central station. Here two first-rate hotels, the Schweizerhof and the Luxernerhof, are lighted by a total of 1,200 Swan lamps, by aid of seven transformers of 7,000 watts each, placed in several parts of the building.

Besides these secondary stations there are several other hotels and public buildings to be provided with electric light from the central station of Dorenberg.

The whole electric plant has been supplied and executed by our firm, being the owners of the Zipernowsky-Déri system for distributing electricity to long distances.—Yours, &c.,

Budapest, 11th August, 1886. GANZ AND CO.

THE LALANDE BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to your interesting account of the Lalande battery, contained in last week's issue, I notice that in the electrical measurements an omission is made as to the percentage of loss incurred by the use of secondary batteries when used in combination with the primary for electric lighting, and when charged in parallel and discharged in series. The energy derived from six cells is computed to be about 23,000 watt-hours. But a great loss seems to come in if we deduct from the primary E.M.F. the counter E.M.F of the secondary, C E = watts; but from E must be deducted e of the secondary, and we have C $(E - e)$, which reduces the watt-hours very considerably. So that taking the E.M.F. of six cells in series as 4 volts, we have $4 - 2{\cdot}5 = 1{\cdot}5$; then multiplying this by the ampere current we only obtain as available energy something like 9,000 watts, representing more than 8lb. of zinc per horse-power hour. This would, of course, be the measurement in the charging circuit, but in the discharging or lamp circuit we should have 6,000, minus a percentage of loss between the charging and discharging current of, say, 5 per cent. × the E.M.F. of secondary battery; and taking this as 2 volts we have as our final result

$$6{,}000 - 5 \text{ per cent.} = 5{,}700 \times 2 = \frac{11{,}400 \text{ watt-hours}}{746}$$

$$= 15{\cdot}2 \text{ horse-power hours.}$$

—Yours, &c, BATTERY.

REMARKABLE INCANDESCENT LAMP PATENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As every little scrap of information in connection with the above subject is devoured and treasured by the users of incandescent lamps, perhaps it may interest some of your readers to learn a few facts respecting two particular inventions, one of which, to my mind, is very remarkable, claiming, as it does, a historical career, and is well worthy of the study of electrical engineers.

The lamp I allude to is the joint invention of Mr. W. E. Sawyer and Mr. Albon Man [? Mann], who a few years back were residents of New York and Brooklyn, who in the year 1877 became somewhat aroused at the success obtained by Dr. Woodward, of Toroto [? Toronto] (an Englishman by birth), to whom, it may be mentioned, the honor is due for having invented and introduced into Canada the first practical Carbon Glow Lamp, which was exhibited by him in the year 1874 at a grand garden party held at Montreal, as recorded in the Canadian Press at that date.

Messrs. Sawyer and Man [? Mann] then began following in Woodward's footsteps, and studying the question of incandescent lighting, and attempted to improve the Woodward and other lamps then known in America, and with the assistance of an expert agent obtained letters patent for an incandescent lamp having 30 claims; which lamp was afterwards patented in England in the year 1878, and known in this country as Cheeseborough's Patent, which invention since that date (whether legally or not remains to be proved) has undergone considerable changes, both financially and scientifically, which makes its history somewhat remarkable, especially as a correspondent in New York informs me that Cheeseborough, of Liverpool, duly assigned his interest in the patent in 1878 to an American by the name of Jacob Hayes, for the sum of 5s., which is a clear proof it was not considered of much value at the time. Mr. Hayes, after going to the expense of keeping the patents afloat for about six years, got tired of his bargain and resold it, and went through the usual form before Mr. W. H. Broadnax, a United States notary public, in May, 1884, by assigning his interest to one James Yate Johnson, an Anglo-American gentleman well known in the Edison circles, for the large sum of one dollar, thus losing tenpence over the transaction, besides transfer fees and the costs and expenses incurred by him during his ownership of the patent.

Next we find this invention, by some miraculous means, on its way back to England, and is then handled by Messrs. Swan and Stearn, and afterwards transferred by the firm of Swan, Stearn, and Johnson to the Swan Electric Light Company, and by them in due season to the Edison and Swan United Electric Light Company (Limited), the present owners thereof.

It would be a little interesting to learn how many profit and loss accounts have been opened in connection with this invention, also how much money has been expended in chopping and cutting up the original specification of the inventors, whose original claims of thirty in number have dwindled down to three.

Another most remarkable fact in connection with this invention is, it has crossed the Atlantic several times, and has been a frequent visitor in the law courts of England and abroad; and, if reports are true, it may yet have to prove its validity, and the payment of the 5s. paid for the parchment.

It may also be of interest to know that the services of Dr. Woodward have been secured by my firm as an expert witness in our case pending against the Edison and Swan Company.

Dr. Woodward is possessed of a store of information in connection with the art of lamp making, and should there be occasion for him to give evidence on our behalf, we have no doubt that his information will bring out many interesting facts of great importance to those interested in the manufacture of incandescent lamps.—Yours, &c.,

ARTHUR SHIPPEY.

King street, Cheapside, E.C.

[For once we go out of our usual course, and insert a letter which seems at first sight to be written in the interest of the general public; but the concluding paragraphs show that such is not the case. What have we to do with the changes as to ownership of a patent, or how much was paid by each purchaser? Surely the questions, legal and moral, are, Who owns the patent now? and, Is it infringed? The object of the letter, it seems to us, is merely to blind the public to the real point, which is:—A owns a patent, B is supposed to be infringing it, and is proceeded against, when he attempts to excuse his action with the statement that "the patent has been sold and resold for small sums of money."—Ed. *E.*]

THE "REGENT" BATTERY.

In our last issue we published a description of the "Lalande" battery, as applied to the charging of accumulators. We have since had the opportunity of inspecting another primary battery for domestic lighting, which is intended to work directly upon the lamp circuit. Dr. Fleming has recently tested one of these cells, and we publish his report *in extenso* below. The "Regent" battery is the invention of Mr. Maquay. Its E.M.F. upon open circuit is 2·19 volts. It will be seen from Dr. Fleming's report that, considering the fact that the cell belongs to the double fluid type, its internal resistance is remarkably low. A cell measuring 3¼in. by 2½in. by 1½in. has a resistance of only about 0·71 ohm.

This result is attained in part by the construction of the porous pot, which is made of a specially prepared clay containing powdered carbon. The most important feature of the battery is, however, to be found in the manner in which the positive plates are prepared. The details of the process are not yet made public, as the patents have not been completed. It is understood, however, that the inventor has produced an alloy of zinc and some other metal, which he claims to be a true chemical compound. This alloy, upon being amalgamated, enters into such intimate combination with the

Digitized by Google

mercury that the external surface of the plate always remains in an amalgamated condition until the whole plate has been dissolved.

It results from this, according to the inventor—and it will be seen that the statement is borne out by Dr. Fleming's report—that little or no local action takes place, notwithstanding that two metals besides the mercury are present in the plate. The constancy of the cell is also very great; in a battery intended to supply eight hours' lighting the E.M.F. falls about 5 per cent. during the first hour after closing the circuit; it then remains perfectly constant during six hours, after which it begins again to fall off. The cost of recharging a battery of 24 cells intended to supply a 16 candle-power lamp at 50 volts is stated to be about 5½d., and including the cost of renewing the zincs after 112 hours' service, this is about equal to gas at 6s. per thousand.

The cell seems to be well adapted for use with a miner's safety lamp. The type supplied for this purpose is of exactly the same weight as an ordinary Davy lamp, and gives from two to three times as much light for a period of 10 hours. The importance of finding a miner's lamp which shall be a real "safety" lamp has been greatly enhanced since (if the report of the survivor at the recent terrible explosion at Leigh is to be relied on) it has been demonstrated that if the gas takes fire inside the Davy lamp the flame may pass through the gauze if any attempt be made to blow it out.

The zinc-alloy plate is immersed in a 5 per cent. solution of sulphuric acid, and the carbon plate stands in a deoxidising solution, the exact composition of which has not yet been made known. It is, however, essentially a bichromate solution.

There can be no doubt that the battery has several very excellent features; of course the weak point is the trouble of changing the solutions and renewing the plates. No doubt the owners of the patents will take steps to minimise this as much as possible.

Dr. Fleming's figures do not, of course, require verification, but it may be of interest to state that some measurements which we had the opportunity of making upon another cell led to entirely concordant results.

It is stated that over 1,200 of these cells are already on order.

Dr. Fleming's report is as follows:—

I have had submitted to me for examination and test a primary battery, called the Regent primary battery, and have carried out experiments upon it at considerable length with the object of ascertaining its character and cost of working. This battery is a two fluid battery, and consists essentially of an outer containing cell, which may be of glass, porcelain, ebonite, or any other suitable material, and an inner cell of porous clay, rendered more highly conductive by a suitable process. The inventor claims to be able to reduce the electrical resistance of the porous septum without at the same time increasing its porosity to liquids, thus limiting the diffusion, whilst reducing the internal resistance. The active or positive element of the battery is an alloy, principally consisting of zinc, so treated that the repeated amalgamation which is so troublesome in ordinary batteries is obviated. The plate remains perfectly bright during consumption, and economy of working by the absence of local action is claimed for it. The other element of the battery is a carbon plate or plates immersed in an oxidising solution. The inventor does not claim special novelty for this oxidising solution, but has arrived by exhaustive experiments at a liquid which combines cheapness with constancy of action, and almost complete freedom from irritating fumes. It is claimed for the battery that, with the greatest simplicity of structure, it surpasses other similarly simple batteries in constancy of electromotive force, and in cheapness of operation. Three samples were submitted to me, a single cell about 5in. by 3¼in. by 1¾in., a smaller cell about 3¼in. by 2½in. by 1½in., and a battery of 24 of these last cells contained in a box about 10½in. by 9½in. by 5in. Calling these two sizes of cells the larger and the smaller respectively, we have the following determinations of the constants of each:—

Large Cell—Internal resistance	=	·26 ohm.
Electromotive force open circuit	=	2·19 volts.
Small Cell—Internal resistance	=	·71 ohm.
Electromotive force on open circuit ...	=	2·18 volts.

The battery of 24 small cells had an electromotive force of 52 volts on open circuit. The large cell was first of all set to generate a current through an external resistance of ·845 ohm., and the value of the current and external activity continually measured. It gave an average current of 1·75 ampere for very nearly five hours, the greatest variation of the current strength during the time being only 2 per cent. on either side of this, and the total drop of strength being about 4½ per cent., that is after five hours the current was 95½ per cent. of the original strength. During this time the cell evolved 8·34 ampere hours of current, and energy developed on the external circuit was 12·38 watt hours. The total consumption of the active plate in the cell was 12 grammes. Hence we may reckon the consumption of the active or positive plate at about 1,000 grammes or 2·2lbs. per 1,000 watt hours. In order to ascertain the amount of waste action a similar cell was allowed to stand unusued for 24 hours, and the loss in weight of the positive plate determined. It amounted to 5·6 per cent. of the original weight. Hence loss by local action is about ¼ p. c. per hour.

Experiments were next made with the small set of 24 cells. It was set up and made to supply current to a 40-volt incandescent lamp. The current and electromotive force at the terminals of the lamp were measured every five minutes for six hours by corrected instruments. During the first two hours there was a drop in electromotive force amounting to about 5 per cent. From the end of the second hour to the end of the sixth hour the current and electromotive force remained *absolutely constant*; the closest inspection did not reveal any change in the reading of the instruments. This is certainly a very remarkable result for cells of this small size. During this time the battery was delivering energy at the rate of 30 watts, and hence in the six hours run delivered 180 watt hours, or about 500,000 foot pounds of energy. During this time the consumption of active plates was about 3 ounces weight in all. At the end of the run the positive plates were as bright and untarnished as when first put in the battery.

The glow lamp used gave during this time an illumination of about 12 candles with remarkable steadiness. The performance of this small battery of 24 cells seemed to me to be worthy of considerable praise. Beginning at 12 o'clock with a current of ·77 ampere, it continued to supply current for two hours at a slightly diminishing rate, falling to ·74 in two hours and then remained nearly constant for four hours more, finally falling ·735 ampere. During this time it did not evolve any perceptible fumes. I have ascertained by independent inquiry what would be the cost of charging these 24 cells, and find that the cost of electrical energy obtained from such a battery would be approximately one penny for 40 watt hours. This means that a 16-candle glow lamp could be maintained in action for about six hours for sixpence, as far as concerns the battery and independent of deterioration of the lamp.

Setting on one side central station lighting, we may say that domestic incandescent electric lighting by means of gas engine and secondary batteries has now arrived at considerable perfection, and can be carried on at a cost very little in excess of gas lighting. Considering all the enormous advantages of incandescent lighting, we may well ask why such method is not in far more general use, and the reply undoubtedly is that people shrink from the first cost of such an installation. Granted that for £10 or £15 a year a small house can be lit by incandescent lamps with gas engine, yet if such installation necessitates £200 or £300 initial outlay the demand will be limited. Now, there is a considerable field of small domestic lighting in which people desire to have a few lamps in their houses, and which could be met and met well by an efficient primary battery. In order, however, that a primary battery may meet the requirements of the case, it must, in my opinion, comply with several conditions:—1. The plates should not require re-amalgamation. This is costly and troublesome. 2. It must have small local action, or small wasteful consumption on open circuit. 3. The electromotive force should not fall off more than five per cent. during the delivery of its normal current in about six or eight hours. 4. There should be no complicated arrangement of pipes and circulation of fluids. These arrangements act well at first, but are excessively liable to get out of order. 5. No mixing of chemicals or strong acids should be required; the exciting solution should be supplied ready mixed and be capable of being put in by any ordinary domestic like oil into a lamp.

Now, these conditions are all of them complied with in the Regent primary battery, and in addition such moderate economy in working, that although the lighting by it will not compete with gas, yet, nevertheless, all things considered, it is not a cost which will inhibit those from using it who desire the luxury of incandescent lighting, and yet do not desire to incur large initial outlay. One thing that very greatly recommends such a primary battery as this for such domestic lighting is that it can be used occasionally or whenever required. Now, no arrangement in which secondary cells are used can be employed intermittently. The secondary batteries rapidly deteriorate under these circumstances. A primary battery can be charged and used one day a week, and then when emptied and cleaned is ready again for use when required.

In addition, I may say that I regard this alloy as used for the positive plates in the Regent battery as a very valuable invention. With a little modification this battery should have large uses in telegraphy and other operations when a constant battery of high electromotive force is required. It can be made small, and there will be useful applications of it in small portable electric lamps. On the whole, I am very well satisfied indeed with the manner in which this battery has comported itself under tests, and am of opinion that under proper management its use should be very extensive, and meet requirements not yet supplied by any existing forms of battery.

We also append the following report from Mr. S. Walker:—

In accordance with your request I beg to report that my further experience of the Regent primary battery has fully borne out the favourable impression I had already formed, as described in my former reports. The particular points in which it appears to me to be superior to other batteries are:—1. The extremely small size and weight within which the inventor has been able to concentrate a given amount of energy. This feature is of paramount importance for miners, and other portable lamps; and I have no hesitation in saying that this invention has rendered a practical portable electrical miner's lamp possible for the first time. 2. Its remarkable constancy. I know of no primary battery for electric light which approaches it in this respect. 3. The special formation of the generating plate, which enables the whole of it to be consumed without attention. 4. The low cost of solution employed. 5. The entire absence of complications. In the matter of cost both of manufacture and maintenance, I consider that the Regent battery compares very favourably with every known battery that can be or is intended to be used for lighting. Its components are the cheapest materials known to commerce for this purpose; and while the cost of the metal consumed in continuous work will be rather less than that of zinc under the same conditions, the cost of the solutions I make out from actual work done under my own eye to be one-sixteenth that given recently by M. Hospitalier as the cost of the best form of battery which had passed through his hands up to that time. I am of opinion, therefore, that the Regent battery may be introduced with every hope of success for lighting either by means of stationary or portable batteries; and that the prices obtainable compared with the prime cost should yield a very handsome margin of profit.

CITY AND GUILDS TECHNOLOGICAL EXAMINATIONS.

Although the information contained in the Report of the technological examinations conducted by the City and Guilds of London Institute last May is not so ample or so relevant as one would desire, it is, so far as it goes, encouraging to the promoters of technical instruction, and creditable to the Institute which has been mainly instrumental in establishing that instruction on a sound basis. This is the eighth year of the examinations, and there has been an uninterrupted increase of students from the beginning. Omitting the first two years, a steady growth is recorded year by year of between three and four hundred candidates; and so far from there being any signs of falling away, the present year shows an unprecedented increase of eight hundred. The proportion of successes has varied at times in a rather unaccountable way, being sometimes only half, and sometimes three-fifths or two-thirds of the whole number examined. At the May examinations, five hundred of the additional eight hundred candidates obtained passes, which, to adopt the ambiguous phraseology of the Report, is at least "satisfactory." What is more unmistakably satisfactory is the large increase of centres of examinations during the previous twelve months, showing that the area of the Institute's influence is being rapidly extended. Another gratifying feature is the unusual strength of the Honours list, which numbers 622 for the present year, against 406 at the 1885 examination, notwithstanding the fact that the standard has been gradually raised from year to year. We gather also fro them returns that the number of pupils who come up for second and third examinations has gone on enlarging, affording proof of the serious aims of the candidates, who thus persevere in their studies over a lengthened period.

These, at least, are some of the inferences we draw from the wording of the Report, which is sometimes obscure, and from the figures of the Tables, which are generally confusing. The City Institute's Report has always been brilliant in Tables. Its tabulated statistics are unique specimens of what figures can be made to do duty for in the absence of anything better to talk about. The Director and Secretary appears to revel in columns, much as the Chronicler delighted in genealogies. They are often unintelligible, their object incomprehensible, and their effect not the least edifying; but they look imposing, and have cost the compiler much pains. If they cost the reader less they would be more tolerable. He wants to know something, for example, as to the relative quality of the teaching in evening classes and collegiate institutions. That it is better at the latter than at the former is explicitly stated (but in the baldest terms), and we are referred to Table III., where the comparative failures are worked into elaborate percentages, which are utterly misleading until all the data are examined, and have no particular significance even then. In several cases there are 0·0 percentages of failures in "classes" when there were really no candidates; and 100·0 failures is credited to "other institutions," against 47·3 from classes, when the former only sent two candidates, who failed, whilst the latter sent 114, sixty of whom passed. In Table II. we find at the outset that in the matter of Salt 75·0 per cent. of candidates failed; whereas in Soap it is gratifying that the failures were only 50·0; but our satisfaction is damped when on further inspection we find that soap had attraction for only two British artisans, one of whom did not wash, or, more technically, did not pass. This is how 50·0 failures is arrived at; whilst the 75·0 of the first item turns out to represent three men of salt who failed, out of a grand total of four. When we reflect what a vast difference it would have made to the Secretary's percentage had only one more soap boiler, or even 50·0 of a soap boiler, presented himself for examination, the relevancy of these formidable Tables becomes rather dubious.

On the whole, however, we like the figures of this Report rather better than its English. Applications for examination, we are told, were received "in all the 49 subjects"—just as if 49 were *the* fixed number of subjects. A little further on mention is made of "The new Syllabus in the Raising and Preparation of Ores;" we shall expect next to hear of a new Table *in the* preparation of statistics. Manchester, it seems, heads the list of provincial centres, from which the largest number of candidates have passed, "the number being 169 as against 147"—of all the rest put together one might suppose; but on more careful study we are led to the conjecture that 147 was Manchester's last year's total, "against" which the present year's compares so favourably. The figures of the Report are as eloquently inconclusive as those of the Tables. On page 9 it is argued that there is a substantial increase this year in the number of successful candidates who were examined for the first time. And so there is; but seeing that the total number examined was increased by more than double the increase of any former year since 1881, the inference is not necessarily what the writer intends us to draw. Turning to more trustworthy details, we notice that the interest taken in Electrical Engineering shows no sign of abatement. Under the heading of Telegraphy there is, it is true, a marked falling off of candidates, which is, perhaps, not to be wondered at; but under Electric Lighting the numbers have risen from 105 last year

Digitized by Google

to 151; and in Electro-Metallurgy the 25 candidates of last year are this year represented by 36. Of the Central Institution we are only told that during the present summer courses of instruction have been given there for the benefit of teachers; and that the attendance at these courses has been satisfactory. We accept the statement gratefully; but in some subsequent Report it would be more satisfactory to be told precisely what *is* satisfactory, and to whom.

THE INSTALLATION AT TILBURY DOCKS.

From the time of Queen Elizabeth to that of General Gordon Tilbury has been a prominent word in the annals of English history. Schoolboys, by a stretch of the imagination or an incapacity to draw correct inferences from records of glamour and glory, think that Tilbury Fort is a stronger fortification than Gibraltar. It was here that Bishop Cedda baptised our Saxon ancestors. It was here that Queen Elizabeth had a camp to oppose the invasion of the Spanish Armada. It was the weakness of the "blockhouse" that permitted the Dutch, in 1667, to attack our ships in the Thames and Medway. As usual, the "door was afterwards locked," and the old blockhouse converted into a regular fortification.

Future history will probably contain records of Tilbury of a far different character to those which grace its pages in the past. Commercial enterprise has singled out this spot as suited for the construction of gigantic docks, upon which many hundreds of thousands of pounds have been spent, and which are now awaiting business to make the scene one of great activity. It can hardly be said by any stretch of the imagination that the scenery on the Tilbury side of the Thames possesses any beauty. It is in strong and striking contrast to that on the Kentish side of the river. But commerce thinks little of scenery, it looks only to utility, and while steep hills offer no advantages for the formation of docks, the low level muddy Essex shore opposite Gravesend possessed the required advantages. The formation of new docks in a district wherein nothing of the kind was known opened up opportunities for a trial of the electric light such as were unknown in the older works, and the directors did not hesitate to accept the advantages this light offers.

It was last autumn that the directors of the East and West India Docks Company decided to light the whole of the new Tilbury Docks by electricity, and Mr. Crompton (of R. E. Crompton and Co.) was asked to send in a report on the best method of carrying out the lighting. His report was accepted, and after the lapse of several months the contract was entrusted to Messrs. Crompton and Co. The order was given out on 1st January and on 1st July the whole was practically completed and the docks lighted up from end to end. Mr. Crompton's report has been carried out practically without any serious alteration.

The area of land and water to be lighted is very conisderable, exceeding 300 acres, a plan of which will be sufficiently clear from Fig. 1, in which the circles, A A, show the position of the arc lights, and R R show the railway lines. In addition to the outdoor lighting of the quays, jetties, and railway, there are 24 large sheds, each about 300ft. long by sidings, 120ft. wide, which had to be lighted in such a manner that goods could be piled all over the floor of

THE TILBURY DOCKS INSTALLATION.

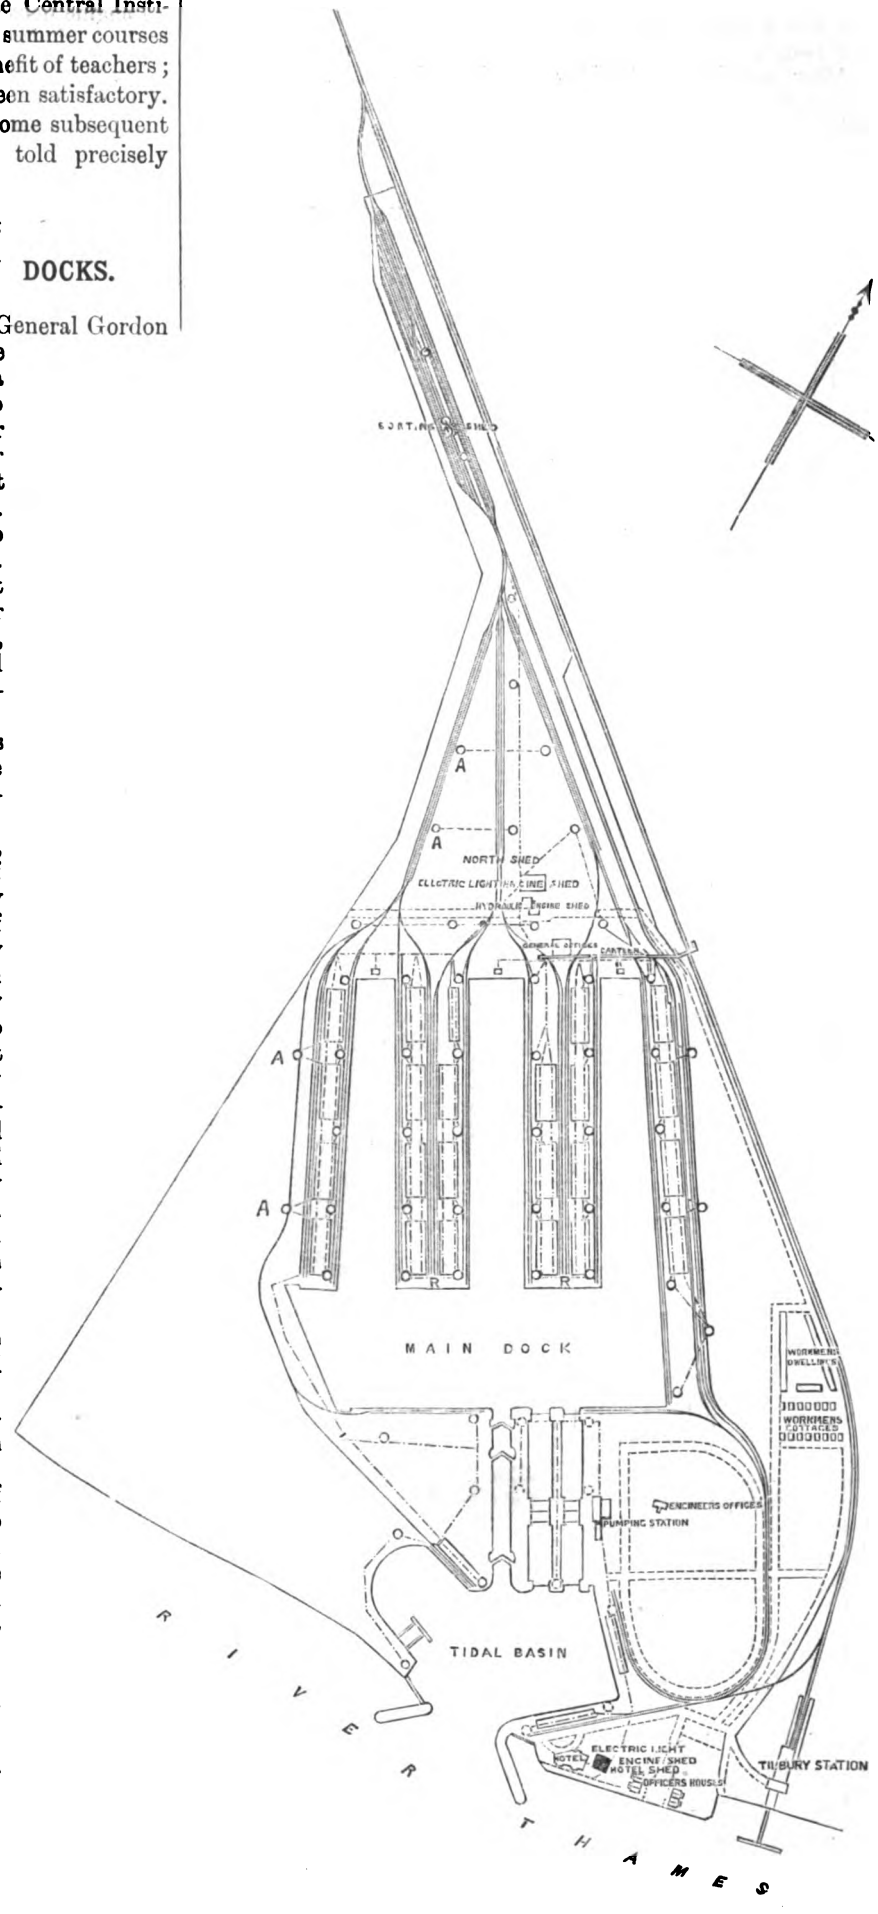

FIG. 1.—Plan of Tilbury Docks.

Digitized by Google

the sheds. In addition to these sheds there was a large number of dock offices and industrial dwellings for the workmen and a large hotel, all requiring to be lighted by incandescent lamps.

After weighing all these considerations Mr. Crompton provided two engine houses, one large one at the north end, containing two engines capable of giving off collectively 360 horse-power, and placed at a point nearly

overhead wires are led along the various lines of sheds to work about 1,000 twenty-five candle-power incandescent lamps, most of which are in the sheds above referred to. From the same engine house current is supplied for working 60 arc lamps, each of about 3,000 candle power, for the quays and railway sidings. A second small engine house is placed close to the hotel, and from it at present eight arc lamps only are worked, but about 400 incandescent lamps are distributed in the hotel

lectively supplying steam for the engines which during the trial run of one week's duration were regularly worked up to 360 horse-power. Each engine has two large fly-wheels, 10ft. in diameter. One of Messrs. Crompton's L type, or 50 unit dynamos, is driven from the outside fly-wheel of each engine, and a piece of shafting can be driven from the inside fly-wheel of either engine, or from both together, so as virtually to couple the two engines, if it be found necessary. Each of the two large dynamos can give a current of 200 amperes, at an E.M.F of 280 volts at the terminals, or about 56 units, and without any undue heating. The arc light dynamos give a current of from 15 to 20 amperes as may be required, according to weather, &c., at an E.M.F. of 700 volts at the terminals. These arc lighting dynamos are separately excited, and as the exciting current can be varied within certain desired limits, so that any of them can supply from 12 to 14 lamps without varying their speed, the current can also be varied from 13 to 20 amperes, according to the amount of light required. The switching and commutating arrangements are such that any of the arc lighting dynamos can be put on to any circuit, or the dynamos can be exchanged, and any one of the three held in reserve can be put in in the place of one temporarily disabled and with no perceptible stoppage of the light. This is carried out by means of two plug-boards of a somewhat similar pattern to those so well known in telephone exchanges. The commutating arrangement for the incandescent lighting is of a simple character, as there are only two large machines to be dealt with; all the leads from the incandescent lamp distributing circuits of one sign are brought to a common terminal, being protected in the usual manner by fusible safety cut-outs. The other leads are each of them brought to the centre of a switch, the arm of which can be swung round to one or other of two terminal plugs, the terminal plugs being attached to the two machines. The eight arc light dynamos are excited by a pair of small machines, either of which is ample to do the whole work, but the two are introduced to render failure of the exciting current an impossibility; the magnets of the dynamos are in parallel circuit and any one of them can be switched off without affecting the others. These last-named switches are so arranged as to insert three grades of resistances, so as to vary the exciting current to each machine. Dr. Hopkinson, who has throughout acted as inspecting engineer for the dock company, made a series of careful measurements of the electrical output of the various dynamos during the official week of trial. The results show that from 70 to to 72 per cent. of the horse-power of the engine cylinders was obtained as useful commercial output at the terminals of the dynamos. The water supply at Tilbury at present is of very bad quality, and has a tendency to make the boilers prime, so that up to the present time the evaporative efficiency of the boilers has not been so good as was expected; but Messrs. Crompton, however, see their way to remedy this. Taking matters as they are at present the consumption of coal per commercial electrical horse-power rendered at the terminals of the machines has been exceedingly low, not exceeding 3·8lb. As has been said above, the distribution of current to the incandescent arc lamps has been almost entirely by means of overhead wires. This piece of work is interesting on this account alone, as the use of overhead wires has allowed a very large area to be lighted with an exceedingly small cost for copper. A separate pair of wires has been carried from each line of sheds direct to the switch-board at the engine room. The total distance from the engine house of the most distant shed, viz., that called the southern transit shed, is as nearly as possible a mile, and yet the lamps, which require the same E.M.F. as those used in the other sheds, can be turned off in pairs without any noticeable change in the brilliancy of the remainder. Such a large quantity of overhead wiring presents some features of novelty. Commencing from the engine house massive standards framed of pitch pine and supported on large blocks of concrete were found to be necessary to resist the strain of such a large weight of copper. It is found necessary to use these framed standards to carry what may be called the trunk line of wires right across the top of the branch docks. From them the wires are carried through the sheds, their insulators being secured to the iron frame work of the roof of the sheds by wrought iron brackets. The wiring of the interior of the sheds is of the simplest possible description, the whole of the wires being in the roof and in full view, and every circuit can be traced, and, if necessary, repaired, without the removal of any casing. The lamps, which require 130 volts each at their terminals, are arranged two in series; one switch and one cut-out is placed in each branch, so that two lamps are turned out at once. The arc lamps throughout are of Messrs. Crompton's well-known pattern. The outside lights are carried on poles, which are of two patterns; the pattern that is employed along the quay walls calls for no special remark. It consists of an octagon taper pitch pine pole, having a wrought iron arm or davit at the top, to which the lamp is hoisted by means of a wire rope and counter weight. The trimming of the lamp, &c., is carried out on a platform about 14ft. from the ground, so as to be out of the way of the traffic. The other form of pole used is entirely novel, and as it requires rather a lengthened description we must defer this

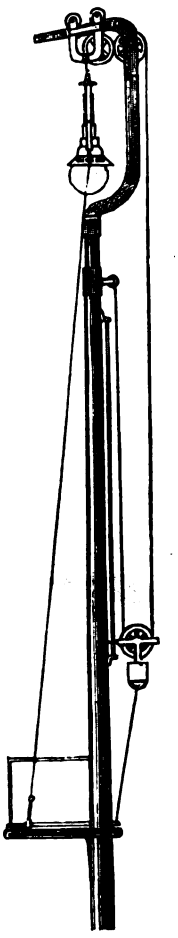

FIG. 5.—Shadowless Pole.

to a future date. Messrs. Crompton, however, have with this pattern succeeded in hoisting the lamp in such a manner that when it is at the top of the pole it is guided into a central position instead of being hung at one side of it as has been heretofore the case. In this case the heavy shadow usually thrown by the pole is avoided, and in place of it there is only a very narrow shadow thrown by the steel arm which carries the lamp itself.

Fig. 5 will enable the reader to understand the peculiarity of this pole. Both classes of poles carry the lamp at about 40ft. from the ground level. In addition to the incandescent lamps inside the sheds, and the arc lights of the quays, a number of portable lights of both classes have been supplied for unloading ships. Portable arc lights can be attached to certain terminal boxes which are provided at regular intervals along the quay walls. Sufficient cable is then payed off a drum hung against the wall of the adjacent shed to enable the lamp to be fixed in a convenient position in the

Digitized by Google

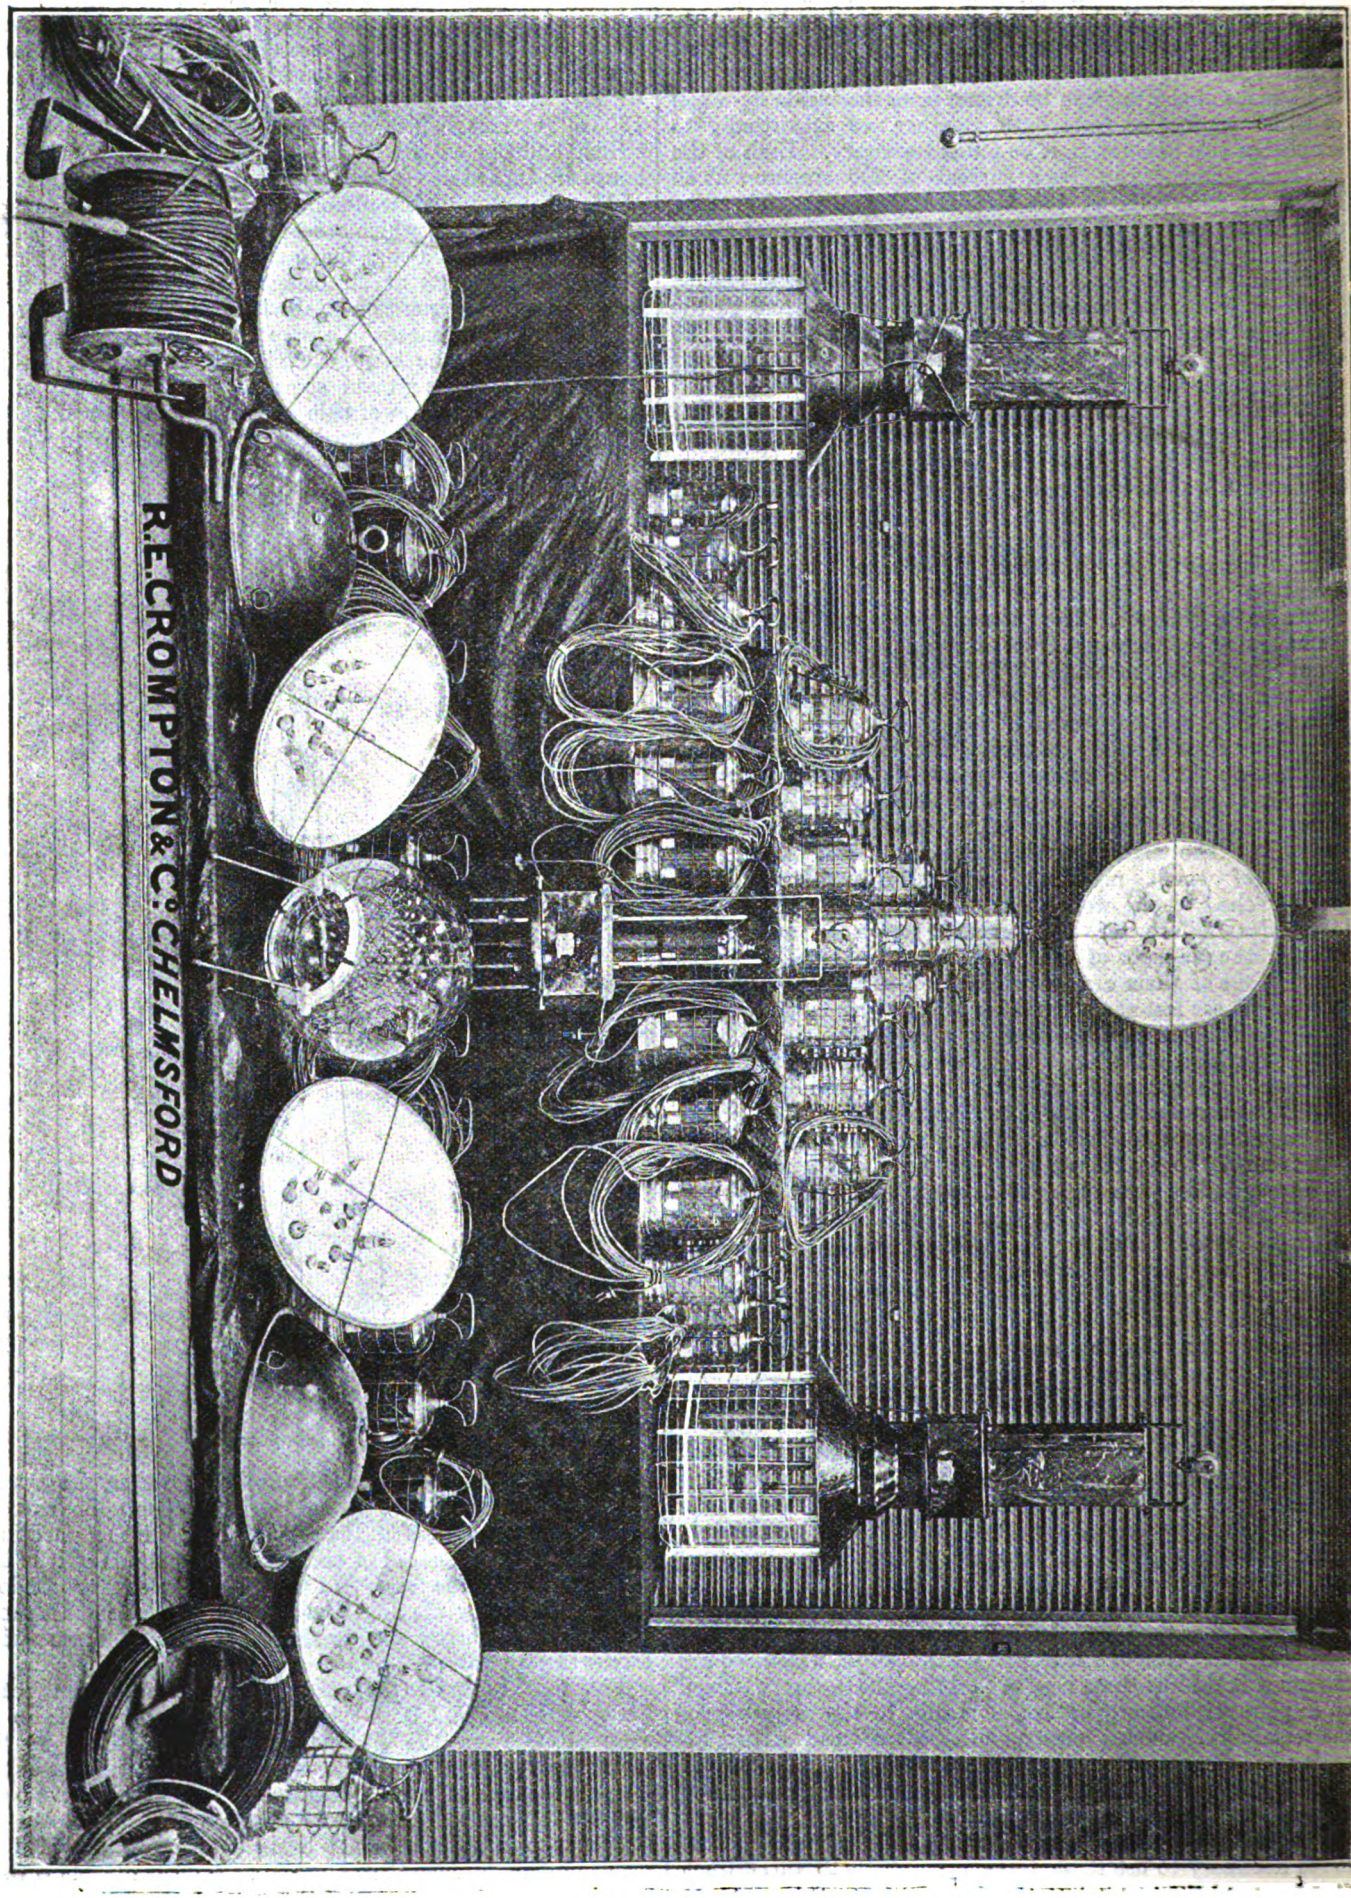

Exhibit of the Various Apparatus Used in the Installation.

THE TILBURY DOCKS INSTALLATION.

Digitized by Google

rigging of the ship that is being unloaded. In a similar manner lanterns containing eight 25 candle-power lamps can be lowered anywhere into the hold of the ship in order to supply the light to the more inaccessible parts, and thus assist in unloading the cargo. The terminal boxes for the insertion of these two classes of cargo lights merit special description, but this we must reserve to a future date. The general arrangements from the southern engine house are very similar, but of course on a much smaller scale than those from the northern one. In this latter engine house are not only contained the whole of the lighting for the southern end, including that for the hotel, but also the sewage pumping apparatus for dealing with the sewage from the hotel itself. Owing to the necessity of charging accumulators in order to afford an all-night supply to the hotel, the switch-board arrangements of this southern engine house had to be very special in character, and also merits separate description. The engines in this south engine house were built by Messrs. Marshall, of Gainsboro', and are exceedingly fine specimens of underneath type of compound engines. A great part of the engineering difficulties that have been encountered in carrying out this very large work were due to the difficulty of getting foundations, either for the engine houses or machinery, or for the frame standards carrying the overhead wires. Nearly the whole of the present ground level of the quay, walls, and sheds is made ground, and has been raised from 10ft. to 17ft. above the original marsh level. In nearly every case the foundations had to be carried down to this original marsh level, with the accompanying difficulties of inrush of water and similar troubles. Those who now see the works in a finished state can form no conception of the chaos that existed when Messrs. Crompton commenced operations in January last. The work as now complete offers a good example of modern electric light engineering applied for lighting by a mixed system an area extending to a radius of a mile from the generating station in the cheapest and most economical manner, both as regards capital expenditure and future cost of maintenance.

ON ELECTROLYSIS.*

BY PROF. OLIVER J. LODGE, D.SC.

When in response to an urgent request by the president of Section B I agreed to open the present discussion, it was only after a good deal of hesitation that I consented. For though convinced of the immense importance of a more thorough study of the facts and phenomena connected with the passage of electricity through decomposable bodies, and of its vital interest to all scientific chemists, yet it was not a subject that I had made specially my own, having been, in fact, to a great extent deterred by the immense area it covered, and by the somewhat repulsive character attaching to any borderland branch of science—in this case not wholly physics nor wholly chemistry—a repulsiveness perhaps only subjective, and probably to be attributed to a feeling of incapacity for grasping both aspects of the subject with equal completeness. This difficulty still remains with me, and though I have made a severe attempt to tackle the subject as best I could during the past month, I have been quite unable to cover the immense field, or to read more than the summaries of its literature; and, accordingly, I shall attempt no historical or chronological survey, but shall endeavour simply to direct attention to certain theoretical points which are undoubtedly of interest and importance, and to suggest the answers which I myself feel inclined to give to debatable questions which bristle round even the most elementary facts, in the hope that attention being thus directed to them, success in finally solving some of them may be attained by a more competent hand.

Naturally I confine myself to the more physical aspect of the subject, because, my chemical knowledge being of a meagre and antiquated description, it is better worth your while that I should attempt reasonably good physics than that I should perpetrate unreasonably bad chemistry. Moreover, no chemical development will be satisfactory and permanent unless erected on a thorough physical basis; and if I may venture an opinion on such a subject, I believe that the work of a few chemical philosophers spent in broadening and deepening the foundations of their science would soon confer upon the superstructure a less unsightly and lopsided appearance than, seen from outside, it at present has

The first question which presents itself is—I. What is an electrolyte? The question may have either of two distinct meanings—*(a.)* Is a substance an electrolyte at all; *i.e.*, when alone? *(b.)* Is it the electrolyte in any particular case; *i.e.*, when mixed with other substances?

First meaning of I.—As answers to *(a)* certain chemical statements have been made, such as "all electrolytes are compounds of a metal with a non-metal" (Miller); "electrolytes are either simple binary compounds, or are capable of being formed from them by double decomposition, the *ions* being the radicles so exchanged" (Wiedemann), &c. Such statements may be true, and if true may be important chemical generalisations, but they are not physical definitions or tests of electrolytic conductivity.

As a physical definition of an electrolyte, we have only to say *an electrolyte is a substanee which conducts electrolytically.* A statement like this only helps by fixing our attention on the real point in question, viz., the difference between electrolytic and metallic conduction—a true physical distinction, which is capable of definite examination, and may be capable of precise statement. Whether we are able thus sharply to divide off electrolytes from other conductors will depend on whether any substance be found which can conduct both like a metal and like an electrolyte. Such a substance is not yet, I believe, certainly known, though it has been often suspected; it has even been suspected that all electrolytes have a trace of metallic conductivity. Though for the present this is quite unproved, and may be regarded as against the weight of evidence, it would be rash to insert the word *wholly* into the above definition; it must be left as meaning that *in so far* as a body conducts electrolytically, so far it is an electrolyte.

Now, electrolytic conduction differs from metallic conduction in several ways. Metallic conduction appears to be a true passage of electricity through matter; it is unaccompanied by any reversible or chemical process, it simply generates heat. Electrolytic conduction is accompanied by certain reversible chemical processes, and appears to be of the nature of a convection of electricity by the atoms of matter. A substance which so conducts is an electrolyte, and whether it be a good or a bad conductor is foreign to the inquiry.

It is important to notice this, because it is often sought to deny that (say) water is an electrolyte by showing that it is a bad conductor. Of course, if it *does not conduct at all* it is no electrolyte but a dielectric. Our definition says, first, that an electrolyte must conduct, and it then proceeds to say how it must conduct. Water, alcohol, turpentine, glass, either conduct a little or they do not. If they do not they are dielectrics pure and simple; but experiments on leaks have always shown a more rapid leak if water, alcohol, or turpentine be used to replace air, and as to some kinds of glass it seems to be a mere question of temperature whether they conduct or not. If it be proved that any of these things, even when pure, conduct, be it ever so badly, they are not simple dielectrics, and it remains only to consider whether their conduction is metallic or electrolytic. But it may happen that some of these bodies, or *perhaps* all liquids, behave as dielectrics to rapidly intermittent or alternating E.M.F.'s, but as electrolytes to slow and long-continued E.M.F.'s, just as pitch is elastic to rapid vibrations (it can transmit sound for instance), but is viscous and essentially fluid to long-continued forces. Whether this is so or not is a vital question in relation to the electromagnetic theory of light, wherein the transparency of conducting liquids has only been provisionally and tentatively explained.

Tests for Electrolytic Conduction as distinct from Metallic —So far as experiment has yet gone, electrolytic conduction is found to obey Ohm's law—a remarkable and important fact, if fact it accurately be—and we will return to it later. The obedience to Ohm's law shown by electrolytes prevents our drawing any easy and sharp line of demarcation between the two classes of bodies. To distinguish between them we have to study what happens at a boundary or junction of the two classes of conductors

At such a place Ohm's law utterly breaks down; a finite E.M.F. is needed to drive any permanent current, however small, and the reason is that the atoms which have conveyed the electricity through the electrolyte can accompany it no longer, and have either to give it up and let it go on without them, or cling to it and stop the current. In either case we have what is called polarisation. If the clinging power of the atoms is greater than the applied E.M.F. the current may wholly cease, and as soon as the E.M.F. is removed will spring back again, the opposition to it being no longer like friction, but like a strained spring. If the applied E.M.F. overcome the atomic force the current flows on leaving the discarded atoms to do what they like. They may combine with each other and separate from the liquid, in which case we have visible chemical decomposition; or they may combine with each other and dissolve in the liquid; or they may combine with the liquid, forming secondary products; or they may combine with the electrodes.

They usually cling tightly to the electrode, even if unable actually to combine with it, and by thus altering its surface they may give rise to a permanent opposite current. The four possibilities are—Combination with, or solution in, the liquid; combination with, or deposition upon, electrodes; combination with something already dissolved in liquid; combination with each other and freedom.

Wherever visible decomposition occurs there is no doubt of electrolysis, so that is the most simple and obvious test of electrolytic conduction. But the conductivity may be so bad that no visible product forms in a century. In that case *polarisation*, if present, is a test. As Helmholtz says: "Galvanometers are sensitive enough to show a current which could only decompose a milligramme of water in a century."* But this test also may fail by reason of secondary actions. It is the merest commonplace that an ordinary voltameter behaves as a very leaky condenser. A continual drain of electricity goes through it, however small the E.M.F. applied; and when charged and left, the charge is found very rapidly to diminish. It is facts like these, of course, which have so often suggested slight metallic conductivity, and which at one time tempted Faraday to postulate this.

With certain fused salts the decay of polarisation is so rapid that polarisation hardly appears to exist; and quite a strong current can be sent through them without any visible decomposition. Clark † has shown that in these cases it is the solution of the liberated ions and their rapid

* From the Report of the British Association.

* One may notice that even such a current as this is still 10 electrostatic units per second.

† J. W. Clark, *Phil. Mag.*, October, 1885.

Digitized by Google

diffusion which causes this apparent metallic conduction. There is probably a full quota of decomposition, but unless special precautions are taken re-composition is just as rapid. The same thing goes on far more slowly in dilute acid, especially if it contain dissolved gases; and the experiments of Helmholtz with an ingeniously-contrived gas-free cell, as related in his Faraday lecture of 1881, may be taken as settling the quantitative question whether this decay of polarisation is any of it due to slight metallic conduction, and whether the whole of it is rigorously due to solution and diffusion of the semi-liberated ions. It is, of course, true that these experiments do not settle it for all electrolytes, but for dilute sulphuric acid, at any rate, they prove that the diffusion and indirect re-combination of the ions accurately account for everything, and that when these are stopped a voltameter behaves as a good and non-leaking condenser up to a certain E.M.F., beyond which it conducts with visible decomposition. It may be as well, perhaps, to avoid misconception by stating that by the solution and re-combination spoken of above, I do not absurdly suppose that nascent O and nascent H, respectively dissolved in the liquid, travel to meet each other and combine. Upon such direct action as that the presence or absence of dissolved air could have no influence. What one supposes to go on is this. Semi-liberated hydrogen, finding dissolved oxygen in its neighbourhood, combines with it; the corresponding oxygen simultaneously liberated at the other pole dissolves in the liquid, and, so replenishing it, keeps the action continuous at a slow rate regulated by the rapidity of diffusion.

I see nothing, however, to prevent a liberated ion from dissolving in the liquid or from diffusing across to the other electrode, where it may combine with the nascent ion, and so reduce the apparent output of the cell; and this action, having nothing to do with dissolved air, might go on even in Helmholtz's gas-free cell. But it could not begin, I imagine, unless the E.M.F. were sufficient to set both ions free;* consequently, by never applying more than a feeble E.M.F., this disturbing action may be obviated. When dissolved oxygen already exists, neither ion has really to be set free; consequently, even a feeble E.M.F. is sufficient to maintain a weak current.

In cases where the polarisation test for electrolysis thus fails, Helmholtz proposes another—viz., Electrolytes do not fall into Volta's tension series. An assemblage of metals at constant temperature can give no permanent current; introduce an electrolyte into the series, and they can.

On this principle Helmholtz considers he has proved that the conduction of glass is not metallic; for he makes a Daniell cell with a complete glass partition in place of a porous cell, and finds that the glass does not stop the current by polarisation, as a metal partition would, but that the cell behaves exactly like any other cell with an enormous internal resistance. One more test those of us who believe in the electrical theory of light may suggest—viz., transparency. A conductor, if transparent, must be an electrolytic conductor. Thus, a fused salt, if it be clear and transparent, and yet conduct well—as argentic iodide does for instance—may be assumed to be an electrolyte, despite the absence of products of decomposition and of polarisation, unless, of course, rigorous proof can be given that its conduction is metallic, which has in no case happened yet. Electrolytes seem necessarily fluid, and it is difficult to imagine the locomotion of atoms which accompanies electrolysis to go on in a solid body. Mr. Shelford Bidwell, Dr. Silvanus Thompson, and others, consider they have found solid electrolytes, but it behoves us to be very careful in accepting such an idea. Extreme viscosity there may be, as in hot glass, but not the true rigidity of a solid, unless certain proof is forthcoming.

(*To be continued.*)

THE HEATING OF AERIAL CONDUCTORS BY ELECTRIC CURRENTS.†

BY J. GILBERT WHITE, PH.D.

(*Continued from page 287.*)

The next set of experiments had for its object the determination of the law of the relations of different currents, and the temperatures which they were able to maintain.

TABLE VII.

R. for bare wire.	R.	R'. for bare + insulated wire.	R'.	Thompson Ammeter. Right.	Thompson Ammeter. Left.

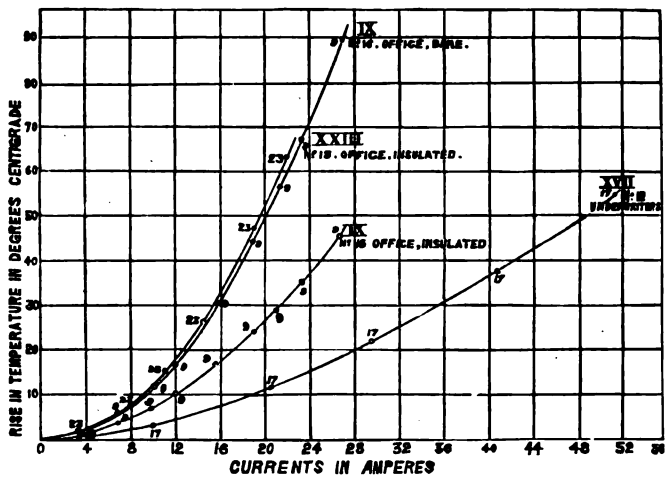
* The E.M.F. required to set an ion free enough to enter into solution is almost enough to set it free altogether. The only difference, I suppose, is pdv; and at ordinary pressures this is negligible.

† From the *Electrician and Electrical Engineer* (New York).

After the current is started in a wire, the emission of heat will increase with the temperature of the wire, until the heat given off just equals the heat developed, when the temperature of the conductor will remain constant. But each current will have its own permanent temperature for any wire under given conditions. To determine the law of this variation, a current was started and allowed to run fifteen or twenty minutes before any observations were taken. Then observations were taken as in the above sample set, the readings of each horizontal line being taken before any of those in the next lower line.

In the following tables all the experimental data were found by taking the average of a number of determinations similar to the above, and the calculations were made from these averages.

Plate II.



The curves on the cross-section paper, Plate II., were laid out by taking the rise in temperature of the wire in degrees centigrade as ordinates, and the currents in amperes as abscissæ.

Experiments 1, 2, 3, 4, 5, 6, were made with No. 16 wire, all of the same piece, the bare part having been stripped of its insulation, which was a double layer of paraffined cotton. Nos. 1, 2, 3 and 4 were conducted with the two parts of the wire suspended side by side in a closed room, about 50 feet of each kind being used.

In 5, 6, 7 and 8 the wires were arranged in a similar manner in the open air, the remainder of the apparatus being inside the laboratory.

TABLE VIII.—Experiment 1.—Set 2.

Resistance of bare wire.	Resistance of both.	Resistance of insul.	% of increase, resist. of bare.	Rise in temp. of bare.	% of increase, resist. of ins.	Rise in temp. of ins.	Current in amperes.
4,019	7,980	3,961	0 0	0·0	0·0	0·0	—
4,194	8,337	4,143	4·35	11·5	4·62	12·2	4·62
4,279	8,470	4,190	6·48	17·0	5·72	15·0	8·30
4,295	8,477	4,181	6·56	17·5	5·64	14·6	8·67
4,442	8,695	4,257	10·42	27·4	7·47	19·6	12·17
4,593	8,938	4,340	14·40	37·8	9·57	25·2	16·63
4,754	9,203	4,448	18·31	48·2	12·26	32·3	18 58
5,075	9,668	4,593	26·02	68 4	15·94	41·9	22·00
5,013	9,582	4,569	24·73	65·1	15·09	39·7	22·10
5,282	9,972	4,690	31·42	82·7	18·14	47·1	25·19
5,624	10,545	4,898	40·50	106·6	23·15	60·9	29·29

The observations of the above table were not all taken the same day, so there is some irregularity, owing in part, at least, to changing atmospheric conditions.

In the preceding set of experiments, Nos. 13, 14, 15, and 16 were made with No. 18 paraffined office wire, cotton wrapped.

The next set of experiments had for its object the determination of the relation of the diameter of a wire to the temperature at which a current could maintain it. To accomplish this with accuracy it is essential that the changing atmospheric conditions should not introduce a variable factor into the results. To avoid this one wire was taken as a standard, with which all the others were compared. By arranging the two wires as previously described they could be compared under exactly similar surroundings; and the standard wire in each set of experiments would show any change in atmospheric conditions and permit of corrections being made.

The diameters of the wires were determined by measuring with a micrometer screw gauge reading to ten thousandths of an inch. Each diameter was measured ten times in different parts of the wire, and the average of these ten readings is the one given in the tables. r, r', and the Thompson ammeter were each read fifty times, and values in the tables are in every case the average of fifty observations. By laying off the diameter in mils. as abscissæ and the temperatures as ordinates we get a curve representing the desired relations.

Another set of experiments had for its object the determination of the effect of an insulating covering upon the temperature which a current would maintain. In order to have as few inaccuracies as possible, Professor Anthony obtained, through the courtesy of the manufacturers, wire in lengths of about 100 feet, of which half of each size was covered with their ordinary insulating material, the other half being left bare. The dimensions given are the average of ten readings on the micrometer screw gauge reading to tenths of a mil., and the values of r, r', and the reading of the ammeter are the averages of thirty observations. Deductions from the results are made later, after the theoretical discussion of this problem has been given.

Having given the data of experiments and the results derived therefrom, it now remains to compare these results with those obtained from theoretical considerations or by other experimenters. From the definitions of the C.-G.-S. system of electrical units, one volt-ampere or watt $=10^7$ ergs $=\frac{1}{9\cdot81}$ kilogrammetres. But $c\,e=c^2\,r$; hence the work done by a current, c, in passing through a resistance, r (c in amperes and r in ohms), $=c^2\,r$ watts $=\frac{C^2\,R}{9\cdot81}$ kilogrammetres per second. Since this energy is all converted into heat, we have the heat developed in a conductor $=\frac{C^2\,R}{9\cdot81}$ kilogrammetres $=\frac{C^2\,R}{9\cdot81\times\cdot424}$ calories, since one calorie (lesser) equal ·424 kilogrammetre.

(To be continued.)

SELECTED CORRESPONDENCE.

[The following further correspondence has appeared in *The Times* on the question of "Judges and Patents."—ED. *E.*]

Mr. Imray's eagerness on the one hand to prove that judges are quite justified in the practice of giving a wider interpretation to patent claims than the language of the claims warrants, is only equalled by the anxiety which, on the other hand, he exhibits to prove that no such practice as the judicial warping of patents exists. He is very desirous indeed to defend the judges, against whom, however, I have made no other accusation than that, to adopt Mr. Imray's own expression, they have been "bamboozled" by professional experts. "If I have sinned," says Mr. Imray, "it has been in good company." Precisely so. In company with experts and counsel who have bamboozled judges into declaring that billiard balls are compressed to half their diameter in falling on a table, that electric light carbon is a semi-conductor of electricity, that leaving a clearance between the piston and cylinder end of a gas engine is an important novelty of construction, and such other deliverances. But I take Mr. Imray again at his word. He says, "in dealing with an invention of a fundamental character judges properly give a wider interpretation to patent claims than when they have to deal with a mere improvement in the details of known inventions." That is a perfectly clear statement of a practice which Mr. Imray holds to be just. I hold it to be essentially unjust to the public and to other inventors. If the invention is so very fundamental let the inventor make a broad fundamental claim; no one can object to that. But it is quite another matter if the inventor draws a mere detail claim. If he, having made a fundamental invention, only draws a detail claim, what right has any judge or bench of judges to stretch that claim beyond what the inventor has claimed as his own? I fail to see the justice of giving to any inventor anything more than the words of his claim, whether wide or narrow in their effect, entitle him to.

But letting even that pass, I say emphatically that, whatever the justice or injustice of this proceeding, there cannot be two opinions as to the justice or injustice of the proceeding by which the inventor of a mere improvement in detail is held up by experts and counsel, as the great and original inventor of a fundamental invention of absolute novelty, in order to procure in his favour the judicial benefit of having his patent stretched. That is one form of the practice of bamboozling that is at present tending

Digitized by Google

to bring the administration of patent law into grievous disrepute. Experts and counsel unite in representing Otto as the great inventor of gas engines and gas engine principles, in spite of the facts that the gas engines of Huzon and of Lenoir were at work years before, and that Otto merely introduced certain improvements some of which were of more than questionable novelty. The Court, impressed by the magnitude of the person thus held up as the original inventor, decided every point in favour of Otto, benevolently stretching doubtful points in his favour. Similarly experts and counsel foisted upon Mr. Justice North the notion that there were no telephones before the date of Edison's specification, oblivious of all the telephones of Reis, of Elisha Gray, of Varley, and of Graham Bell. Their object in doing this was of course to take advantage of the "benevolent construction" put by judges upon the claims of fundamental inventors, and their success showed their consummate knowledge of the ways of Courts. Poor Mr. Justice North fell into the trap, and declared that Edison—not Reis, nor Varley, nor Graham Bell, nor Elisha Gray—was the true inventor of the telephone, and he did not hesitate to stretch everything in his favour, even going so far as to declare that a tube was a diaphragm because it could vibrate! This was a point, however, which the Court of Appeal was too wise to confirm, and which with grim humour it declares it will consider when the case arises. In this instance, perhaps the most glaring that has recently occurred, the invention which was thus professionally distorted into the original and fundamental invention of the telephone, was literally a mere improvement in detail. A telephone consists necessarily of at least three parts; a transmitting instrument, a circuit, and a receiving instrument. Edison's sole claim was for improvements in the transmitting part; and it related only to one of the three possible kinds of transmitters, namely, that kind which works upon the principle of variations in the resistance of the circuit. It was therefore only a detail of a detail; and so far as there was any general principle in it, in the application of the principle of variations of resistance, that general principle was in terms disclaimed by its inventor. The one claim is for a "combination"—the mere putting together of two things, the "diaphragm or tympan" and the "tension-regulator," both of which things were old, and for which the inventor does not now make any separate claim! This device of putting together two old and well-known things to make a new "combination" is a favourite one with inventors, especially with American inventors; and I am not going to say that there is no merit in new combination. But in this case not even the combination itself was novel, inasmuch as there had been shown years before by Philip Reis a telephone transmitter having a diaphragm or tympan of bladder in combination with a platinum tension-regulator, which is identical in its mode of action with the platinum tension-regulator described in Edison's specification. Moreover, there had been shown at the Philadelphia Exhibition of 1876 another instrument having in it a liquid tension-regulator identical with one of those described in Edison's specification, combined with a diaphragm. How, in view of these things, even a professional expert can maintain that Edison's "combination" was an invention so great and glorious that language must be warped and common sense violated in order to do justice to its "fundamental character," it is difficult to understand. But Mr. Imray goes even further than the judges. Says, Mr. Imray: "So long as 'in an instrument for transmitting electric impulses by sound' there is the combination of something that vibrates to the voice and by its vibrations acts on something which 'varies the resistance in a closed electric circuit,' that instrument is *obviously* within the scope of Edison's claim." Here is patent stretching with a vengeance. Although Edison had declared his diaphragm or tympan was to be, as his drawings also showed, "like a drum," Mr. Justice North declared that a wooden tube was a diaphragm because it could perform the functions of a diaphragm! The Appeal Court, happily for its own reputation, did not confirm that dictum. But now we have Mr. Imray stretching the plain term diaphragm so as to include anything that vibrates to the voice—say, a dewdrop, a candle flame, or the air itself—for they all come within Mr. Imray's definition, though they are none of them "like a drum." I can only ask which is right, Mr. Edison, the inventor, who says that the diaphragm or tympan must be like a drum, or Mr. Imray, the expert, who says it must be "something that can vibrate to the voice," whether like a drumhead or not? We have Mr. Imray's word for it that diaphrapms and tympans, and "indeed objects of all kinds," can vibrate to the voice. Mr. Imray is not going to say that objects of all kinds are diaphragms because they can vibrate to the voice. Mr. Imray is very desirous of defending Lord Justice Cotton for having—as reported in *The Times*' report of the suit of the United Telephone Company *v.* Bassano—declared that amongst Edison's tension regulators the one ultimately adopted was one consisting of "carbon blocks" and "suspended pencils of carbon." I had pointed out that no such things were described in Edison's specification, but that these words described Hughes's microphone, which was only invented in 1878, the year after Edison's specification. In defence of Lord Justice Cotton Mr. Imray coolly makes a new definition of the term microphone to suit the case, and also quotes from Edison's specification a passage in which neither "carbon blocks" nor "suspended pencils of carbon" are mentioned. Would Mr. Imray, who is so anxious to justify Lord Justice Cotton in this matter, having put Hughes's microphone of 1878 into Edison's specification of 1877, be surprised to learn that Lord Justice Cotton did not do anything of the kind? I stated that this was what had occurred if *The Times*' report be correct; and having since seen the verbatim judgment of Lord Justice Cotton I have ascertained that the impression conveyed by the necessarily brief abstract in the law report of *The Times* is not justified by the words of the learned Lord Justice Cotton. I have reserved to the last Mr. Imray's new definition of the microphone, because it is a fine example of the very practice of which I complain, the stretching of patents on expert testimony. "What is a microphone," asks Mr. Imray, "but 'an instrument in which semi-conducting material' is arranged in a 'telegraphic circuit' in connection with a 'a diaphragm,' so that there is a variable resistance resulting from 'greater or less intimacy of surface-contact' produced by minute vibrations of the diaphragm?" It is a magnificent definition, but, unfortunately, not correct. Does not Mr. Imray remember how, in 1878, Prof. Hughes took the Royal Society and the Society of Telegraph-Engineers by storm when he showed that a microphone consisting of three French nails, or of a gold chain, or of three little bits of good conducting gas carbon, would transmit speech and even the most minute sounds perfectly well without any semi-conducting material or any diaphragm or drumlike thing of any kind! Does he not remember how it astonished everybody that no diaphragm was necessary—that the microphone might be placed directly upon the works of a watch, or upon the speaker's throat, or even on the top of his head? Does he not remember how Mr. Edison instantly cabled across the Atlantic that his invention had been pirated, and was so exceedingly anxious to prove that he, not Hughes, was the inventor of the microphone, that he wrote off in hot haste to the *New York Tribune*, declaring that he, Edison, had discovered some months before that he "could dispense with the vibrating diaphragm?"

Yet now Mr. Imray speciously puts back the vibrating diaphragm into the definition of the microphone—and why? In order to demonstrate triumphantly, as he thinks, that the Hughes microphone was included in the one combination that Edison can claim. Again, I can only ask which is right; Mr. Edison, the inventor, who, in order to gain credit for the discovery of the microphone, declares that a microphone has not a diaphragm, and that he discovered that it did not require one after he took out his patent, or Mr. Imray, the expert, who, in order to drag the microphone into Edison's patent, declares that a microphone must have a diaphragm?

I am extremely indebted to Mr. Imray for such an apt illustration of the expert method of distorting language, though happily, in this case, he will not bamboozle the court of public opinion into a mistaken judgment.

I am, Sir,

Yours faithfully,

(Signed) SILVANUS P. THOMPSON.

NOTES.

CHILI.—The theatre at Valparaiso is now lit by incandescent light.

BERLIN.—The University of Berlin is to be provided with 600 incandescent lamps.

INDIA.—Telephonic communication is about to be adopted for station to station signalling on the Madras Railway.

THE TELEPHONE IN GERMANY.—There are now 68 telephone exchanges in the German Empire, with a total of 12,328 subscribers.

LOCOMOTIVE HEAD LIGHTS.—Several of the leading railroads in the United States are about to adopt electric headlights as part of their equipment.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ended 13th and 20th inst. amounted to £3,309 and £3,326 respectively.

SAFETY LAMPS IN MINES.—The *Colliery Manager*, commenting upon the disastrous explosion at Leigh, expresses an opinion that the adoption of the electric light should at once be made compulsory in all mines.

PREVENTION OF FORGERY.—A letter appears in the *City Press* from Mr. R. Herring, on the subject of forged bank notes. Mr. Herring is the inventor of an electrical method of water-marking, which renders forgery difficult if not impossible.

WAY-LEAVE.—The Brooklyn Bridge Administration makes a good thing out of the annual toll charged for each wire laid along the bridge. Last year it received £1,790 from this source. The total number of wires crossing the bridge is now 292.

CHINESE TELEGRAPHS.—It is stated that the Chinese are extending their telegraph line from Wuchang, on the river Yangtzi, to the city of Yunnan, the capital of the province of the same name. This line will be completed about the end of the present year.

PERSONAL.—Mr. Allen, General Superintendent of Telegraphs of the Argentine Railway, has retired after 20 years service, in which he has brought the department into a state of great efficiency. Mr. Allen leaves the country amid general expressions of regret.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ending 13th and 20th inst., were £2,532 and £1,913, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

A CENTRAL STATION IN PARIS.—It is reported that a central station for the supply of electricity is about to be established in Paris, in the neighbourhood of the Porte St. Martin. Two theatres and a considerable number of private establishments are already on the list of consumers.

SUGAR BY ELECTROLYSIS.—It is stated that at Lyons a process has been introduced by which both glucose and sucrose can be separated by electrolysis. It is also said that the process is sufficiently economical to render it available for the extraction of sugar from potatoes as well as from beetroot.

THE AMERICAN EXHIBITION OF 1887.—We are told that the President of the United States has consented to open the forthcoming American Exhibition *by telegraph*. Our Yankee friends will probably take this opportunity of arranging for something which the general public will regard as "sensational."

FIRE ALARMS.—A system of electric fire alarms has been in operation for some time in Paris, and has given such satisfaction that it is about to receive a very considerable extension. It is also intended to establish a school for the instruction of the firemen in the duties required for the maintenance of the system.

PARIS.—The Municipality of Paris has taken into consideration the means of supplying motive power to small artisans at their own dwellings. Two schemes are before them, one based upon the employment of compressed air, and the other making use of a "vacuum" motor. Electricity does not appear to have been suggested.

LA ROCHE-SUR-FORON.—The central lighting station at this town, which has just been completed by M. Sansoube, has been taken over by a newly formed company, entitled the Société Lyonnaise d'Electricité. This company proposes to undertake electric lighting upon a large scale at Lyons and in the neighbouring towns.

THE LALANDE BATTERY.—We are informed that the Standard Electric Light Company, which owns this battery, during the last twelve months has completed and maintained installations in two or three establishments in the City, as well as in several country houses, in addition to those which we mentioned in a recent issue.

DEODORISING SEWER GAS BY ELECTRICITY.—Mr. Hartley Fewson has recently devised a process for "the withdrawal and destruction of sewer gas by electrolysis." The invention seems to be of a practical character if we may judge by the encomiums passed upon it by several sanitary inspectors, medical officers of health, and others.

THUNDERSTORMS.—Severe thunderstorms continue to be reported from various parts of the Continent. At Presburg the palace of the Archduke Frederic was struck; the discharge actually passed through the room where the family were seated, and did a great deal of damage to the furniture, but fortunately no personal injury was inflicted.

TELEPHONE EXTENSION IN BELGIUM. — The Belgian Government has established a telephone exchange at Ostend with a trunk line to Brussels. The rate of subscription is 170fr. per annum for the first kilometre, and 17fr. 50c. for each half kilometre beyond the first. Public stations are open at a charge of 25c. for ten minutes' conversation.

THE PARIS EXHIBITION OF 1889.—It is asserted that the General Secretary of this Exhibition estimates that the electric lighting of the buildings will absorb 25,000 horse-power. Allowing one-half for arc lights and the remainder for incandescents, this would be equivalent to more than 30,000,000 candle-power! We must decline to vouch for the accuracy of our information.

A LOUD-SPEAKING TELEPHONE.—The firm of Hartmann and Braun are introducing a loud-speaking telephone, which seems to be a successful instrument. The result is attained simply by considering the diaphragm as a part of the magnetic circuit, and by arranging the poles of a double horseshoe magnet in such a way as to cause as many lines of force as possible to pass *through* the disc.

THE EDISON COMPANY OF BERLIN.—This company has just completed the reorganisation of their factory, and they now announce that they are prepared to supply lamps of from 5 to 100 candle-power at any required voltage from 1 to 120, guaranteed to consume energy at any required rate between 2 and 3·5 watts per candle. The capacity of the works is said to be equal to an output of 2,000 lamps per day.

TELEGRAPHS ON WEST AFRICAN COAST.—We are informed that the Silvertown Telegraph Company have received a

Digitized by Google

telegram, announcing the completion of the Accra Porto Novo and the Porto Norvo St. Thomé sections for the West African Telegraph Company. These stations, and that of the Grand Bassam, will be opened on the completion of the Sierra Leone Accra section, which it is expected will shortly take place.

THE BRITISH ASSOCIATION.—Although the presidential address at the forthcoming meeting of the British Association is scarcely likely to deal at any length with electrical science, it has always been our custom in the past to reproduce this address, and it is probable that we shall do so this year. From the programme already announced it seems probable that the Birmingham meeting will in all respects be a highly successful one.

A BELGIAN INSTALLATION.—The residence of M. Montefiore, at Esueun, is lit by 200 incandescent lights. The motive-power is obtained from a Parson's high-speed engine of 18 horse-power. This engine drives a Victoria dynamo, and the latter charges a secondary battery of the Jullien type. M. Montefiore is himself an electrician and possesses a well appointed laboratory, which is warmed as well as lighted by electricity.

DIRECT COMMUNICATION BETWEEN LIVERPOOL AND HAVRE. The Liverpool Chamber of Commerce some time since petitioned the Post Office to give them direct telegraphic communication with several towns upon the Continent. The Post Office has now replied that they find that the amount of traffic would only justify such an arrangement in the case of Havre; and that they hope in this instance to be able to carry the wishes of the Chamber into effect.

A NEW INSULATING MATERIAL.—We recently gave some account of the electric tramway at Hamburg. An interesting feature which we omitted to mention is the fact that a new material has been adopted for the construction of the accumulator cells. This substance, which at present does not appear to have received any distinctive name, is said to have a higher insulation resistance than ebonite, and at the same time to be of lighter weight, more highly flexible, and of greater strength than that material.

NEW ARC LIGHTING SYSTEM.—To the number of American companies owning or working complete systems of arc light illumination must now be added the "Tesla Electric Light Company." It is claimed that the self-regulation of their dynamo is obtained by means of an "entirely novel principle" which does not involve any reaction detrimental to the output of the machine. We cannot attach much importance to a statement of this kind in a mere prospectus, but if it can be substantiated this should prove both interesting and important.

WHERE ARE THE ELECTRIC LIGHT COMPANIES?—Under this heading a correspondent from Spain sends us the following note, which certainly indicates a somewhat archaic state of things in that country:—"Villa Real has been *en fête!* A band has been parading the town! The Governor of the province has been entertained at a luncheon, and the priest has blest the ceremonial. This enthusiasm has been evoked by the inauguration of a gas works (!) Many other towns are tired of the oil lamps of their grandfathers. The only alternative offered them is gas."

THE SOMZÉE INCANDESCENT LAMP.—The Belgian electricians have recently been engaged in a somewhat warm controversy over the question of precedence in the invention of the incandescent lamp as between Somzée and Edison. Without prejudice to this particular dispute we cannot help fearing that there will soon be almost as many claimants for incandescent lamp patents as there are original inventors of the telephone. One of the American journals recently published as "startling intelligence" the fact that no new "original inventor" of the telephone had appeared for nineteen days.

COMING INSTALLATIONS.—We are informed that Mr. H. Bury, electric light engineer, Manchester, has received instructions to light up the following, viz.:—Messrs. Dickens and Co., dye house, &c., Middleton; Messrs. Walker and Carver, paper works, Pendleton; Messrs. J. King and Sons, weaving shed and spinning rooms, Rochdale; Messrs. W. Thompson and Sons, weaving shed and spinning rooms, Burnley. And also from the well-known firm of John Rylands and Sons (Limited) through Mr. Acheson, agent for R. E. Crompton and Co.'s dynamos, to light Swinton Mill, containing about 1,100 lights.

ELECTRICITY AND ROOT GROWING.—An ancient but interesting experiment showing the influence of electricity on the growth of roots has recently been repeated in Germany by Prof. Holdefleiss. Plates of copper were thrust upright into the earth, and connected by wires with similarly placed zinc plates about 100ft. distant—an electric battery being thus formed, with the earth between the copper and zinc in the circuit. It is stated that potatoes and beets planted between such plates gave an increased yield—beets 15 per cent., potatoes 25 per cent.—as compared with other parts of the same field.

THE EXPLORATION OF MINES.—At the scene of the recent accident, in which several quarrymen lost their lives at Chancelade, some of the deeper pits of the quarry, which remained inaccessible after the accident, were explored by means of a photographic apparatus to which an incandescent lamp was attached. The apparatus was lowered into the pit, and photographs were secured at different levels with the view of discovering any lateral openings in which the entombed miners might have taken refuge. The lamp was fed from a primary battery, and some very successful photos were secured.

ELECTRO-METALLURGY.—In a paper upon the application of electricity to metallurgy, contributed by M. Védrinsky to the *Moniteur Scientifique*, it is stated that in the electrolytic reduction of copper ore the presence of tin in the bath exercises a very beneficial influence. The copper deposited upon the cathode in the presence of tin is said to be of a uniform texture and of malleable quality. The resistance of the liquid is also said to be considerably reduced under these circumstances. Antimony produces the same result as tin. The effect of introducing other metals has been studied, but the results were in general either neutral or disadvantageous.

"FURTHER HISTORICAL NOTES ON THE ELECTRIC LIGHT." Under this heading a special number of the *Journal* of the Society of Telegraph-Engineers contains a continuation of the abstracts of patents connected with electric lighting, which have been prepared by Colonel Sir Francis Bolton, hon. secretary to the society. The previous papers of this series appeared in May, 1879, and in November, 1882. The latter brought the record down to within a few weeks of the date of publication. In the present paper the list is brought up to the close of 1885. This is a work which must have entailed a vast amount of labour, and is of incalculable value to all electricians who are in any way concerned in patents or inventions.

AUTOMATICALLY SIGNALLING TRAINS.—Not long since the *Societé d'encouragement pour l'industrie Nationale* offered a prize of 3,000fr. "for an apparatus strongly and simply made which should announce automatically and in a certain and regular manner the passage of a train in motion at any required dis-

Digitized by Google

tance." M. Jourdain, without claiming the prize, has written a note to the society, suggesting that a telephone transmitter at the required spot would answer the purpose. We presume that M. Jourdain intends to employ some particularly loud-speaking receiver. In the event of the prize not having as yet been awarded we would suggest that an electric bell and a suitable mercury contact would seem to fulfil all the required conditions.

An Improved Speed Gauge.—The Compagnie Générale d'Electricité of Antwerp has introduced a modification of the well-known Hedges or Ramsbottom speed-gauge. The principal feature of novelty is that by means of an electric bell an alarm is given when the speed either rises or falls beyond certain limits. The arrangement is as follows:—(1) When the speed falls the depression of the central portion of the liquid decreases, contact is thus made with a metallic stem which projects into the centre of the cup; and (2), when the speed increases, contact is made by the upper surface of the liquid at the side of the cylinder, the upper part of which is insulated from the lower. There is also an ingenious arrangement for driving the containing vessel either from the top or the side of the shaft whose speed is to be measured.

Long Distance Telephony in the Western Counties. From information furnished us by the Western Counties and South Wales Telephone Company, we gather that exchanges have up to the present been established by this Company in the following towns:—Bristol, Plymouth, Torquay, Portsmouth, Bournemouth, Cardiff, Newport, Southampton, and Bath. To this list Worcester, Exeter, and Swansea will shortly be added. The following trunk lines are in working order:—Bath and Bristol, Cardiff and Newport, Bournemouth and Poole, Torquay and Paignton. By the end of October Bristol will also be placed in communication with Newport, Cardiff, and Swansea, and Worcester with Great Malvern. It is also intended, if the new exchange at Exeter proves to be a success, to connect that city with Bristol and with Plymouth.

Covent Garden Lighting.—The electric lighting for the Promenade Concert season at Covent Garden Theatre is being this year carried out by Messrs. Paterson and Cooper, on a more magnificent scale than in former years. The power is supplied by a 30 horse-power nominal Marshall's engine driving on to a counter shaft from which are run the five dynamos supplying the current. Of these, three are arc machines, giving 8 amperes at 700 volts, but only two are used for the lights, the third being kept as spare. The two remaining machines for the incandescent lighting are of 300 and 200-light capacity respectively. Twenty-four Pilsen lamps, as constructed by Messrs. Paterson and Cooper, are employed for the arc lighting. The incandescent lamps are 446 in number, and the interior of the theatre presents a most brilliant appearance.

Industrial Exhibition at Birmingham.—An Industrial Exhibition of an interesting character will be opened to-day at the Bingley Hall, Birmingham, in connection with the approaching meeting of the British Association in that town. The exhibition is intended to show visitors the varied industries of the town and its neighbourhood, and this it will do most effectually. Industrial exhibits are confined to a radius of 15 miles of Birmingham, and specimens of natural history, botany, and geology collected within 20 miles of the borough. At night the entire building will be illuminated by electricity. The exhibitors are 254 in number, and comprise among them nearly all the leading names of Birmingham industry. The mayor, Alderman Martineau, will open the exhibition to-day, and it is understood that he will be accompanied by Sir William Dawson, the president of the British Association.—*The Times.*

Telephonic Extension at Bradford.—There has just been opened a trunk wire connection between Bradford and other West Riding towns which are comprised within the district of the National Telephone Company and the Manchester exchange of the Lancashire and Cheshire Telephone Company. The *Bradford Observer* says:—"At present two wires have been completed, but three others are only wanting a short link to perfect the connection. We (*Bradford Observer*) yesterday evening (23rd inst) had an opportunity of speaking with Manchester from the *Observer* office, and the telephone worked admirably. It will now be possible for every subscriber on the Bradford exchange to talk through the Manchester exchange to Manchester, Liverpool, Blackburn, Bolton, Burnley, Southport, Blackpool, and other Lancashire towns. This extension of the telephone will doubtless lead to the more general adoption of the system."

The Indian Telegraph Department—On Monday last Mr. Conybeare asked the Under Secretary of State for India whether any and what steps had been taken to remedy the admitted grievances of the officers of the Indian Telegraph Department; and whether he would lay upon the table of the House the whole of the correspondence that had been passed on this subject, as well as between the Director-General of Telegraphs and the Indian Government as between the latter and the India Office.—Sir J. Gorst replied that a scheme relating to the Telegraph Department in India was prepared by the late Secretary of State in Council and transmitted to India on July 8th. The Government of India was authorised to give effect to it if, after obtaining the views of the Commission which has been appointed to consider the possibility of effecting reductions in the public expenditure, they should think it right to do so. Until the decision of the Government of India has been received it is impossible to undertake to publish the correspondence.

Electrical Foot Warmers.—The acetate of soda foot warmers now used for railway carriages gradually become cool by radiation; but M. Tommasi, the French electrician, proposes to keep them up to a certain temperature by means of the heat due to an electric current traversing a high resistance. Only the heat lost by radiation is thus compensated for, so that the original high temperature is obtained on the cheaper plan of heating by a fire, or rather by plunging the warmers in boiling water. The current employed to maintain their heat is to be supplied by a dynamo driven off an axle of the train, and the circuit passes through all the warmers. A simple device allows of the foot warmer being thrown out of circuit should it become unbearably hot. The plan will require fewer foot warmers than are now used, since it will be unnecessary to change them during a lengthy journey. This combination of fire and electric heating is perhaps more likely to be successful for the present than a purely electrical arrrangement. Most of the latter which have been devised are of feeble power. *Engineering.*

Bernstein's New Filament.—Mr. Alexander Bernstein has succeeded in producing a carbon filament by a novel and interesting process. He takes a vessel containing a liquid hydro-carbon or some other carbon compound, such as the bi-sulphide. In this liquid he suspends a fine metallic wire while a copper plate is placed at the bottom of the vessel. He then passes a current through the liquid from the wire to the plate. This determines the decomposition of the hydro-carbon and the growth of a hard and dense deposit of carbon upon the

Digitized by Google

end of the wire. By means of a clockwork attachment, the wire is gradually withdrawn at a suitable rate of motion, and in this way a filament of any desired length can be obtained. The cross-section of the deposit is regulated by adjusting the strength of the current and the size of the wire. By employing two wires as electrodes, and an alternating instead of a continuous current, two filaments are produced at one operation. One would imagine that the process might be carried out upon a large scale by employing a sufficiently large current and grouping the filaments in parallel.

ELECTRIC PHOTOGRAPHY.—Dr. Boudet has presented to the *Société Internationale des Electriciens* an account of a series of experiments with which he has recently been occupied, and which has led him to devise an interesting method of reproducing designs of a certain class by electricity. Dr. Boudet builds up a condenser, of which a single sheet of metal forms one coating, a gelatino bromide film, mounted on glass, in the usual way, forms the dielectric, and the object whose image is to be taken occupies the place of the second coating. If this object be not a conductor a sheet of metal is placed behind it. The condenser is then charged from a Voss machine, or other source of high tension electricity. After discharge the plate is developed in the usual way, and the photographic image is found upon its surface. The most suitable objects for this treatment are metallic plaques, either engraved, etched, or stencilled; but by means of placing a second metallic surface at the back Dr. Boudet has obtained very fair pictures of ivory miniatures and similar objects, and he has even reproduced pen and ink drawings with some degree of success.

LEEDS MUSICAL FESTIVAL.—The arrangements for illuminating the Victoria Hall for the purposes of the Musical Festival are still incomplete. The Electric Lighting Committee of the Corporation, it may be remembered, recently experimented with a number of arc lamps, for which electricity was supplied by engines belonging to the borough in the base of the Municipal Buildings. The Festival Committee have seen these lamps tried, and have come to the conclusion that they do not seem to be so likely to serve the purpose as the electroliers of Messrs. Crompton, by means of which the hall was artificially illuminated at the last festival. The Festival Committee, anxious again to secure the adoption of the Crompton system, have offered the Electric Lighting Committee £100 towards the cost of lighting the hall by this method for the festival. Apparently wishful, if possible, to meet the desire of the Festival Committee, the Electric Lighting Committee have asked Messrs. Crompton what they would charge to put the old electroliers into working order, and to light the hall with them for the festival, the power and other apparatus of the Corporation to be used. There the matter now stands.—*Yorkshire Post*

THE SUBMARINE TELEGRAPH SYSTEM.—A correspondent writes to *The Times* from Copenhagen, Aug. 21:—"Mr. John Pender, who is at present on a visit to Denmark, was last night entertained at a large banquet by Mr. Tietgen and the directors of the Great Northern Telegraph Company. Many distinguished citizens were present, including the Minister of Marine and Sir Edmund Monson, the British Minister. In concluding an able and cordial speech, Mr. Tietgen, in alluding to the fact that to England and Denmark was mainly due the credit of carrying out the great submarine telegraph system which now brings the civilised world into daily communication, and to the part borne by Mr. Pender in its initiation and development, paid him the graceful compliment of offering him the telegraphic championship of the world. In replying, Mr. Pender emphasised the great and growing importance of the system, which was now playing such an important part both in political action and commercial development, and stated that those entrusted with the direction of the submarine telegraphs were unanimous in their desire to provide all possible facilities, and thus extend and increase its usefulness and value to the world at large."

ANCIENT ELECTRICAL LITERATURE.—It is not, perhaps, generally known that among the distinguished men who have written upon the subject of electricity we should recognise Marat. In 1779 he published a pamphlet, entitled "Découvertes sur le feu, l'electricité et la lumière," and a little later appeared his "Recherches sur l'electricité," a handsome volume, illustrated with woodcuts. About the same date a work was printed in Berlin with the title "Physica mystica, Physica sacra, sanctissima." At the beginning of the last century the world was enlightened by the publication of a voluminous work in quarto under the title of "Dissertatio de Nocti luca Mercuriale seu de luce quam argentum vivum in tenebris fundit." But one of the strangest contributions ever made to the literature of science was contained in Johan Hartmann's *De Electricitate psittaci plumæ notata quadam* (on the electricity of a parrot's wing). In No. XXIII. of the *Phil. Mag.* is a paper "On a Galvanic Battery composed exclusively of Beans." A vast amount of nonsense has been written about electricity as a curative agent—John Wesley wrote a treatise on the subject—but, on the other hand, in 1840 Sir James Murray published a tract, entitled "Electricity as a Cause of Cholera and other Epidemics." This list (the greater part of which is taken from *L'Ingenieur Electricien*) might of course be extended *ad nauseam*.

AUTOMATIC FIRE EXTINGUISHERS.—At the meeting of the Balloon Society on the 20th inst., a paper was read by Mr. H. Stokes, F.G.S., upon the Percival Automatic Fire Extinguisher. This system depends in part upon an electric arrangement which is brought into operation by the melting of a plug of fusible metal. A somewhat similar arrangement has been introduced to the notice of the International Society of Electricians by Messrs. Thetinet. This consists of a cable for telephones and bells, which at the same time forms an automatic fire alarm. This cable is formed of two copper wires, covered in a special manner with a thin coating of a fusible metal. One is insulated by gutta percha, the second is simply glued to the first. They are then united by twisted cotton, and covered by thick gutta percha, and finally by an outer coating of cotton or silk. This wire may be carried around the building wherever a fire is specially to be feared. The daily use of the circuit will ensure that it and the batteries are always in working order; this presents an advantage over those apparatus which are used for fire alarms only. If a fire occurs, the double envelope of gutta percha and cotton being very combustible, the heat lays bare the two conductors and melts the fusible metal coating. In melting, this metal makes contact between the wires all along the part burnt, which closes the circuit of the battery, and sets the bells ringing.

THE TELEPHONE IN 1664.—The following remarkable paragraph occurs in the works of Robert Hooke, published in 1664. Hooke assisted Robert Boyle in his famous experiments, and was appointed curator and afterwards secretary to the Royal Society:—"And as glasses have highly promoted our seeing, so 'tis not improbable but that there may be found many mechanical inventors to improve our other senses of hearing, smelling, tasting, touching. 'Tis not impossible to hear a whisper a furlong's distance, it having been already done; and perhaps the nature of the thing would not make it more impossible though that furlong should be ten times multiplied. And though some famous authors have affirmed it impos-

Digitized by Google

sible to hear through the thinnest plate of Muscovy glass, yet I know a way by which it is easy enough to hear one speak through a wall a yard thick. It has not yet been thoroughly examined how far Otocousticons may be improved, nor what other ways there may be of quickening our hearing, or conveying sound through other bodies than the air; for that is not the only medium. I can assure the reader that I have, by the help of a distended wire, propagated the sound to a very considerable distance in an instant, or with as seemingly quick a motion as that of light, at least, imcomparably swifter than that, which at the same time was propagated through the air; and this not only in a straight line, or direct, but in one bended in many angles."

THE PUBLIC LABORATORY AT MUNICH. — From the *Centralblatt für Electrotechnik* we learn that the electrical laboratory, which has been established at Munich by the Bavarian Government, will undertake the following duties:—(1). Experiments will be carried out at the request of any private individual, and at such charges as may be separately arranged in each case. The results of this class of experiments will be kept strictly secret. (2). Experiments upon industrial products which are brought to the laboratory to have their electrical properties tested. These tests are made gratuitously; the results, if of general interest, will, as a rule, be published; but if the client should formally express his desire for secrecy the publication may be withheld. (3). Experiments initiated by the staff of the laboratory, the results of which will be published at convenient intervals. The laboratory will be able to undertake experimental work relating to any of the following subjects:—Dynamos and motors, arc lamps and carbons, incandescent lamps, regulators of current and similar apparatus, transformers, galvanometers, voltmeters, ammeters, resistance boxes, primary and secondary batteries, thermopiles, wires, cables, and insulators, and also processes connected with electrolysis. The laboratory will also be prepared to undertake tests upon any established circuits, either for telegraphs, telephones, or electric lighting, or for lightning conductors. It is further proposed to establish a technical museum, and contributions either of money or of exhibits for this purpose will be welcomed.

AT HOME AND ABROAD.—The following letter has recently appeared in the *Birmingham Daily Post*:—"I wish to draw attention to the fact that English travellers, as soon as they leave their own shores, discover how very far behind other countries we are in the matter of the electric light. They see that the chief cities in France, Belgium, Holland, and Italy are so lighted. The traveller to America, on leaving the shores of the Mersey, finds himself, when the sun disappears below the horizon, in presence of electric light whilst enjoying his first dinner on board. If he land at New York by night he sees this illuminant in steamer and railway depôts, in the streets, squares, public buildings, stores (shops), hotels—everywhere. In the New York hotels where I sojourned the dining rooms and passages were so lighted, the machinery for producing the light being in the basement. The same thing may be said of all the chief cities, and of some at least of the smaller ones, in the States. Salt Lake City, which contains only 27,000 inhabitants, has its electric light both in streets and houses. The statement, therefore, that electric light is simply the "light of luxury," and nothing more, must, I submit, be regarded as a fallacy. It may also be safely asserted that the knowledge of the science of lighting by electricity is sufficiently advanced at the present moment, not only for purposes of luxury, but also for the production of a useful and economical luminant. The true reason why on this point we are so far behind other countries probably is the tenderness of our legislators for vested interests."

TINNED IRON.—A writer in *Industries* makes the following observations upon the subject of the regeneration of tinned iron. After describing the precautions necessary in the acid process, he proceeds:—"Persons in the trade say that the metal is injured by absorption of the acid, and affirm that occasionally it is necessary to repeat the annealing in order to remove rottenness engendered in this manner. To the writer it appears more probable that the effect is due to occlusion of hydrogen, for the iron can scarcely be porous enough to absorb the liquid, while the power of occluding gases is a well known property of iron and some other metals. If a piece of sheet iron be immersed for some time in hydrochloric (muriatic) acid, and then be well rinsed in a stream of water for half a minute, and the acid thus removed from the surface, careful observation will reveal an interesting phenomenon. For some time after the washing, minute bubbles may be seen bursting through the film of water left upon the iron, and the sound of effervescence may be heard if the metal be held near the ear. This is probably due, not to any evolution of hydrogen by acid, since this has been removed by washing, but to the escape of hydrogen from the pores of the iron. Producers of wrought iron say that the scrap stripped by acid always makes inferior iron if mixed in any considerable proportion with new metal. Yet this tin plate is rolled originally from good iron, and can be made so again if suitably treated. The reason, doubtless, is to be sought, not in the imperfect removal of tin, as often stated, but in the occlusion of hydrogen gas." If this view be correct it is probable that the hydrogen could most speedily be removed in an electrolytic bath, containing a suitable oxidising agent in which the iron was made the positive electrode.

TRANSMISSION OF POWER IN SWITZERLAND.—At Uster, in Switzerland, a very successful application of the electric transmission of power has been in operation since January last. The generator converts about 12 horse-power into electricity, and about 7·3 horse-power is obtained upon the shaft of the motor, showing an efficiency of transmission of 61 per cent The line is rather more than one kilometre in length. The potential at the terminals of the generator does not exceed 350 volts. The speed of the motor is regulated by the introduction of resistance. The installation is not perhaps to be considered as affording an example of the most recent progress in this class of work, but its performance has given entire satisfaction to the owners. We also hear that a company is about to be formed in Switzerland, with a capital of one million francs, in order to develop the industrial resources of the country by the introduction of electric transmission of power upon a large scale, and also for electric lighting. They have obtained a concession which will empower them to erect works at Montreux, where water power is abundantly available. It is intended to supply electric light to the district Vevey-Montreux, to supply motive power for domestic purposes, and to work an electric tramway 12 kilometres in length between Vevey, Montreux, and Chillon. This concession grants the company exclusive privileges for a period of fifty years. For a lamp of 14 candles it is contemplated to make a charge not exceeding 3·25 centimes per hour. The country to be traversed by the projected tramway has a population of 20,000, but it is also annually visited by thousands of tourists, and as the line runs through a very picturesque country by the banks of the River Vaudoin, and afterwards upon the shores of Lake Leman, there is every prospect of the undertaking proving thoroughly successful.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XXXII.

BY OLIVER HEAVISIDE.

(Continued from page 297.)

The Equations of Propagation Along Wires.—Elementary.

In another place (*Phil. Mag.*, Aug., 1886, and later) the method adopted by me in establishing the equations of V and C, Section XXIX., was to work down from a system exactly fulfilling the conditions involved in Maxwell's scheme, to simpler systems nearly equivalent, but more easily worked. Remembering that Maxwell's is the only complete scheme in existence that will work, there is some advantage in this; also we can see the degree of approximation when a change is made. In the following I adopt the reverse plan of rising from the first rough representation of fact up to the more complete. This plan has, of course, the advantage of greater intelligibility to those who have not studied Maxwell's scheme in its complete form; besides being, from an educational point of view, the more natural plan.

Whenever the solution of a so-called physical problem has been obtained, according to which, under such or such conditions, such or such effects *must* happen, what has really been done has been to solve another problem, which resembles the real one more or less in those features we wish to study, which we regard as essential, whilst it is of such a greatly simplified nature that its solution is, in comparison with that of the real problem, quite elementary. This remark, which is of rather an obvious nature, conveys a lesson that is not always remembered; that the difference between theory and empiricism is only one of degree, even when the word theory is used in its highest sense, and is applied to legitimate deductions from laws which are known to be very true indeed, within wide limits.

It is quite possible to imagine the solution of the general problem of the universe. There does not seem to be anything against it except its possible infinite extent. Stop the extension of the universe somewhere; then, if its laws be fully known, and be either invariable or known to vary in some definite manner, and if its state be known at a given moment, it is difficult to see how it can be indefinite at any later time, even in the minutest particulars in the history of nations or of animalculæ, or in the development of a human soul (which is certainly immortal, for the good and evil worked by a soul in this life live for ever, in the permanent impress they make on the future course of events).

But if this be imagined to be all done, and the universe made a machine, no one would be a bit the wiser as to the reason why of it. (Even if we ask what we mean by the reason why, we shall in all probability get into a vicious circle of reasoning, from which there is no escape.) All that would be done would be the formulation of facts in a complete manner. This naturally brings us to the subject of the equations of propagation, for they are merely the instruments used in attempts to formulate facts in a more or less complete manner.

The first to solve a problem in the propagation of signals was Ohm, whose investigation is a very curious chapter in the history of electricity, as he arrived at results which are, under certain conditions, nearly correct, by entirely erroneous reasoning. Ohm followed the theory of the conduction of heat in wires, as developed by Fourier. Up to a certain point there is a resemblance between the flow of heat and the electric conduction current, but after that a wide dissimilarity.

Let a wire be surrounded by a non-conductor of heat, in imagination; let the heat it contains be indestructible when in the wire, and to be in a state of steady flow along it. If C is the heat current across a given section, and V the temperature there, C will be proportional to the rate of decrease of V along the wire. Or,

$$-\frac{dV}{dx}=RC,$$

if x be length measured along the wire. The ratio R of the fall of temperature per unit length, to the current, is the "resistance" per unit length, and is, more or less, a constant. Or, the current is proportional to the difference of temperature between any two sections, and is the same all the way between.

The law which Ohm discovered and correctly applied to steady conduction currents in wires is similar to this. Make C the electric current in the wire, and V the potential at a certain place. The current, which is the same all the way between any two sections, is proportional to their difference of potential. The ratio of the fall of potential to the current is the electrical resistance, and is constant (at the same temperature). But V is, in Ohm's memoir, an indistinctly defined quantity, called electroscopic force, I believe. Even using the modern equivalent potential, there is not a perfect parallel between the temperature V and the potential V. For a given temperature appears to involve a definite physical state of the conductor at the place considered, whereas potential has no such meaning. The real parallel is between the temperature gradient, or slope, and the potential slope.

Now, returning to the conduction of heat, suppose that the heat current is not uniform, or that the temperature gradient changes as we pass along the wire. If the current entering a given portion of the wire at one end be greater than that leaving it at the other, then, since the heat cannot escape laterally, it must accumulate. Applying this to the unit length of wire, we have the equation of continuity,

$$-\frac{dC}{dx}=\frac{dq}{dt},$$

t being the time, and q the quantity of heat in the unit length. But the temperature is a function of q, say

$$q=SV,$$

where S is the capacity for heat per unit length of wire, here regarded, for simplicity of reasoning, as a constant, independent of the temperature. This makes the equation of continuity become

$$-\frac{dC}{dx}=S\frac{dV}{dt}.$$

Between this and the former equation between C and the variation of V, we may eliminate C and obtain the characteristic equation of the temperature,

$$\frac{d^2V}{dx^2}=RS\frac{dV}{dt},$$

which, when the initial state of temperature along the wire is known, enables us to find how it changes as time goes on, under the influence of given conditions of temperature and supply of heat at its ends.

Ohm applied this theory to electricity in a manner which is substantially equivalent to supposing that electricity (when prevented from leaving the wire) flows like heat, and so must accumulate in a given portion of the wire if the current entering at one end exceeds that leaving at the other. The quantity q is the amount of electricity in the unit length, and is proportional to V, their ratio S being the capacity per unit length. With the same formal relations we arrive, of course, at the same characteristic equation, now of the potential, so that electricity diffuses itself along a wire, by difference of potential, in the same way as heat by difference of temperature.

A generation later, Sir W. Thomson arrived at a system which is formally the same, but having a quite different physical significance. Between the times of Ohm and Thomson great advances had been made in electrical science, both in electrostatics and electromagnetism, and the quantities in the system of the latter are quite distinct. We have

$$\left.\begin{aligned} -\frac{dV}{dx}&=RC, \quad q=SV,\\ -\frac{dC}{dx}&=\frac{dq}{dt}=S\frac{dV}{dt}, \end{aligned}\right\} \quad \frac{d^2V}{dx^2}=RS\frac{dV}{dt} \quad . \quad . \quad (71b)$$

where on the left appear the elementary relations, and on the right the resultant characteristic equation of V.

Here C is the current in the wire, R its resistance per unit length, and V the electrostatic potential. So far there is little change. But S is the electrostatic capacity per unit length of the condenser formed by the dielectric outside the wire, whose two coatings are the surface of the wire and that

Digitized by Google

of some external conductor, as water, for instance, which serves as the return conductor. Thus S, from being in Ohm's theory a hypothetical quantity depending upon the nature of the conducting wire, its size and shape, has become a definitely known quantity depending on the nature of the dielectric, and its size and shape. Here is the first step towards getting out of the wire into the dielectric, to be followed up later. The equation $q = SV$ is the electrostatic law expressing the relation between the charge of a condenser and its potential difference, q being the charge on the wire per unit length, and V its potential. It is assumed that $V = 0$ at the outer conductor, which requires that its resistance must be very small, theoretically nothing. This makes V definitely the potential at the surface of the wire, and it must be the potential all over its section at a given distance x, if the current is uniformly distributed across the section.

The meaning of the equation of continuity is now that when the current entering a given length of wire on one side is greater than that leaving it on the other, the excess is employed in increasing the charge of the condenser formed by the given length of wire, the dielectric and the outer conductor. In the wire, therefore, comparing the electric current to the motion of a fluid, such fluid must be incompressible. It can, however, accumulate on the boundary of the wire, where it makes the surface charge. This is exceedingly difficult to understand. But in any case, whether electricity accumulates in the wire or only on its boundary, is quite immaterial as regards the form of the equation of continuity, and of the characteristic equation. (Of course it is the equations which give rise to it, and their interpretation, that are of the greatest importance.)

There is very little hypothesis in this system. We unite the condenser law with Ohm's law of the conduction current, on the hypothesis, which is supported by experiments with condensers and conductors, that the equation of continuity is of the kind supposed. But is assumed that the electric force is entirely due to difference of potential. As, when the current is changing in strength this is not true, there being then also the electric force of inertia, or of electromagnetic induction, this should also be taken into account in the Ohm's law equation, making a corresponding change in the characteristic equation. What difference this will make in the manner of the propagation will depend upon the relative magnitude of the electric force of inertia and of the charge, and materially upon the length of the line. The necessary change will be made in the next section. At present we may only remark that electrostatic induction is most important on long submarine cables, and that the (71) equations are those to be used for them for general purposes, as the first approximate representation of the facts of the case.

In 1854 the practicability of Atlantic cables was being discussed. The time was coming, and the man was ready. If the man had not been forthcoming, although there can be little doubt, from the irresistible nature of modern progress, that we should now have long cables worked practically as they are, yet it is nearly equally certain that the preliminary waste of money, literally sunk to the bottom of the sea, or to the bottom of the pockets of speculative inventors, would have been enormously greater than it was.

Now, as regards the accumulation difficulty. This is entirely removed in a beautifully simple manner in Maxwell's theory. The line-integral of the magnetic force round a wire measures the current in it, a fact that cannot be too often repeated, until it is impressed upon people that the electric current is a function of the magnetic field, which is in fact what we generally make observations upon, the electricity in motion through the wire being a pure hypothesis. Maxwell made this the universal definition of electric current any where. There is no difference between a current in a conductor or in a dielecteic as a function of the magnetic field, though there is great difference in the effect produced, according to the nature of the matter. All currents are closed, either in conductors alone, or in dielectrics alone, or partly in one and partly in the other. In a conductor heat is the universal result of electric current, and energy is wasted; in a dielectric, on the other hand, the energy which would be wasted were it conducting is stored temporarily, becoming the electric energy, which is recoverable. In a conductor, the time integral of the current is not a quantity of any physical significance; but in a dielectric it is a very important quantity, the electric displacement, which can only be removed by an equal reverse current. The electric displacement involves a back electric force, which will cause the displacement to subside when it is permitted by the removal of the cause that produced it. Put a condenser in circuit with a conductor and battery. The current goes right through the condenser. But it cannot continue, on account of the back force of the displacement; when this equals the impressed force of the battery, there is equilibrium. Remove the battery and leave the circuit closed. The back force of the displacement can now act, and discharges the condenser. As for the positive and negative charges, they are numerically equal to the total displacement through the condenser. They are located at the places of, and measure the amount of discontinuity of the elastic displacement, and that is all.

If we must have a fluid to assist (keep it well in the background), then this fluid must be everywhere, and be incompressible, and accumulate nowhere. I am no believer in this fluid. Its only utility is to hang facts together. But when one has obtained an accurate idea of the facts it has to hang together, it has served its purpose. A fluid has mass, and when in motion, momentum and kinetic energy. But the facts of electro-magnetism decidedly negative the idea that the electric current *per se* has momentum or energy, or any thing of that kind; these really belong to the magnetic field. It is therefore well to dispense with the fluid behind the scenes.

But when one thinks of the old fluids (of surprising vitality), and of their absurd and wholly incomprehensible behaviour, their miraculous powers of attracting and repelling one another, of combining together and of separating, and all the rest of that nonsense, one is struck with the extremely rational behaviour of the Maxwell fluid. When, further, one thinks of the greatly superior simplicity of the manner in which it hangs the facts together (it is remarkably good in advanced electrostatics, impressed forces in dielectric, &c.), one wonders why it does not take the place of the commonly used two-fluid hypothesis, merely *as* a working hypothesis, and nothing more.

Returning to the wire. It is important to remember that there are two conductors, not one only, with a dielectric between. When we put an impressed force in the wire we send current across the dielectric as well as round the conducting circuit. The dielectric current ceases as soon as the back force of the elastic displacement supplies that difference of potential which is appropriate to the distribution of impressed force (which difference of potential depends entirely on the conductivity conditions). The equation of continuity means that when the current entering a unit length of wire on one side is greater than that leaving it on the other, the excess goes across the dielectric to the outer conductor, in which there is a precisely equal variation in the current. The time integral of this dielectric current $\dot{q}$ is q, which is the total displacement outward per unit length of wire. The quantity V is the back E.M.F. of the displacement. On removing the impressed force, there is left the electric energy of the displacement, which is $\frac{1}{2}Vq$ per unit length of wire; the back forces act, discharge the dielectric, and this energy is used up as heat in the conductors.

We can now make some easy extensions of the system (71*b*). R must be the sum of the resistances of the wire and return, per unit length, thus removing the restriction that the return has no resistance. S, of course, remains the same. But V cannot be the potential of the wire, because V cannot = 0 all along the return. We may, however, call V the difference of potential (although that is not exactly true, on account of inertia, unless we agree to include a part of the E.M.F. of inertia in V). It is, however, definitely the E.M.F. of the condenser, given by $q = SV$. We need not restrict ourselves, in these first approximations, to round wires, or to symmetrically-arranged returns. The return may be a parallel wire. Of course the proper change must then be made in the value of S.

(To be continued.)

M. LEVY'S REPORT ON THE PARIS-CREIL EXPERIMENTS.

The report which has been furnished by M. Maurice Levy upon the latest series of experiments by Marcel Deprez, and which is endorsed by thirty-eight members of the *Académie des Sciences*, we fear will have but little tendency to enhance the scientific reputation of any one concerned therein. Not a few of the statements, both of fact and of opinion, which are to be found in this document will certainly excite considerable astonishment—upon this side of the Channel, at any rate.

We apprehend that a report of this nature, issued in the name of a responsible and an important body, should at least be characterised by a conscientious endeavour to ascertain actual facts, and by scientific accuracy in the statement of the facts ascertained; and further, if under the existing circumstances it is to have any definite or lasting importance, it should certainly have contained an impartial estimate of the results of the experiments, regarded not merely as a demonstration of known principles, but as an indication of the direction in which further progress is to be attained. In all these points the report now before us falls lamentably short.

Before criticising the document in detail, it will be convenient to state what were the results which M. Deprez set himself to accomplish, and how far he succeeded in carrying out his programme. Briefly stated, it was proposed to take 200 horse-power at Creil, to transmit the energy over a line 56 kilometres in length to La Chapelle, and *to effect the distribution of power* from this point with a total loss not exceeding 50 per cent. It is evident that the interest of this programme (of course we are now speaking solely of scientific or industrial interest) centres in two points. First, in the manipulation of the current over so long a line under the very high potential which must be employed; and, secondly, in the *distribution* of the energy from the receiving station under the conditions laid down. The mere *experimental* transmission of a considerable quantity of energy over a considerable distance, noteworthy and marvellous though the experiment may be in itself, is not from the point of view of the modern electrical engineer—and especially after the verification of theory which M. Deprez has himself already amply supplied—a result of any special interest or value, save as a demonstration of established principles. It is perfectly well understood that any given power can be transmitted over any given distance with any given loss *en route*, if it is permissible to employ a sufficiently high electromotive force. And if we are allowed to build a machine containing an unlimited quantity of iron and copper the necessary difference of potential can always be attained. Since, then, M. Deprez avowedly did not aim at economy in the construction of his "modified Gramme" machine—which, in fact, cost some £2,000—we are justified in asserting that the interest of the programme is practically confined to the two points already mentioned.

The question next arises how far was this programme actually carried out? In the first place, owing to difficulties connected with the construction and insulation of the generator, the total brake-power to be transmitted was incontinently reduced one-half, so that 100 horse-power was the maximum actually dealt with. The precise efficiency of transmission obtained between the pulley of the generator and that of the receiver remains a matter of some uncertainty. It was probably, however, within 10 or 12 per cent. of the figure aimed at. But the grand problem of a *distribution* of power from a distant source with a total efficiency of 50 per cent. was not in reality so much as attempted. The so-called distribution was effected by means of a second Gramme machine which was driven as a dynamo *from the pulley* of the receiver, and the low tension current so generated was employed to operate a lathe, a hammer, a pump, and so on by means of an additional number of small motors. Now, this method may or may not have been the most appropriate means for the distribution of the energy of the high tension current, but inasmuch as the 45 or 50 per cent. efficiency which is claimed was measured *upon the pulley of the first receiver*, we are justified in stating that the original programme was not carried out, even upon the reduced scale.

Turning now to the question of the management of high potentials, it is a sincere pleasure to be able to congratulate M. Deprez on having successfully demonstrated that a potential of more than 6,000 volts may be maintained under practical conditions upon a very long and exposed cable, and may be manipulated by the men employed without any special difficulty and apparently without any special risk. It is true that M. Deprez's record is not perfectly clear in this matter. An unfortunate mishap occurred at the very time when the installation was being inspected by some of the members of the Academy—an accident which involved the destruction of two unoffending telegraph instruments at St. Denis, as well as that of the armature of the generator. But notwithstanding this mishap, now that the installation has been at work for a period of over six months without further difficulty of this character arising, M. Deprez is undoubtedly entitled to the honour of being recognised as the first to achieve the practical employment of high tension electricity upon so large a scale.

We take it that this is by far the most important result—if not, indeed, the *only* important result—of these experiments. It is therefore the more surprising that this matter should have been passed over entirely without mention in M. Levy's report. He certainly makes reference to the employment of a high electromotive force, but although his vocabulary proves to be amply supplied with expressions of admiration and astonishment, he has nothing to say in praise of this particular achievement. As a matter of fact, we are enabled to add from an authentic source the information that for purposes of experiment M. Marcel Deprez has more than once employed a tension of over 10,000 volts at the terminals of the generator, and although the receiver showed some signs of distress no other difficulty was experienced.

We may yet have some further criticisms to offer with regard to M. Deprez's method of procedure, but we return now to M. Levy's report, from which we take the following tabular statements:—

TABLE I.

—	(1)		(2)		(3)		(4)		(5)	
	Creil.	Paris.	Creil.	Paris.	Creil.	Paris	Creil.	Paris.	Creil.	Paris.
Current	6·879	6·827	7·554	7·457	8·229	8·103	9 129	8·936	9·879	9·824

	Resistances.	ohms.
Generator	Armature	29·00
	Field-magnets	5·75
Receiver	Armature	38·15
	Field-magnets	3·82
Line	.....	97·45

Table I. gives the principal measurements which were taken, and it should be noted that the whole of these figures were obtained between the hours of 10:20 a.m. and 11:10 a.m. on one single morning. The readings cannot, therefore, have been submitted to much verification. This will to some extent account for the striking discrepancy of nearly 50 per cent. which M. Levy has himself noticed in his calculation as to the loss of power upon the line. From the figures given in the table it is easy to calculate the work apparently lost in the machines, and, deducting this from the total loss of horse-power, we ought to obtain the work expended in the line. Taking Experiment No. 5 as an example, we find in this way the figure 7·3 as the horse-power expended in the line. But

Digitized by Google

we may also obtain an approximate estimate of this loss from the known resistance of the line and the *average* current measured at either end. We thus obtain the figure 12·7 as representing the horse-power wasted in the line. M. Levy is, however, careful to explain that his measurements only aim at "industrial," and not at "scientific" accuracy. However unsatisfactory such a discrepancy may be in itself, we are not disposed to attach any serious importance to the matter save as an illustration of the value which is to be attached to the figures supplied. M. Levy disposes of the difficulty by remarking that as the higher figure for the loss in the line is undoubtedly correct, the work expended in the machines themselves as determined by dynamometer and brake is too high by 5·4 horse-power, and it "will be fair to share this difference between the two machines." He proceeds accordingly to increase the calculated efficiency of each machine in this proportion.

But perhaps the most remarkable part of the report is that in which M. Levy deals with the question of the line and its insulation. He is of opinion that it is "*infiniment désirable et important*" to carry out a similar experiment *with an earth return*, and he expresses an earnest desire to witness the attempt. For our own part, we shall have much greater confidence in the "desirability" of this idea after M. Levy has successfully tried the experiment for himself than we have at present. In fact, it is somewhat doubtful whether there would be any "earth return" for the experimenter himself. A friend of ours even suggests that if the results of the observation are not to be entirely lost to science, it will probably be necessary for some one to repeat the expedition of the great mediæval poet of Italy. To say the least, the absence of a return wire must tend vastly to increase the chances of a catastrophe. With a return wire we are told that a distance of 0·75m. to 1m. appears sufficient to avoid "absolutely" all inductive effects upon adjacent telephone circuits. If this is an experimental result—which is not very clear—the observation is one of some value. M. Levy has also arrived at the conclusion that it is wiser to allow the overhead wire (if placed upon sufficiently high posts) to remain entirely uncovered. This is a point upon which opinions will probably be found to differ. We entirely fail, however, to see any advantage whatever in the arrangement adopted in the first instance by M. Deprez. He employed a lead-cased wire, apparently made after the pattern of the well-known Berthoud-Borel cables. An overhead lead-cased line seems to be open to several serious objections, not only would it considerably add to the cost of construction, but the loss by Foucault currents would probably be distinctly perceptible over so great a distance, the current not being absolutely continuous. In addition to this, the static charge might prove decidedly inconvenient. On this point, M. Levy's ideas are not a little singular. He says that "in wet weather, or when the insulation of the line is not perfect," the cotton and resin placed between the copper and the lead will play the part of the glass in a Leyden jar, and dangerous results may ensue. In what way the dielectric action is supposed to be increased, or to become more dangerous because of the defective insulation, we are at a loss to imagine. It is, however, for this reason that M. Levy prefers the use of a bare wire. At this point we are informed that the weight of the lead increases the sag of the wire, unless the latter "be submitted to an electric tension capable of breaking it."

Similar observations of equal value and importance are lavishly scattered over this document, but our space will only permit us to refer to one more point in detail, and here our criticisms will be directed to the work of M. Deprez more than to that of his reporter. The latter, however, declares the arrangement in question to be both "*neuf et heureux.*"

We have already referred to the somewhat complicated arrangements at the receiving station, where the armature shaft of the receiver is mechanically coupled to that of another machine from which the *distribution* of power is effected. In reality, however, there are two separate and distinct dynamos driven from the shaft of the receiver. The current from the second of these machines is employed to excite the field-magnets of the receiver itself. This arrangement is adopted because of the powerful extra current which would be generated in the field-magnet coils if they were in the line circuit, and the latter were suddenly interrupted at any point. It will, however, scarcely be considered that this arrangement affords a satisfactory or, indeed, a practical solution of the difficulty. In order to start the machines under these conditions it is necessary to employ a switch which first puts the armature and a portion of the field-magnet coils together in series with the line. The armature having commenced to move, the magnet coils are successively cut out of the main circuit, and introduced in parallel into the circuit of the exciter. This, at least, is the description of the arrangement which we find in the report; but we are inclined to think that if the machines are started with the full difference of potential there must be some additional resistance to be inserted when the current is first switched on. If so, however, this could hardly have escaped M. Levy's attention, as it would appear that the resistance coils would have to be of decidedly large dimensions. In any case it seems to us that the method must incur a very considerable risk of placing the full potential upon the armature of the machine when no counter electromotive force was being generated. In such a case, to quote from another portion of the report, "it may be that the recipient which has hitherto lasted without repairs will in turn come to require them."

A THERMO-MAGNETIC PHENOMENON.

It is well known that at a high temperature iron loses its magnetic properties. It is therefore evident that if we take an iron ring and balance it upon an axis passing through its centre, then if we can keep one half comparatively cool while the other half is maintained at a red heat, the presence of a magnetic pole at the junction of the hot and cold sections should cause a rotation of the ring.

The idea is not new, and as a laboratory experiment it has already been carried out upon a small scale. In a recent number of the *Journal de Physique*, M. Schwedoff contributes a paper on the theory of this action, pointing out that it is quite evident that the motive power is derived indirectly from the source of heat, and proceeding to inquire into the successive steps of this transformation. In order to reduce the experiment to its most simple conditions, he considers first the case of a ball of iron suspended by a thread or wire in the neighbourhood, say, of the flame of a Bunsen burner. A magnet is placed in such a position that its attraction draws the ball into the centre of the flame. As it grows hot the ball gradually loses its magnetism, and moves slowly away from the magnet and out of the flame. Here it begins to cool, and presently it slowly returns towards the magnetic pole, and this action may be repeated indefinitely. M. Schwedoff then proposes the use of the term *elastic force* in somewhat the same sense as the old phrase *coercitive force*, only he distinguishes two actions tending to limit the value of the coefficient of magnetisation; one the inherent resistance of the material to any change in the relative position of its molecules, the other to the increase of polar repulsion between the molecules when the magnetic action tends to give them the same orientation. It is to the former resistant effect that he alone applies the term "magnetic elasticity." Returning to the suspended ball, he supposes that in the neighbourhood of a red heat the "coefficient of the magnetic elasticity" increases directly with the temperature. Work is done upon the ball in the first instance in order to direct its molecules into magnetic orientation, and this work is done solely at the expense of magnetic potential. The action of the flame then tends to restore the molecules to their initial condition; this requires the expenditure of energy, which appears in the shape of an increase of the potential of the magnet upon the ball. In order to furnish anything like a complete theory it would, of course, be necessary to take account of the electro-magnetic reactions due to Foucault currents in the ball.

But the above simple explanation is sufficient to enable one to trace the order in which the transformation of energy takes place.

AN ELECTRICAL THEORY OF THE UNIVERSE.

If Germany is the home of speculation there is a gentleman at Dunkirk, N.Y., who was evidently born in the wrong place. Dr. HENRY RAYMOND ROGERS bears a name which is at least half Anglo-Saxon, and his language betrays that he is wholly American; yet he has lately been delivering himself in a speculative way befitting only a German professor at the most German of German Universities. His lecture, which has been forwarded to us in pamphlet form by the author, and for which we greatly thank him, was originally read before a Society of History and Natural Science. This society is mysteriously designated "The Chautauqua." Whether the title has any influence on the science which prevails there, or whether it is merely descriptive, we know not; all we say is that the "New Philosophy of the Sun," as expounded by Dr. ROGERS, is very much Chautauqua. By which we do not mean anything disparaging of the author, much less of his philosophy; far from it. All we intend to convey is that, like Chautauqua, it is hard to swallow straight off; and wants more explanation before we even understand it.

We advise our readers to obtain Dr. ROGERS' pamphlet for themselves; it is certainly entertaining, and is worked out with a boldness, vigour, and originality which more than compensate for its literary and logical shortcomings. The author does not stick at trifles, and his manner of overcoming objections to the new philosophy—on the few occasions when he condescends to see them—is of the hop-skip-and-a-jump order. But this is always the way with innovators; and we cannot expect even a new philosophy to be ushered into the world with a perfectly philosophical spirit. For this reason we propose not to criticise it, but simply to give a brief outline of its main features. Whether Dr. ROGERS be right or wrong he will not be wanting in critics; and if he should prove some day to have been in the right, we would like to be among those who received him with an open mind. Journalistic instincts for the moment get the better of our scientific prepossessions.

On the concluding page of his pamphlet Dr. ROGERS quotes a prediction of FARADAY'S that a "glorious discovery in natural knowledge," explaining the purpose and uses of the earth's magnetism, was looming in the near future. Dr. ROGERS claims to have made this discovery. Nay, more, he has discovered that the Sun, the Earth, and all the planets are magnetic, and that the phenomena of their orbital and axial movements are accounted for by their magnetic relations towards each other; moreover, that sunlight and sunheat are not what they seem to us to be, but are magnetic, or, what is really the same thing, electric emanations from the sun converted into light and heat by the earth's atmosphere. Sun spots are explained away as magnetic disturbances which temporarily interfere with the current lines between sun and earth, but have no substantial existence as spots on the surface of the great luminary. Similarly the Corona, the Zodiacal light, and other puzzling solar peculiarities, are attributed to atmospheric and local causes. Lastly, gravity is in reality electrical attraction, and, according to our author, Sir ISAAC NEWTON himself had some inkling of this fact; whilst in recent times FARADAY was quite certain about it.

There is some ambiguity as to the part played by the Moon in this philosophy; but the author leaves it so, and so will we. About the Sun he is very explicit. It is not bright, and it is not hot. At great elevations it is pale and cold like the Moon; and is therefore only a light and heat giver by reason of the atmosphere, whose resistance converts the solar electrical influences into a sort of terrestrial electric light. The magnetism of the heavenly bodies, it is needless to say, becomes electricity with the motion of those bodies in relation to one another; their magnetism makes them attract and repel each other within circumscribed orbits, and the movements so maintained give rise to their electrical currents. The Sun is inhabitable; and the earth is as bright to the inhabitants of the Sun, as Venus, Mars, and Jupiter appear to be to us. What we take to be heat rays are really electrical rays, as is proved by the identity of effect on passing the sun's rays and electrical rays through a block of ice. From the assumption that a "vacuum is the most perfect condition for electrical transmission," the analogy is drawn that the region beyond the earth's atmosphere offers no obstacle to the instantaneous passage of electricity between sun and earth.

Having set the balls a rolling our author follows them throughout their wondrous courses. Starting from FARADAY'S axiom that the rotation of all bodies opposite to magnets induces circulating electric currents, the inference is drawn that the stellar worlds whirling in space evolve between them electrical currents in great cosmical circuits; and that the sun and earth, revolving on their axes and in their orbits, constitute a vast terra-solar electrical machine, to the action of which is due the currents which incessantly come from the sun to the earth. In this way the sun and all the stars have, so to speak, been put in harness for the performance of the work of

Digitized by Google

the universe. Thick bars of hardened steel have been cut through by a disc of thin sheet iron revolving with great velocity, but never touching the steel. The atoms of metal held by the electrical force of mere cohesion become loosed by the action of a stronger electrical force due to the revolving disc. Sparks flew and drops of liquid steel fell freely, but they *were not hot*. Our readers will draw the proper inference without further help from us. It is some satisfaction to know that when this round Globe shall be dissolved—possibly through human meddling with the electrical balance—the resulting sparks and things will *not* be hot.

We have only space to add a quotation or two by way of further elucidating this new solar theory. Of the identity of gravity and electricity we are told that "the sun and earth being magnets excited into activity by their motions become constituents in an electrical circuit, and thoroughly vitalised with the power we call gravitation. Thus the relation between electricity and gravity is simply that of *cause* and *effect*." In a section devoted to sunheat and sunlight, the author remarks: "If our sun and the many millions of star-suns were incandescent, and disseminated heat and light in all directions, all space would be heated and lighted. There would be neither cold nor night on this earth of ours." A better philosophy is needed; and here it is, summed up in a sentence: "The sun's current, like the current from an electric dynamo, is invisible, gives no manifestation, passes through space like electricity through wires; without being itself hot it develops heat; without being itself luminous it develops light, and endues with attractive powers that which it pervades."

BELLING THE CAT.

It will be seen from an account in another column that a meeting of a somewhat unusual character has been held at the Cannon-street Hotel. This assembly, which was attended by an influential gathering of reporters, was convened by a firm who have interested themselves in the question of incandescent lamp patents, and have even entered an action against one of the larger makers for "intimidating their customers and interfering with their trade." The real purpose for which the meeting appears to have been summoned was that they might be invited to form a committee charged with the duty of assisting the promoters in the conduct of this action. The names of the gentlemen who were found to be willing to accept this task will be found in our report, but, as may readily be supposed, the names of those who are most interested in the question of lamp patents are conspicuous by their absence.

The proceedings were commenced by a very charming little address, delivered in the popular lecture style by Mr. Arthur Shippey himself, in which, after having expounded his views upon the future of electricity ("yet in its infancy" and so on), the audience was treated to a *réchauffé* of the history of incandescent lamps. It is only fair, however, to add that a certain number of the facts adduced really do appear to have been hitherto unknown, and they may even yet prove to have considerable practical importance in the history of this subject.

The outcome of Mr. Shippey's researches will be seen to have led him to the conviction that there are only four absolutely original and valuable patents covering a complete incandescent lamp. Of these Lane-Fox, Edison, and Bernstein will, we are sure, feel infinitely obliged to Mr. Shippey for putting their work upon a level with his own. If the whole thing were not so transparently ludicrous, we should deem it our duty to enter a most emphatic protest against this latest development of the great modern art of advertising.

CORRESPONDENCE.

ABSOLUTE NEGATIVE CHARGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The writer of the letter entitled "Absolute Negative Charge" in your journal dated the 6th inst. invites a discussion on that theory. Hardly expecting that he will be overburdened with letters in support of the theory, I take the opportunity of asking him if he will kindly explain the relation between the word "static," used in connection with electricity, and the theory he expounds in his letter, at least, in the last paragraph?

In that paragraph he refers to the "electrostatic circuit" (would not "electro-inductive" convey the meaning better?) "which is absolutely analogous to the conductive circuit." I translate the sentence as analogous, not only in forming a complete circuit, but also in transmitting electricity.

This refers me to the second paragraph of the letter.

The cracks and squeaks which proceed from a rope when under strain seem to imply that there is considerable yielding going on among its molecules while under this strain. Does not much the same kind of action take place in an inductive circuit? Is not electricity being transmitted, in however small quantities, along the inductive circuit? If not, how is it that a dielectric, or an insulated conductor, can never keep its charge? Where does the charge go to, and how does it go there? It certainly combines with its opposite charge by passing along the lines of inductive resistance, which separates it from the opposite charge (the canal explained in the letter referred to). If this is true, why call it static or stationary electricity? Is it not advisable in science to use words which carry the ideas as much as possible exactly to what is meant without its being necessary to explain that a certain word does not mean what it generally means? Why continue to use old and obsolete terms when the theories which they referred to are dead and buried, and making subjects that are already sufficiently difficult doubly difficult to understand?

Why this application of old patches to new garments.—Yours, &c.,

LIONEL E. CAINE.

Villa Real, Algarve, August 13th, 1886.

THE LALANDE BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your correspondent, "Battery," in his letter of last week on the subject of the Lalande battery, appears to have some misconception as regards "available energy." Referring to six Lalande cells charging accumulators he says:—"Taking the E.M.F. of six cells in series as four volts, we have $4 - 2{\cdot}5 = 1{\cdot}5$; then multiplying this by the ampere current we only obtain as available energy something like 9,000 watts." He surely must see that this 9,000 watts (which should be watt-hours by the bye) is *loss*, and not available energy. He further states that this 9,000 watt-hours is, "of course, the measurement in the charging circuit," and that in the discharging a lamp circuit it must be 5 per cent. less. He, however, finishes up by bringing his final calculation to 12 per cent. more, namely, 11,400 watt-hours. The last part of his calculation I admit as being correct, and in accordance with my figures as published in your issue of 13th inst, the only difference being that I allow for accumulators from the fact that there is usually *over* 6,000 ampere-hours for 120lbs. of zinc consumed. This is the case when the primary battery is worked in conjunction with accumulators The 4·2lbs. of zinc per horse-power refers to when the primary battery is worked alone, as is the case in many instances at the present time, both for light and power. The reason for using the combination (and consequent extra consumption of zinc per horse-power) is the advantage gained in space occupied and labour of re-charging. If it is not encroaching too much on your space, I should like, whilst on the subject, to make a few remarks with regard to estimating the cost of obtaining electric light from batteries. I notice that in almost all the calculations on the subject the bare cost of materials required and their equi-

Digitized by Google

valent in watt-hours is taken into consideration. This no doubt would be all very well if the public would undertake the re-charging of their own batteries; but such is by no means the case. Having had considerable experience in the practical working of batteries on a large scale for lighting purposes, I have no hesitation in asserting that for any system of primary batteries to be largely adopted the user must have little or nothing to do with the re-charging of the cells. This must be entirely undertaken by those supplying the batteries. Now, the cost in labour, carts, horses, &c, to keep such installations going is considerable. The more complicated the battery the greater the cost. One of the first points to be aimed at is simplicity in construction and manipulation of the cells. Then, again, a great deal depends upon how the various installations are distributed, how many one cart and horse can deal with in a day, the nature of the liquid or liquids to be removed. These and a great many other important matters over and above the actual cost of materials have to be taken into account when calculating the cost of maintenance, &c. It practically comes to this. With a given battery how many watts-hours can a cart and horse and two men distribute amongst installations of a given size per diem, and at what cost? Apologising for the length of this letter,—Yours, &c.,

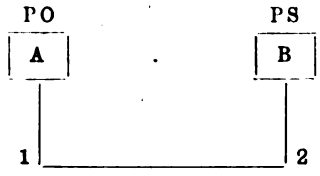
STANLEY CURRIE.

75, Jermyn-street, St. James's, August 26.

UNDERGROUND INSULATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I make a drawing sufficient for all practicable purposes to illustrate what I am about to state.



The distance between the President's office, Penna-road (PO) and passenger station (PS) is 9,500ft., and underground cable insulated with oil extends from the cellar of each building. We mark these cellars as 1 and 2. There are telegraph and telephone wires working in this cable, but from cellar of 1 and 2 to the switch-boards A and B lead-covered cables are used with a solid substance for insulation.

If we put a telephone at the junction of the liquid with the hard insulation in the cellar at 1 upon one of the conductors open at B—the switch-board, which is 65ft. above the cellar—we hear the Morse click or signals; but if we open the same conductor at 2 cellar we hear nothing, the telephone being connected to earth in the cellar. Similarly, if we put the telephone on a conductor at 2, connected to earth, and open the circuit at 1, we hear nothing; but if we open at A we hear the same Morse signals; in other words, if the wires are insulated with hard matter for 60ft. we get inductive disturbance, but if confined entirely to oil 9,500ft. we hear nothing, there is no inductive disturbance.

If at the switch-boards we put on telephones, each connected to the conductor and the earth with telephones of equal resistance, we get double the disturbance with circuit open at the farther end that we do if the circuit is closed in the usual manner of working, as all the disturbance passes through the telephone to the earth if the farther end is open; but if both ends are connected to earth then it is divided, or very materially lessened; but if the farther end of the circuit is connected directly to earth and the telephone taken out of the circuit, then the disturbing effects are less than when the telephone at the farther end is in the circuit. They (the disturbances) go to the earth through the channel of least resistance.

Now, measuring these underground wires for electrostatic capacity with all the other spare conductors connected to earth, they show about four-tenths of a microfarad per mile, while those in the lead-covered cable show less than two-tenths per mile.

I have given these facts, which corroborate the others that have heretofore been published indicating that inductive disturbance in telephones is more a question of acoustics than of electrostatic capacity of the insulator.—Yours, &c.,

Philadelphia, Aug. 13, 1886. H. C. FREMPT.

EARTH CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of August 6th, a diagram is given showing the great earth current storm on the cable between Shanghai and Nagasaki on March 30th last, the storm commencing at 4:20 p.m. and disappearing at 11 p.m., Shanghai time. In *The Electrician* of April 2nd, p. 404, is an account of the same storm as observed in London, Bombay, Madras, and Singapore. On the evening of March 30th I noticed from my house at Kingstown, co. Dublin, a splendid auroral display. Between 9:30 and 10 p.m. the maximum brilliancy occurred. The same aurora was seen in Prussia; but the only British notice of this unusually fine aurora that I can find is in a paragraph in *Nature* for April 8, where Mr. G. H. Kinahan gives an account of an aurora seen by him in Donegal on March 30th, between 8 and 9 p.m. The appearance of the aurora as seen by both Mr. Kinahan and myself was different from the type usually observed in this country, consisting of bright streamers, and columns of light rolling rapidly from the northerly horizon up to near the zenith.

My object in writing is to draw attention to this remarkable and widespread earth current storm, and to point out that, as might be expected, it was coincident with the occurrence of a brilliant auroral display. I should be glad if you would allow me also to ask your readers for any other information they may be able to give in connection with this great electric disturbance.—Yours, &c., W. F. BARRETT.

Royal College of Science, Dublin, August 21.

LITERATURE.

Ueber die Darstellung der Farbstoffe so wie über deren gleichzeitige Bildung und Fixation auf den Fasern mit Hilfe der Electrolyse.*

This pamphlet, of 140 pages, is a reprint of articles which originally appeared in an Austrian paper, "Oesterreich's Wollen und Leinen-Industrie." As such it appeals chiefly to a class of readers who are interested in textile fabrics, and who have some knowledge of dyeing processes, and is intended to give them a popular account of investigations in which the author has been engaged for the last eleven or twelve years. The first three chapters are introductory, and contain a short sketch of the history of electricity and electro-chemistry, and a general description and explanation of electrolytic action, together with an acknowledgment of the author's indebtedness to Prof. Schoenbein, who was formerly his teacher and afterwards his colleague, and whose important investigations into the constitution and properties of ozone led the author to take up the line of research, the results of which are described in the present work.

In chapter IV. the author describes his process of preparing aniline black by the electrolytic decomposition of the sulphate or chloride of aniline by means of the current from a dynamo or a strong battery. The electrodes, consisting of platinum or carbon plates, were placed in separate vessels communicating by means of a bundle of cotton or linen threads, or a strip of filter-paper, enclosed in a tube of parchment to check evaporation; or a capillary siphon tube, dipping into both the vessels.

When the current is allowed to pass, a precipitate begins to form in the vessel containing the positive electrode, and the solution in this vessel soon begins to show a green colouration, passing gradually through violet to a dark indigo blue, and which ultimately becomes nearly black.

This reaction is so delicate, and so characteristic, that it may be advantageously employed to detect traces of aniline salts in solution.

By increasing the strength of the solution other colours can

* On dyes, and their simultaneous production, and fixing in fabrics by means of electrolysis. By FRIEDRICH GOPPELSROEDER.

Digitized by Google

be obtained, *e.g.*, yellow, orange red, and red. The bundles of threads used to connect the two vessels were also found to become coloured, and among the colours observed were violet, red, salmon, green, grey, and brown.

The negative electrode also became covered with a black or yellowish brown precipitate, and the solution containing it sometimes remained colourless—as also occurred in some cases with the positive electrode—and sometimes showed a brown, yellow, or red colouration.

The colours are due to the formation of a mixture of various colouring matters, but the author succeeded in separating the principal product at the positive pole, aniline black, in the form of a perfectly black powder, which can be transformed into various other colour compounds by methods which he describes. Chapter V. contains an account of some of the more important chemical reactions of aniline black, and of methods of preparing dyeing solutions of various colours from it. Chapter VI. is devoted to the consideration of colouring matters obtained by the electrolysis of various aromatic substances, such as compounds of toluidine, of methyl—and ethyl-aniline, of diphenylamine, &c. Chapter VII. treats of the separation, by capillary action, of different colouring matters mixed in the same solution. The most simple and convenient method is to dip the ends of slips of white filter-paper into the dye, when, if the solution contains a mixture of several colouring matters, a series of well-marked horizontal bands of colour will be produced on the paper. The author points out that the adulteration of wine with colouring matters may be detected in this way, and he has also employed the method with success to determine the sources of contamination of water, and of the soil, in the immediate neighbourhood of several chemical factories. In Chapter VIII. the author gives an account of results obtained by the electrolysis of anthraquinone, and describes a method of converting crude indigo into indigo-white by means of electrolysis. The crude indigo is kept in suspension by continual stirring in a hot solution of alkali, such as caustic potash, during the process, and the solution of indigo white obtained in this manner can be used without further preparation in the dyeing vat. After immersion in the vat the fabrics are exposed to the air, as in the ordinary process, in order to reconnect the indigo white into blue indigo by the absorption of oxygen. The author finds that the transformation of indigo blue into indigo white by means of electrolysis takes place even in a cool solution, but very imperfectly. The best results are obtained by raising the temperature of the solution until the evolution of hydrogen practically ceases, as all the hydrogen set free is then employed in effecting the transformation instead of being wasted. The current must not be allowed to flow for too long a time, as in that case, even in a cool solution, the indigo white undergoes further changes, which weaken the solution.

In Chapter IX. a description is given of the author's method of effecting, by means of electrolysis, the transformation of crude indigo into indigo white, and simultaneously fixing it in the fabric to be dyed. A series of experiments are described in which the fabric was placed between the two electrodes and in contact with each of them, and it was found that the sides of the fabric in contact with the positive and negative electrodes respectively, became differently coloured, even when the two electrodes were of the same metal, and a number of different shades of blue were obtained by varying the metal of which the electrodes were formed, and by using, in some of the experiments, different metals for the positive and negative electrode. Methods are also described of simultaneously producing and fixing upon various animal and vegetable fabrics, other dyes, such as persulphocyanogen or canarine, and dyes belonging to the aromatic series, including aniline black. Some experiments are described, in which the aniline black was produced in the form of patterns or written characters. A metal plate, forming the negative electrode, was supported on a sheet of caoutchouc and covered by a piece of stuff thoroughly soaked either in a solution of an aniline salt or dilute sulphuric acid, and on this was placed the fabric destined to receive the pattern, having been previously saturated with the aniline solution. The pattern was produced by means of a gold, or platinum tipped metallic pencil which formed the positive electrode. The author has made some attempts to produce these patterns mechanically by means of an engraved plate or roller forming one of the electrodes, and having its uncut portion covered with non-conducting varnish, the other electrode consisting of a plain plate or roller, and the fabric, previously saturated with a thickened aniline solution, being placed between them, but he has not yet succeeded in obtaining satisfactory results.

The author then goes on to describe methods of bleaching by electrolysis, fabrics already dyed, and describes the results obtained in a series of experiments upon fabrics which had been dyed with indigo and with Turkey red respectively. The rest of this chapter is devoted to the consideration of the electrolytic transformation of cellulose into oxycellulose, and of electrolytic methods of producing new shades of colour in fabrics which have been previously dyed. In the two following chapters the author describes an electrolytic method of fixing *mordants* consisting of metallic oxides, on fabrics which are to be dyed, and gives a preliminary account of some researches, which are not yet completed, on the direct fixing of metallic particles in fabrics by means of the electrolysis of their salts.

Chapter XII., which concludes the work, contains some notes on the electrolytic transformation of bases of the aniline series into bases of the leucol, or quinoline series, and on the electrolysis of some natural dyes; some general remarks on the chemical action of frictional electricity, with references to memoirs on the subject, and a short historical sketch of chemical telegraphs.

The work is well worthy the attention of all who are interested in dyeing processes, and it is to be hoped that the publication of these interesting and suggestive researches in an easily accessible form may induce practical workers in this country to devote their attention to the further investigation of the electrolysis of colouring matters, and to the application of results, hitherto tested only in the laboratory, to the further improvement and development of the dyeing industries.

WIND POWER FOR ELECTRIC LIGHTING.

We are not aware that any attempt has hitherto been made in this country to utilise the windmill as a source of power for charging accumulators. It seems not unlikely, however, that under favourable conditions, and with properly devised machinery and apparatus the attempt might be made with success. The subject has recently attracted some attention in America, and a discussion has taken place in the columns of the *Electrical Review* of New York. It is stated that prolonged experience has shown that in that country the average velocity and duration of the wind currents may be relied on to give results equivalent to eight hours' work *per diem* at a velocity of sixteen miles per hour. The following table shows the power produced, which, of course, varies with the size of the wheel employed :—

TABLE SHOWING CAPACITY OF WINDMILLS.

Designation of mill.	Velocity of wind in miles per hour.	Revolutions of wheel.	Gallons of water raised per min. to an elevation of 100ft.	Equivalent actual useful h.-p. developed.	Average No. of hours per day during which this result will be obtained.
8½ft. wheel	16	70 to 75	1·58	0·04	8
10 ,,	16	60 to 65	4·750	0·12	8
12 ,,	16	55 to 60	8·485	0·21	8
14 ,,	16	50 to 55	11·246	0·28	8
16 ,,	16	45 to 50	16·150	0·41	8
18 ,,	16	40 to 45	24·421	0·61	8

Windmills can now be constructed which will revolve at a given speed within certain wide limits of wind-pressure, and with a constancy amply sufficient for the purpose of charging accumulators. This result is attained in part by an arrange-

Digitized by Google

ment which automatically varies the sail surface as the pressure of the wind changes. The type of mill referred to in the above table can be made to run at the same speed when the velocity of the wind has fallen as low as six miles per hour—a figure which represents a very gentle breeze. If the sail area remains constant the power given out varies inversely as the cube of the velocity of the wind. The cost per horse-power per hour for the larger sizes is given as 2½ cents. It will, however, be observed from the figures that the system is only applicable upon a comparatively small scale.

ELECTRICAL THEORIES.

BY PROF. J. J. THOMSON, M.A., F.R.S.

(*Concluded from page 264.*)

The following values of u, v, w satisfy this condition :—

$$u = \frac{1}{\mu}\left\{\frac{d^2}{dy\,dt}(FG) - \frac{d^2}{dz\,dt}(HF)\right\},$$

$$v = \frac{1}{\mu}\left\{\frac{d^2}{dz\,dt}(GH) - \frac{d^2}{dx\,dt}(FG)\right\},$$

$$w = \frac{1}{\mu}\left\{\frac{d^2}{dx\,dt}(HF) - \frac{d^2}{dy\,dt}(GH)\right\},$$

where μ is the magnetic permeability and F, G, H are the components of the vector potential, or if ψ be the electrostatic potential

$$u = \frac{d}{dy}\left\{\frac{d\psi}{dz}H\right\} - \frac{d}{dz}\left\{\frac{d\psi}{dy}G\right\},$$

$$v = \frac{d}{dz}\left\{\frac{d\psi}{dx}F\right\} - \frac{d}{dx}\left\{\frac{d\psi}{dz}H\right\},$$

$$w = \frac{d}{dx}\left\{\frac{d\psi}{dy}G\right\} - \frac{d}{dy}\left\{\frac{d\psi}{dx}F\right\},$$

If the values of u, v, w which satisfy these conditions be denoted by the (u_1, v_1, w_1), (u_2, v_2, w_2) . . . then the flow across any element of surface might have for its x component

$$\frac{1}{4\mu}(R'\beta - Q'\gamma) + \lambda_1 u_1 + \lambda_2 u_2 + \lambda_3 u_3 + \ldots$$

where λ_1, λ_2, λ_3 are arbitrary constants, thus we see that the components of the flow of energy, instead of being uniquely determined by this process are really left quite indeterminate by it. Though this is so, it is very instructive to follow Prof. Poynting's description of the way in which the energy flows in some special cases; we shall select a very simple one, the case of a current flowing along a straight wire. Here the lines of electromotive force are straight lines parallel to the wire, the lines of magnetic force are circles with their centres on the wire, and their planes at right angles to it. Then, since according to the view expressed in the paper, the energy moves at right angles both to the electric and magnetic forces, it must in this case move radially inwards to the wire where it is converted into heat. The energy, instead of being supposed to be transmitted through the wire, is regarded as transmitted by the dielectric; and though we may not regard the exact law of flow of the energy as established, still it is very important that this view should be brought into prominence. Another important point brought prominently forward in this paper is the view that magnetic force is always the sign of transference of energy, according to Prof. Poynting; indeed, there must be transference of energy from one part of the field to another to give rise to magnetic force. Thus, according to his view, no magnetic force would be exerted by the discharge of a leaky condenser, because in this case he considers the energy to be confined to the space between the plates of the condenser and to be converted into heat where it stands. If the plates were connected by a metallic wire, the energy could flow out and be converted into heat in the wire and this motion of energy would give rise to magnetic forces, so that magnetic forces would be produced by the discharge of a condenser in this way, but not by leakage. In this case the theory differs from Maxwell's, as according to that theory the alteration in the electromotive force would produce magnetic forces in either case.

In Prof. Poynting's second paper, which we have already mentioned, the fundamental principles of electrodynamics are described as the results of the motion of the tubes of electromotive and magnetic force. Maxwell develops electrodynamics from the principles :—

1st. That the total electromotive force round any closed curve is equal to the rate of decrease of the total magnetic induction through the curve.

2nd. The line integral of the magnetic force round any closed curve is equal to 4π times the current through the curve.

Prof. Poynting restates these principles in the following way :—

"1. Whenever electromotive force is produced by change in the magnetic field, or by motion of matter through the field, the E.M.F. per unit length is equal to the number of tubes of magnetic induction cutting or cut by the unit length per second, the E.M.F. tending to produce induction in the direction in which a righthanded screw would move if turned round from the direction of motion relatively to the tubes towards the direction of the magnetic induction."

The second principle he states in the following way :—

"Whenever magnetomotive force is produced by change in the electric field, or by motion of matter through the field, the magnetomotive force per unit length is equal to 4π times the number of tubes of electric induction cutting or cut by unit length per second, the magnetomotive force tending to produce induction in the direction in which a righthanded screw would move if turned round from the direction of the electic induction towards the direction of motion of the unit length relatively to the tubes of induction."

By magnetomotive force is meant the line integral of the magnetomotive force round a tube of induction. This statement includes the more special one that the line integral of the magnetic force round any closed curve is equal to 4π times the number of tubes passing in or out through the curve per second.

The development of these principles leads to equations which are practically the same as those obtained by Maxwell, the chief difference being that the quantity corresponding to Maxwell's J is no longer arbitrary or rather redundant.

Prof. Poynting also introduces into his equations the time integrals of the components of the magnetic force as fundamental quantities, and regards the components of the magnetic as the differential coefficients of these quantities with regard to the time. This method of representing magnetic force was also used by Prof. Fitzgerald in his paper on "The Electromagnetic Theory of the Reflection and Refraction of Light."* It has the advantage of calling attention to the dynamic character of magnetic phenomena. In Prof. Poynting's paper some of the applications of his method of regarding electrical phenomena are worked out with great detail for some of the simpler cases.

APPENDIX II.—*On the Stress in the Dielectric.*

In the preceding report we have had so frequently to refer to the action of the dielectric that it may be convenient to give a very brief account of the work which has been done on the stresses which are supposed to exist in it. We shall confine ourselves to the work which has been done on the stresses in the electrostatic field; those existing in the electromagnetic field are of a similar nature, so that any remark applying to one will also apply to the other. The idea of explaining the forces in the electrostatic field by means of stresses in the dielectric seems to be due to Faraday, who describes† the stress in the medium by saying that the lines of force tend to contract and also to repel one another. The magnitude and distribution of this stress was investigated by Maxwell;‡ he found that in a medium whose specific inductive capacity was K, and at a point where the electromotive force is R, a tension equal to $K R^2/8\pi$ per unit area along the lines of force combined with a presssure of the same amount at right angles to these, would produce the effects observed in the electrostatic field—that is,

* *Phil. Trans.*, 1880, Part. II.

† "Experimental Researches," Section 1297.

‡ "Electricity and Magnetism," second edition, p. 149.

Digitized by Google

at a point in the dielectric, the resultant of these stresses would be a force whose components, parallel to the axes of x, y, z, are eX, eY, eZ respectively, e being the charge of electricity at the point, and X, Y, Z the components of the electromotive force. It may be observed that this system of stress could not be produced by the strain in an elastic solid at rest. This points to the kinetic origin of electrostatic phenomena.

These stresses are in equilibrium at a point in a dielectric where there is no free electricity. At the junction of two media, whose specific inductive capacities are K_1 and K_2, and in which the electromotive forces are R_1 and R_2, and whose interface is perpendicular to the lines of forces, the stresses are not in equilibrium, but there is an unbalanced stress $(K_1 R_1^2 - K_2 R_2^2)/8\pi$ which will tend to make the boundary move towards the medium whose specific inductive capacity is K_1; if these dielectrics are liquids, their interface may become curved so that the forces due to surface tension balance this stress.

Quincke,* who has experimentally investigated the effects of electrification on various dielectrics, such, for example, as the effects on the glass of a Leyden jar, has found that the effects on different bodies are very different; he finds, for example, that though the effect of the electrification on the dielectric of the Leyden jar is generally to produce an expansion, yet in some substances, such as the fatty oils, contraction takes place.† This diversity in the effects of electrification on different dielectrics shows that the distribution of stress cannot be so simple as was supposed by Maxwell. It also shows that there must be forces in the electric field which are not recognised either by Maxwell's theory or the theory of action at a distance. More general theories have been given in order to meet this difficulty.

Von Helmholtz‡ has supposed that a change in the density of a dielectric might alter its specific inductive capacity, and he has investigated the consequences of this supposition. Korteweg and Lorberg§ have investigated the more general case, when the specific inductive capacity of a strained dielectric is supposed to be a function of the strains. Korteweg supposes that if the body suffers dilatation e along the lines of force, and dilatations f and g at right angles to them, then the specific inductive capacity $= K - \alpha e - \beta (f+g)$. Helmholtz assumed that $\alpha = \beta$. The presence of strain in a dielectric must influence the specific inductive capacity, for Quincke has shown that the various coefficients of elasticity are altered under the influence of electricity. Lorberg, l.c., has found the distribution of stress in the medium when the specific inductive capacity alters in this way. He finds that there is a tension along the line of force equal to

$$\left(\frac{K}{8\pi} + \frac{\alpha}{2}\right) R^2$$

and a pressure at right angles to them equal to

$$\left(\frac{K}{8\pi} - \frac{\beta}{2}\right) R^2$$

The force in the medium parallel to the axis of x

$$= -\rho \frac{d\phi}{dx} + A$$

where

$$A = -\frac{R^2}{4\pi}\frac{dK}{dx} + \frac{d}{dx}(\beta R^2) + \frac{d}{dx}(\alpha - \beta)\frac{d\phi^2}{dx} + \frac{d}{dy}(\alpha - \beta)\frac{d\phi}{dx}\frac{d\phi}{dy} + \frac{d}{dz}(\alpha - \beta)\frac{d\phi}{dx}\frac{d\phi}{dz}$$

Where ϕ is the potential, and ρ the volume density of the free electricity. The part A of this force exists even when there is no free electricity at the place under consideration; if the dielectric were a fluid, these terms would indicate forces tending to move the fluid when placed in a variable electric field; this motion, however, seems not to have been observed. The supposition made by Korteweg and Lorberg is not the most general one that could be made; we might assume that the specific inductive capacity of the strained body became different in different directions, so that the body would behave like a crystal. Dr. Kerr's experiments on the double refraction in liquids placed between the poles of a powerful electrical machines seem to point to this conclusion.

Kirchhoff* has made similar assumptions to those of Korteweg and Lorberg on the effect of strain on the specific inductive capacity, and has arrived at similar equations; in the second paper he applies these equations to some cases which Quincke investigated experimentally.

ON ELECTROLYSIS.†

BY PROF. OLIVER J. LODGE, D.SC.

(Continued from page 308.)

The tests of electrolytic conduction are these four:—1. Visible decomposition. 2. Polarisation. 3. Non-agreement with Volta's series law. 4. Transparency.

We may thus pretty safely distinguish electrolytes from metals, but to certainly distinguish electrolytes from dielectrics is not always easy. True, a dielectric does not conduct, but it may break down. How to distinguish an electrolyte from a *weak* dielectric, as, for instance, rare air, is not easy. An initial E.M.F. is needed to commence disruptive discharge, but that may be easily confused with electrolytic polarisation of electrodes; indeed, some facts suggest that there is a considerable surface or boundary resistance which opposes the passage of electricity from metal into rare air, and may altogether stop it when very small terminals are used.

Second Meaning of I.—Now pass to the second aspect of the question. What is an electrolyte, viz. (*b*)? Is a particular substance the electrolyte when mixed with other matter? If a voltameter had a glass partition with a hole in it, no supporter of the view that glass was an electrolyte would contend that the glass conducted some of the current. Similarly with a water partition, or with any water existing in *a mass* in any part of the vessel. Non-conductivity or bad conductivity has thus everything to say to this question, What is *the* electrolyte? But then, in a solution of acid or salt water, it is not merely mixed with the substance, it is combined with it; and it is very possible that water in this state may conduct readily enough. Information on this head, sure and definite as it seems to me, is given by the simple fact that pure H_2O and pure liquid HCl both almost insulate when separate, but conduct well enough when mixed.

There are then four hypotheses concerning the apportionment of the current among the substances in a salt solution:—1. That the salt alone conducts; 2. That the water alone conducts; 3. That the salt and the water share the conduction between them; 4. That neither salt nor water exist, but that a hydrate is formed, and that this conducts and is decomposed as a whole.

To decide whether, when substances are mixed, both conduct the current, Hittorf mixed KCl and KI in various proportions, and concluded that the current always travelled through both sorts. Buff has made many similar experiments, and agrees. Gore has deposited brass from a cyanide solution of copper and zinc. True the combined resistance is not the semi-harmonic mean of the separate resistances; bnt there is no earthly reason why it should be. It is a mere superstition to expect such a result. Even if the substances were really mixed and not combined it would not be so; unless there were a boundary surface between the media made wholly of stream lines, *i.e.*, a surface across which no electricity flowed.‡

Another mode of discriminating between the hypothesis is to use intense currents,§ for with intense currents you are more likely to get off the real ions. Secondary actions are hurried, and cannot go on properly. With intense currents the ions are very apt to come off in a very self-combined and energetic state—as ozone instead of oxygen, &c., and an extra polarisation force accounts for this extra energy; but they do not so easily combine with other matter in the solution.

Now Magnus showed that from a solution of $CuSO_4$ weak currents deposited copper only, while strong currents liberated hydrogen as well. In fact, the observation is now a commonplace; but it is much easier to turn copper out of combination than hydrogen. So if copper were the real primary ion there is no call for hydrogen to appear. It looks, therefore, as if hydrogen were at least a primary ion, and possibly the only one. But, then, as pointed out by Smee, local exhaustion of the liquid near the cathode may cause such a deficiency of copper in the liquid touching the plate, that, if the current is too intense for diffusion to keep up the supply, hydrogen must perforce be liberated from the simple acid coating of the cathode. Hence in repeating any experiment of this kind it will be necessary to stir or scour the plate constantly and vigorously; and even then there would be some uncertainty about the matter, supposing hydrogen

* *Wied. Ann.*, XXIV., p. 52, 1885; *Ibid.*, XXV., p. 601, 1885.

† From the Report of the British Association.

‡ This fact, that no crossflow between "multiple arc" conductors must occur, if their combined conductivity is to be the sum of their separate conductivities, is sometimes overlooked. The covering on ordinary wires supplies the necessary condition; but if the wires touch the law breaks down. To the parts of one conductor the "divided circuit law" is by no means necessarily applicable.

§ Meaning always by "intensity" of current, *strength of current, per unit area*, or what is sometimes inconveniently styled "density" of current.

Digitized by Google

persistently appeared. Is there any more direct and simple mode of answering the question as to whether the salt or the water, or both conduct the current? Yes, what seems to me a very simple and satisfactory one; by determining at which pole free acid appears, and, if it appears at both, by determining how much appears at either.

For the sake of clearness, it may be well to point this out in detail, though, indeed, it is so simple as hardly to be necessary. Consider a solution of copper sulphate in water, decompose it with platinum electrodes, and first make the assumption that the *salt* conducts the whole current, or that the real ions are Cu and SO_4. At the cathode Cu appears and is deposited—nothing else happens. At the anode SO_4 appears, decomposes water, forming sulphuric acid, and setting free oxygen. Thus, on this hypothesis, all the free acid appears at the *anode*. Next make the the assumption that *water* conducts the whole current, so that hydrogen and oxygen are the true ions. At the anode oxygen appears and is liberated—nothing else happens. At the cathode, hydrogen appears, decomposes $CuSO_4$, forming sulphuric acid, and setting free copper. So on this assumption, all free acid appears at the cathode. Finally, let the water conduct $\frac{1}{x}$th, and the salt $\frac{x-1}{x}$th of the current, then the ratio of the free acid formed at anode to that formed at cathode will be $x-1$.

Now, I have made many preliminary experiments, avoiding porous partitions of course, as introducing electric endosmose, capillary forces, and all kinds of unknown disturbances, using only two vessels connected with a syphon U tube, and other such arrangements. I find in all cases acid at *both* poles, though with *platinum electrodes* usually most at anodes. I do not press these preliminary results; a great deal of easy quantitative work suggests itself in this connection, and it is necessary to specify and to vary the concentration of solution and the strength of current used. The *method* is the important thing, and I should like to have it either approved or condemned. If one uses copper electrodes, the results are somewhat different. On the hypothesis that the salt alone conducts, no free acid should be formed anywhere; the solution should become impoverished at cathode and concentrated at anode—phenomena which are well known to occur to a greater or less extent. If, on the other hand, the water alone conduct, free acid should appear at cathode, but not at anode; the solution near cathode should again become impoverished of copper, though not of SO_4, while upon the anode is liable to form a coat of oxide which there is no sufficient supply of free acid near to dissolve off. And all these phenomena are also found to occur. The deposit of oxide on a copper anode is with intense currents most marked, so much so as almost to stop them. It is most instructive to put some dead-beat instrument like Ayrton and Perry's ammeter into circuit with a copper voltameter too small for the current, and watch the needle descend from the stops quickly almost to O*. Free acid *does* make its appearance at the cathode, and, with intense currents, plenty of it. Roughly one may judge perhaps that the salt conducts about three fourths of the current and the water one fourth, but I have no certain data yet for any such statement; and the proportion may well vary, for all I know, with the current intensity. One may, however, definitely accept hypothesis 3 or 4 as certainly truer than 1 or 2. The fact that acid is produced at anode, and alkali at cathode, in the decomposition of, say, sodic sulphate, proves that the salt conducts at least some of the current, and an estimation of the amount of acid and alkali respectively generated would decide what proportion was so conducted.

Again, experiments with electrolytes in series, as made by Hisinger, by Berzelius and by Davy, are interesting in their bearing on this point.† Thus, take three vessels containing say HCl, HNO_3, and AgNO, or Na_2SO_4, HCl, and $BaCl_2$, respectively; and the formation of a precipitate is a good identification of a true ion. The *locality* of such precipitate is still more instructive, since it conveys information as to the relative rates at at which the opposite ions travel, and so leads us on to the next question, concerning what is called the "migration of ions."

II. The Migration of Ions.

Do the Opposite Ions in Solutions Travel at Different Rates? And in any case, at what Rate do they Travel?—Here, as is well known, we must draw a distinction between fused and dissolved compounds. Fused or homogenous electrolysis, in which no solution occurs, must always remain of uniform composition. Consequently, considering any bounded region exactly equivalent quantities of either ion must pass out of it, on the whole. It is not evident that the two constituents must pass out in opposite directions, but in so far as they pass out in the same direction there is no true electrolytic decomposition. There is only a kind of electric endosmose, affecting the level of the fluid as a whole. Given that the level remains uniform, and that ions are only liberated at electrodes, then it is plain that the opposite corresponding ions must pass through any imaginary plane in the fluid at the same rate in opposite directions, for, if not, the constitution of the fluid would not remain uniform. This argument fails to apply to dissolved salts, and it breaks down before long, even with fused salts if they dissolve one of the liberated elements, or any other body, because in a solution no necessity for uniformity of composition exists. One portion may be concentrated while another is quite weak, and it is well known that such weakening and concentrating actions do occur in electrolysed solutions, *e.g.*, to specify a hackneyed but sufficiently instructive case, in the electrolysis of dilute sulphate of copper. With copper electrodes the solution near cathode becomes weaker, while that near anode becomes stronger than before. If the anode is arranged above the cathode visible blue streaks descend; if the arrangement is inverted the top liquor gets almost clear. If platinum electrodes be used both sides get weaker; but the cathode side weakens two or three times as fast as the anode side. It is customary to explain these well known and perfectly certain experimental facts by the obvious and plausible hypothesis that the two ions do not travel both at the same rate through the liquid, but that the SO_4 travels quicker than the Cu. Such an explanation accounts for the phenomenon, but it does not follow that it is certainly the true explanation; and for the sake of examining it more particularly I may be allowed to suggest doubts concerning it. If these doubts have no sound physical basis their statement will only result in their removal, and can do no harm.

First, let us quickly see how the hypothesis of unequal velocity accounts for the unequal concentration of solution which is called migration. Let SO_4 travel, say, three times as fast as Cu, and consider an imaginary partition about the middle of the cell. Three atoms of SO_4 travel unit distance through it towards the anode, for every atom of Cu travelling unit distance in the other direction; but the number of the atoms of Cu and of SO_4 liberated against the electrodes in the same time is four of each; hence the anode region of the cell loses only one SO_4, while the cathode region loses three Cu. The reasoning may be made to look more general. Consider a compound, AC, arranged in two vessels with a joining tube. Let A be anion and C be cation, and let A travel n times as fast as C, so that through the tube we have n equivalents of A passing for every equivalent of C. By the time one equivalent of each ion has been liberated against the electrode the ions transmitted by the tube will be x and nx equivalents respectively; hence the anode vessel will have lost altogether $1-x$ equivalents of each ion, and the cathode vessel will have lost $1-x$ equivalents. But x and nx together convey the whole current, so $x+nx=1$.

Thus, then, we have as the respective losses of the liberated elements by the two vessels—

$$\text{Loss in anode vessel} = 1-\frac{n}{1+n}=\frac{1}{1+n};$$

$$\text{Loss in cathode vessel} = 1-\frac{1}{1+n}=\frac{n}{1+n}.$$

Hittorf's well-known expressions.

Or consider it this way: By the time one equivalent of copper has been deposited, and one of SO_4 has attacked either, the anode itself, if of copper, or the water in its neighbourhood, if of platinum, forming $CuSO_4$ in the one case, H_2SO_4 in the other—no matter which. By the time all this has happened, $3x$ atoms of SO_4 have passed from neighbourhood of cathode towards anode, and x of copper have gone the other way. The cathode liquid has thus lost $1-x$ of copper, and so must have lost $1-x$ of SO_4 too, no more and no less, or else it would contain isolated radicles. The anode liquid has gained these $1-x$ atoms of SO_4, and they may be also reckoned as $3x$, as we just now saw, wherefore $x=\frac{1}{4}$. The cell happens not to lose any SO_4 by deposition, but, instead, it either loses an equivalent of O or gains an equivalent of Cu according to the nature of the anode. So the final result in any case is a transfer of $\frac{3}{4}$ equivalent of SO_4 from cathode vessel to anode vessel, combined with a transfer of $\frac{1}{4}$ equivalent of Cu in the opposite direction; a net loss of $\frac{2}{4}$ equivalent of copper sulphate by the cathode solution, and, in the anode liquid, either a net gain of $\frac{3}{4}$ equivalent of $CuSO_4$, if the anode be copper; or a gain of a whole equivalent of H_2SO_4 combined with a loss of $\frac{1}{4}$ equivalent of $CuSO_4$, and of a whole equivalent of oxygen, if the anode be platinum. All this is in fair agreement with experiment. The only obviously weak place is that relating to the production of free acid. According to the above it ought to appear, if at all, only at anode. Now, in practice, if the experiment be tried, it will be found to appear at cathode too. Still, the local concentration changes are satisfactorily and very simply explained by this customary migration hypothesis.

But before we decide that the sufficieney of this explanation proves its necessity or actual truth, let us try whether we cannot get the same results on another and not only plausible, but really quite necessary, hypothesis, viz., the hypothesis that the solvent conducts some of the current as well as the salt dissolved; and let us see whether this alone will not account for the whole "migration" phenomenon, even though opposite corresponding ions be supposed to travel at equal rates. By drawing a scheme, say, for the electrolysis of $CuSO_4$ solution with platinum electrodes, we can soon see that this hypothesis will do what is wanted; for we find that if $CuSO_4$ conducts the whole current, the decomposed equivalent comes half from each half of the cell—the anode half and the cathode half; whereas, by supposing H_2O to conduct the whole current $CuSO_4$ is decomposed by secondary action only in the neighbourhood of the cathode, and the amount of salt in the anode portion of the solution remains unchanged. The proper apportioning of conduction, therefore, explains migration just as well as the direct Hittorfian hypothesis. Moreover, we shall find that this mode of regarding the subject is capable of explaining the formation of free acid or other secondary products exactly where experiment shows them to be formed. If it be found to account for their appearance in precisely right amount, it may be held to to be proved; let us therefore examine more closely the full effect of supposing the current to be shared between the two ingredients of a doubly compound liquid in any assigned proportion.

Theory of Double Electrolysis, or the Decomposition of a Mixture of two Substances.—We must begin by excluding the possibility of double decomposition or interchange of radicles, because if such occur there are really not two substances mixed, but four. No stress is to be laid on the word "mixture," as distinct from combination; and I shall consider a solution of copper sulphate as a mixture of $CuSO_4$ and H_2O, dilute acid as a mixture of acid and water, without troubling about the perfectly certain fact that all these cases (and probably most other cases) of mixture are really cases

* Hence in arranging voltameters the anode should be larger than the cathode.

† An old experiment of Faraday's ("Exp. Res. 494) on "The formation of magnesic hydrate at a junction of Epsom salts and water, when a current passes, is now accepted even by Kohlrausch as proving that water may in some cases conduct."

Digitized by Google

of—it may be very feeble—chemical combination. But commonly-called "mixed" solutions, such as the heading might at first sight suggest, like, say, KI+NaCl, or even KI+KCl—are excluded, not only by double decomposition, but by the presence by water, which is distinctly a *third* substance.

Limiting ourselves strictly, then, to two substances—*e.g.*, a salt and water, there are still several possible cases :—1. The liberated ions may belong wholly to one of the two compounds. 2. The liberated ions may belong one to each of the two compounds. 3. They may each belong to both.

At first sight the first case is a mere simple decomposition, like that of a fused salt, but not necessarily so. It all depends upon whether the substance is *primarily* decomposed or not—*i.e.*, or whether it conducts the whole current or not. If the other substance, whose ions are not liberated, either wholly or partially, conducts the current, it is a true case of double electrolysis.

To simplify the problem, we will use unalterable electrodes—*e.g.*, platinum, and we will suppose that the liberated ions do not dissolve, or at any rate *have not* dissolved, in the liquid, else the mixture will not remain merely dual, but will become more complex.

We have next to make some hypothesis concerning the relative speeds of opposite corresponding ions, *i.e.*, of the anion and cation of one and the same substance. For the sake of simplicity, I will first make the simplest assumption, in favour of which several considerations may be urged, though none of them are conclusive, viz., that opposite corresponding ions travel at equal opposite rates. We shall find this sufficient to explain every migration phenomenon, and we can see the effect of generalising it afterwards. Consider now the mixture, A C+A′C′, where A and A′ stand for anions, C and C′ for cations. Let the current be conducted by these two compounds in the ratio λ to λ, so that $\lambda+\lambda'=1$; and, in order to isolate the portion of the liquid near either electrode and study the changes therein occurring, we may picture the whole fluid as contained in two vessels united by a siphon tube, and we shall call the two vessels the anode vessel and the cathode vessel respectively. Further, we may, if we like, think of A C as sulphate of copper, and of A′ C′ as water. The product of deposition or liberated ions will then be C and A′ respectively, and the bye-product A C′ will be free sulphuric acid. This example, therefore, belongs to case (2) above, one ion belonging to each compound, and this will serve well enough as an example to work out.

Picturing the convection of electricity by the ions through the tube, we see that A carries a quantity of negative electricity $\frac{1}{2}\lambda$, A′ a quantity $\frac{1}{2}\lambda'$; C carries $\frac{1}{2}\lambda$ of positive electricity, and C′ a quantity of $\frac{1}{2}\lambda'$. So by the time a unit quantity of electricity has been conveyed, and an equivalent of anion and cation deposited on anode and cathode respectively, the following changes have occurred in the ingredients of the fluid in the two vessels. The cathode vessel has gained $\frac{1}{2}\lambda$ equivalent of C from the anode vessel, but it has lost a whole equivalent by deposition, so its net loss of C—which we may write dC—is $1-\frac{1}{2}\lambda$. Of the other cation it has lost none, and has gained $\frac{1}{2}\lambda'$ from the other vessel, so we may write $d\mathrm{C}'=-\frac{1}{2}\lambda'$. Of anodes it has lost some of both, but only by travelling to the other vessel, and accordingly $d\mathrm{A}=\frac{1}{2}\lambda$, and $d\mathrm{A}'=\frac{1}{2}\lambda'$. Similar reasoning easily applies to the anode vessel. Then passing from the elements only to consider the compounds, we recognise at once that a compound is lost by the loss of *either* of its elements, and that those elements may be either lost absolutely or may be found in new combinations. We thus soon perceive that the loss of the compound AC in the cathode vessel is equal to its loss of C, *i.e.*, to its major loss ; that is, $d(\mathrm{AC})=d\mathrm{C}=1-\frac{1}{2}\lambda$. The loss of A′C′ in this same vessel is equal to whichever is the bigger of the two losses dA′ or dC′ ; and as dC′ is, in the present instance, not a loss, but a gain, there is no doubt but that $d(\mathrm{A}'\mathrm{C}')=d\mathrm{A}'=\frac{1}{2}\lambda'$. Similarly with the other vessel.

But there remains to be considered what becomes of the unpartnered balance of all the various elements, for unless dC equals dA in both vessels, there will be in one or other an excess of either A or C—in the present case of A ; and, again, unless dC′ equals dA′ there will be an excess again in this case of the C′ ; hence we have the new compound a C′ formed: in amount, $d(\mathrm{AC}')=d\mathrm{A}-d\mathrm{C}=d\mathrm{C}'-d\mathrm{A}'$. The equality of dA−dC and dC′−dA′ is necessary, unless it is possible to obtain isolated ions ; and it will be found that they come out equal from the preceding values, and that $d(\mathrm{AC})=-\lambda'$ in the cathode vessel, while in the anode vessel $d(\mathrm{AC}')=-\lambda$.

Represent all this now in a table.

Result of Double Electrolysis on the liquid in anode and cathode vessels, by the time one equivalent of an ion belonging to each substance has been deposited :—

Substance.	Loss in cathode vessel.	Loss in anode vessel.	Total loss.
A	$\frac{1}{2}\lambda$	$-\frac{1}{2}\lambda$	0
A′	$\frac{1}{2}\lambda'$	$1-\frac{1}{2}\lambda'$	1
C	$1-\frac{1}{2}\lambda$	$\frac{1}{2}\lambda$	1
C′	$-\frac{1}{2}\lambda'$	$\frac{1}{2}\lambda'$	0
AC	$1-\frac{1}{2}\lambda$	$\frac{1}{2}\lambda$	1
A′C′	$\frac{1}{2}\lambda'$	$1-\frac{1}{2}\lambda'$	1
AC′	$-\lambda'$	$-\lambda$	−1

The facts of migration are thus perfectly accounted for, and a good deal beside. Thus free acid is shown to appear both at anode and cathode in the electrolysis of sulphate of copper with platinum electrodes: the amount at anode being $\frac{\lambda}{\lambda'}$ of that at cathode. Hence a determination of the relative amount of free acid in anode and cathode vessels at once gives a means of determining $\lambda:\lambda'$, the proportion in which the current is shared by the two substances, if the above hypothesis be true.

It is easy enough to put Hittorf's migration number n into the above table instead of λ : one has only to write $\frac{1}{2}\lambda=\frac{1}{n+1}$; but only three lines of the table have any meaning on the Hittorfian hypothesis—viz., the first, third, and fifth lines—relating to the loss of the compound AC in the respective vessels ; the solvent, or other compound, A′C′, is ignored, and the production of free acid near cathode is not supposed to occur. But it *does* occur, as some preliminary experiments I have made prove. Our hypothesis makes the formation of acid and everything else independent of intensity of current. Experiment may not confirm this ; but then we must remember that we have assumed no *mixture of ions* to be liberated, and it is known that with intense currents some hydrogen is given off at cathode as well as copper deposited. If this be taken into account the reasoning must, of course, be generalised.

A more formidable objection, however, may be made to the theory, viz., that it virtually assumes the conduction by the two sets of atoms to be independent ; for instance, the λ portion of current starting fairly away from the neighbourhood of electrodes *via* $CuSO_4$ is supposed to go through $CuSO_4$ all the way, and not to come across patches of water or to take either ingredient of the liquid at random. Consider for a moment what would happen if this did occur. Take a chain, $CuSO_4$, $CuSO_4$, H_2O, H_2O, H_2O, H_2O, $CuSO_4$, $CuSO_4$, H_2O. Imagine the usual Grotthus action to go on through the chain : the result is $2H_2SO_4$ and 1CuO. This is an unstable condition, or condition of non-minimum energy ; so one H_2SO_4 will combine with the CuO ; but it need not combine at once, because there is no need for the two compounds to be formed close together. Hence we must expect free acid sometimes to make its appearance *in the middle of the liquid away from either electrode*, and also for CuO to appear (in the form of some basic salt I suppose) too. Choosing proper materials, an action of this kind might be readily looked for, but I have never heard of its being detected, and it is so unlike what we know the behaviour of electrolytes in general that until proof to the contrary is forthcoming I feel compelled to believe that a current fairly starting in AC continues in it all the way, that a current starting in A′C′ likewise continues in that, and that secondary actions, or passage of current from AC to A′C′, only occur in the immediate neighbourhood of the electrodes.* It is easy to illustrate the preceding table of the changes in the solutions by a diagram of a special case :—

Scheme of Decomposition of Sulphate of Copper solution with platinum electrodes on the gratuitous assumption that water conducts $\frac{1}{4}$ the whole current :—

Cathode			Anode
←$CuSO_4$	$CuSO_4$	..... $CuSO_4$	$CuSO_4$
H_2O	H_2O	H_2O	H_2O ↑
←$CuSO_4$	$CuSO_4$	$CuSO_4$	$CuSO_4$
H_2O	H_2O	..... H_2O	H_2O ↑
←$CuSO_4$	$CuSO_4$	..... $CuSO_4$	$CuSO_4$
H_2O	H_2O	H_2O	H_2O ↑
←$CuSO_4$	$CuSO_4$	..... $CuSO_4$	$CuSO_4$
H_2O	H_2O	H_2O	H_2O ↑

The arrangement of the symbols indicates the constitution before passing the current ; the dotted lines and arrows indicate the state of affairs after four units of electricity have passed, on the arbitrary assumption (only made for the sake of illustration) that the $CuSO_4$ conducts three times as much current as the water does, *i.e.*, that $\lambda=\frac{3}{4}$ and $\lambda'=\frac{1}{4}$. Inserting these values in the previous table, and multiplying by four, to represent that four units of electricity have passed, it becomes :—

Substance.	Loss in cathode vessel.	Loss in anode vessel.	Total loss.
SO_4	$1\frac{1}{2}$	$-1\frac{1}{2}$	0
O	$\frac{1}{2}$	$3\frac{1}{2}$	4
Cu	$2\frac{1}{2}$	$1\frac{1}{2}$	4
H_2	$-\frac{1}{2}$	$\frac{1}{2}$	0
$CuSO_4$	$2\frac{1}{2}$	$1\frac{1}{2}$	4
H_2O	$\frac{1}{2}$	$3\frac{1}{2}$	4
H_2SO_4	−1	−3	−4

And all this is exactly borne out by the above scheme ; for one notes that 3 atoms of acid make their appearance in the anode vessel and 1 atom in

* It is assumed, in the text, that the ingredients of the liquid are thoroughly mixed. If they are purposely arranged in layers, free acid or free base may certainly make its appearance at the bounding surfaces. In fact, Faraday has observed the phenomenon, Exp. R. § 494 ; for he passed a current from strong $MgSO_4$ solution into "water" (*i.e.*, really weak $MgSO_4$ sol.), and found a deposit of magnesic hydrate at the layer of demarcation. It is interesting to note that in January, 1886, Kohlrausch accepts this experiment as proving that water does in some cases share in the conduction, though he still considers its share as negligible in all but exceedingly weak solutions.

Digitized by Google

the cathode vessel; that ½ an atom of O is transferred one way, an ½ an atom of H_2 the other way; that ¾ atoms of Cu travel from anode vessel to cathode vessel, but that 4 are deposited, making the net loss in this vessel $4 - 1\frac{1}{2} = 2\frac{1}{2}$; and so on.

(To be continued.)

ON THE NUMERICAL VALUES OF CERTAIN COEFFICIENTS OF SELF-INDUCTION.*

BY MM. VASCHY AND DE LA TOUANNE.

The theory of electrical apparatus is generally established under the hypothesis that the current has already arrived at the permanent state. Although this method gives only a first approximation at the best, it was yet practically admissible during the earlier period of telegraphy when the currents transmittted had always a relatively prolonged duration, but it is very doubtful whether we ought to rest satisfied with this treatment under modern conditions where very rapid reversals or makes and breaks are quite usually employed. In these cases the receiving instrument is, or may be, always at work during the "variable period." This weak point in the usually accepted theory has often been indicated, and in a note published in the *Annals Télégraphiques* (p. 585; 1877) upon the winding of electro-magnets, M. Raynaud appended the remark that the formulæ which had been given required to be followed with circumspection in certain cases, inasmuch as no account had been taken of the duration of the extra current. Since this date several special cases have been studied, in particular by Mr. Oliver Heaviside,† but always from a purely theoretical point of view.

Amongst the phenomena which more directly intervene in the case of rapid transmission are those which relate to the self-induction. We can easily take account of this function in examining a simple case such as that of an electro-magnetic recorder acting in a local circuit under the influence of currents of very brief duration.

Let R be the resistance of the external circuit,
R′ ,, ,, battery,
E ,, E.M.F. ,, ,,
L ,, coefficient of self-induction for the whole circuit.

If we take for the commencement of the time t, the moment when the circuit is closed, the value i_1 of the current must satisfy the relation

$$(R+R')\,i_1 + L\frac{d\,i_1}{d\,t} = E;$$

from which on integrating

$$i' = \frac{E}{R+R'}\left(1 - e^{-\frac{R+R'}{L}t}\right) \quad . \quad . \quad . \quad . \quad (1)$$

For a time t, sufficiently prolonged to correspond with the permanent state, this reduces to the ordinary equation

$$i = \frac{E}{R+R'}$$

But this is not at all the case if we consider only the first instant of closure. Suppose that t is very small, so that in the development of $e^{-\frac{R+R'}{L}t}$ in a series we may neglect the terms of a higher order than the first, we have sensibly,

$$e^{-\frac{R+R'}{L}t} = 1 - \frac{R+R'}{L}t$$

Equation (1) then becomes

$$i_1 = \frac{E}{L}t \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1')$$

At the moment, then, of contact the self-induction acquires a preponderating importance, and the actual resistance of the circuit is negligible; the current has a value such as would be given (in the permanent state) if we had subsituted a resistance equal to $\frac{L}{t}$.

Now, if we take t equal to a very short period θ, and suppose that at the end of this period the current suddenly ceases, we may take the mean intensity of the current during the interval θ as

$$i'_1 = \frac{E}{L}\frac{\theta}{2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

So far we have made no hypothesis as to the grouping of the elements of the battery.

Suppose that $m\,n = K$ be the number of these cells, each having an E.M.F. equal to ε, and a resistance ρ; m and n representing respectively the number of cells in series and in parallel.

Equation (2) shows that the most advantageous arrangement when working with currents of brief duration corresponds to the case in which all the cells are connected in series. The current at the end of time t is then expressed by

$$i_1 = \frac{k\varepsilon}{R+k\rho}\left(1 - e^{-\frac{R+k\rho}{L}t}\right)$$
$$= \frac{m\,n\,E}{R+m\,n\rho}\left(1 - e^{-\frac{R+m\,n\rho}{L}t}\right) \quad . \quad . \quad . \quad . \quad (3)$$

Upon the other hand, we know that under the hypothesis of the permanent condition we should obtain the maximum effect when the resistance of the battery is equal to that of the external circuit. The current in this case is given by the formula

$$i_2 = \frac{m\,e}{R+\frac{m\rho}{n}}\left(1 - e^{-\frac{R+\frac{m\rho}{n}}{L}t}\right) \quad . \quad . \quad . \quad . \quad (4)$$

where $$\frac{m\rho}{n} = R$$

The curves I. and II. (Fig. A) are drawn from the formulæ (3) and (4) respectively, the time t being taken as abscissæ, and value of

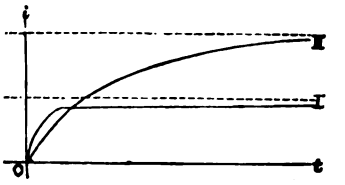

FIG. A.

current as ordinates. During the first moments of contact curve I. rises above curve II., but if the contact be prolonged the latter gives the greater current. The grouping of battery cells, which is habitually given as the most favourable, is therefore not advantageous for circuits upon which very brief contacts are employed. Practical experience has already confirmed these theoretical deductions. For instance, the coils of the relays employed with the Wheatstone apparatus are found to give better results when joined in parallel, and Mr. Preece recently mentioned the case of two relays, one of which permitted the transmission of 400 to 450 words per minute, while the other could not be worked beyond 50 or 60, the only difference between the two being in the value of their coefficients of self-induction. It has again been found necessary in the systems of harmonic telegraphy to increase the number of cells in the battery considerably beyond the number which would be required upon the same line by the ordinary methods of working. The same observation applies to all other systems in which very brief contracts are made, and it is certain that in these cases the currents actually transmitted have much smaller values than would be given by the simple application of the law of Ohm.

Self-induction has again much to answer for in the cases of damage resulting to telegraphic apparatus from lightning. The discharge is of such brief duration that the self-induction actually determines a virtual resistance in the coil superior to that of the insulation between the wire and the magnet cores. The insulator is consequently perforated. In the case of lightning conductors, self-induction is therefore by no means a negligible term. M. von Helmholtz and Sir William Thomson called attention to this fact in the discussion upon lightning conductors at the International Congress held at Paris in 1881, without, however, attributing to this function the predominating importance which it probably has.

From what has hitherto been said one might be led to suppose that the influence of self-induction was always of an injurious character. This is not, however, invariably the case. Take, for example, the multiple synchronous telegraph of M. Delany.* In this apparatus the current passes at the receiving station through the coils of an ordinary Morse instrument, but instead of being continuous from the sending station during the time in which each signal, whether long or short, is being made, the current transmitted is really a succession of very short impulses, and the interval between each said impulse is five times as long as the actual contact. Nevertheless, thanks to the influence of the self-induction in the coils, and by the aid of a condenser, the tongue of the relay is continuously attracted during each such signal, so that the instrument works in the same manner as if the currents were actually continuous.

Lastly, we know that self-induction plays an important part in dynamo machines, and that it is impossible to make an adequate study of the condition of telephonic transmission without taking this factor into account. One of us has already written upon this subject,† but the corresponding measurements are very difficult to carry out.

Although it is not our intention at present to deal at length with the various problems indicated below, and we intend to make a separate study of many of them, yet we believe that it will be useful to make known at once the numerical results obtained in a first series of experiments, and the principle of the method that we have employed. And as the subject is one that has been very rarely dealt with, we think that these figures will be found to possess some interest.

In the following table, R is the resistance, L the coefficient of self-induction, and M the coefficient of mutual induction for each apparatus. We postpone the description of the methods employed until these results have been stated.

	R (in ohms).	L.

We have employed two distinct methods in making the measurements of self-induction, one being a bridge method, and in the other making use of a differential galvanometer. For the measurement of mutual induction we have employed a special zero method.

Differential Galvanometer Method.—Fig. 1 shows the connections employed. L is the coil or apparatus to be measured; C a condenser connected to the terminals; A and B, of a rheostat r without self-induction; S a shunt in the battery; f f' a stretched wire, having a sliding contact piece K'.

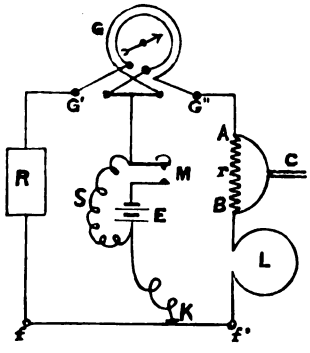

FIG. 1.

We first depress the battery key M, then by means of the variable resistance R (which is also without self-induction) we establish approximate equilibrium of the current in the two branches of the galvanometer. We then remove the shunt on the battery, and make a final adjustment by means of the slider K. Equilibrium being thus obtained, we open the key M, and observe the throw (a) of the needle. We now remove the condenser of capacity C, replace it by another whose capacity is C', and take a second reading (a'). It can then be shown that we shall have

$$\frac{L-Cr^2}{a}=\frac{L-C'r^2}{a'}$$

whence

$$L=\frac{C'a-Ca'r_2}{a-a'}.$$

As a verification we can take a fluid reading (a'') with another condenser, and on combining this with both a and a' separately we should have three equal results.

For high values of L it is advantageous to proceed in the following way:—Take C=0, this makes a very large; then find by trial such a value for C' as will make a' as small as possible. We have then

$$L=C'r^2\left(1+\frac{a'}{a-a'}\right)$$

This is practically a zero method, with the addition of a correction term $\frac{a'}{a-a'}$ when the value a' cannot be made to disappear altogether with the values of capacity at our disposal. (In our experiments we made use of a condenser of five microfarads graduated in hundredths of microfarad.) This zero method avoids errors due to any variation in the battery between the two readings, or to an incorrect graduation of the galvanometer scale, &c.

We have taken for granted that the self-induction of the other parts of the circuit is negligible. If this is not the case, and especially when L is of small value, we must deduct from both a and a' the value a_0 which is obtained when L is replaced by a coil of the same resistance, for which the self-induction is negligible, at the same time making C=0. We have then

$$\frac{L-Cr^2}{a-a_0}=\frac{L-C'r^2}{a'-a_0}$$

In the case where L is a straight wire this correction is not sufficient, and the method is not applicable.

Wheatstone Bridge Method.—Fig 2 shows the corrections for the bridge test. The coil L, the resistance r, and the condenser C, are placed in one branch of the bridge. The keys are manipulated in the same way as before, the variable resistance c serving to make the preliminary adjustments. We obtain the same formula,

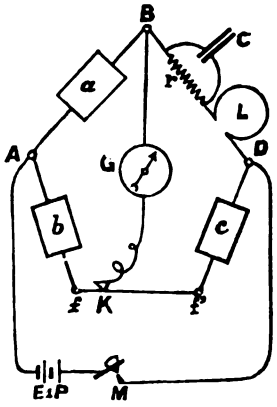

FIG. 2.

$$L=\frac{C'a-Ca'r^2}{a-a'}$$

By this method we were able to take a measurement for values of L as low as 0·006 with an accuracy of 10 per cent. with a current of 0·005 amp. For larger values of L the precision of the method is much greater, and might easily be increased, if necessary.

Measurement of the Coefficient of Mutual Induction.—In Fig. 3 M represents the two coils whose mutual induction is to be measured.

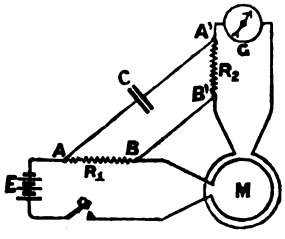

FIG. 3.

The primary is placed in circuit with the battery E, a rheostat R_1, and a key. The secondary circuit contains a galvanometer, G, and rheostat, R_2. The terminals A and B of the first rheostat are joined

Digitized by Google

respectively to A′ and B′ of the second, the wire AA′ being interrupted by the condenser C. When the primary circuit is closed the galvanometer needle makes a throw (α) which is due to the combined effects of the condenser and the induced current in M. On opening the primary circuit we should get an equal throw in the contrary direction. If we repeat this operation with a condenser of capacity C′, we get a second reading (α'). We have then the equation

$$\frac{M - C R_1 R_2}{\alpha} = \frac{M - C' R_1 R_2}{\alpha'}$$

where M is the coefficient of mutual induction ; whence

$$M = \frac{C'\alpha - C\alpha'}{\alpha - \alpha'} R_1 R_2$$

If M is very large, we may first make C = 0 ; next we find by trial a value for C′ which will make (α') zero, or as small as possible. We have then

$$M = C' R_1 R_2 \left(1 + \frac{\alpha'}{\alpha - \alpha'}\right)$$

This is a zero method, with the correction term $\frac{\alpha'}{\alpha - \alpha'}$.

We have found one cause of trouble and error in these measurements arising from the bad insulation between the two coils.

In all measurements of induction in or to avoid the use of general formulæ of a very complicated character it is necessary, (1) to place the coils whose induction is to be measured at a distance from the rest of the circuit ; (2) to make sure that the self- and mutual induction in all other parts of the circuit is negligible.

INCANDESCENT LAMP PATENTS.

Yesterday a meeting of "engineers, incandescent lamp makers, and important shareholders in the leading Electric Light Companies" was held at the Cannon-street Hotel, having been convened by Messrs. Shippey Brothers.

Mr. ARTHUR SHIPPEY said that it had been intended to ask Dr. Woodward, one of the earliest inventors of incandescent lamps, to take the chair, but that gentleman was in Liverpool. He therefore proposed that General Alexander should take the chair.

The CHAIRMAN then stated that he was not an electrician, but he took a great interest in electricity ; and he was very proud at having been invited to preside over such a meeting.

Mr. ARTHUR SHIPPEY addressed the meeting at some length, and after entertaining the company with his views on the present position of the electric lighting industry, he proceeded to observe that the Edison and Swan Company were elated at their success in the action with Messrs. Woodhouse and Rawson, but in that case there was going to be an appeal. The Edison Company, after their success, issued a notice to users of the lamps made by his firm, who had not had any notice from the Company, that they were infringers, and he was happy to say that at the trial they would be able to prove that they were not. He thought it would be best to call that meeting in order, if possible, to frustrate the attempt of the Edison and Swan Company to obtain a monopoly. He then gave a history of the principal incandescent lamp patents since the year 1838. The incandescent lamp was not, he said, due to the inventive genius of either an Englishman or an American, but to a Belgian, M. Jobard, of Brussels, who, however, did not actually make a lamp. The first idea, however, emanated from that gentleman, whose pupil, M. de Chanay, took up the question with earnestness. For many reasons he (Mr. Shippey) maintained that the Edison and Swan Company were not entitled to a monopoly. He thought that electric lamps might be divided into four classes — arc lamps, semi-incandescent lamps, incandescent lamps of high resistance, and glow lamps of low resistance. The incandescent and glow lamps should be defined in order to prevent complications for the future. He had seen about 140 patents in connection with incandescent lamps ; but to his mind there were only four lamps in existence worthy of the name of patents connected with the branch of incandescent lighting. The four which would stand on their merits were the Lane-Fox and the Edison lamps for high resistance, which he considered were the best lamps for running in parallel, and for central station lighting. Mr. Edison was entitled to the sole right to manufacture lamps of 100 to 500 ohms resistance, as shown by his specification. The other two lamps he referred to were those in connection with the Zanni-Shippey inventions (under which he claimed the manufacture of lamps up to 50 ohms registered), and the Bernstein lamp, which was also a lamp of low resistance. With the amalgamation of these four he considered that they had all they required—lamps for parallel lighting, lamps for series lighting, lamps for single domestic installations. There was an action pending against the Anglo-American Brush Corporation, and his firm had an action against the Edison and Swan Company for interfering with their customers. They were quite prepared to fight that action, but it would cost a good deal of money ; and he appealed to the meeting to express their opinion as to the best course to be adopted with the view to frustrate a monopoly. They would be saved some £3,000 by the action in which Messrs. Woodhouse and Rawson had been engaged, as they would simply bring forward in their action new features, which, he said, would have the effect of causing judges to hold a different opinion from that which they expressed in the late action.

Mr. LOVERING then proposed the following resolutions :—

1. That this meeting hereby expresses its opinion that the course of action adopted by the Edison and Swan Electric Light Company towards customers using incandescent lamps and against the makers and vendors thereof is highly detrimental to the development of electric lighting.

2. That Mr. Shippey's firm be requested to actively defend the said action, and avail themselves of every possible opportunity of frustrating the threatened monopoly of the incandescent lamp trade by the said Edison and Swan Company.

3. That a committee be formed for the purpose of watching and protecting the interests of the trade, and assisting makers, vendors, and customers of lamps in resisting the action taken by the said company, and that the following gentlemen be appointed to act upon such committee (the names were filled in afterwards) and report to a subsequent meeting of the trade to be convened by them ; power being reserved to add to the committee.

4. That a fund be subscribed for the purpose of enabling the committee to resist the action taken by the said company.

Mr. LE FEVRE seconded the motion, observing that he had no interest in the matter except that he desired to see fair play done.

Mr. JOEL took exception to the contention of Mr. Shippey as to the four patents enumerated by that gentleman. There were other patents undoubtedly. For a committee to do any good it ought to be as influential and general as possible.

Mr. FYFE also spoke, moving that the committee be appointed for the purpose of investigating the information supplied by Mr. Shippey. This amendment was, however, lost sight of by the meeting.

Mr. SHIPPEY stated that the committee to be formed that day would be only provisional.

The following gentlemen were then appointed members of the committee :—Mr. Fyfe, Mr. Joel, Mr. Tongue, Mr. Shippey, Mr. Lovering, General Alexander, and Mr. Le Fevre.

These names were included in the third resolution, as above.

The CHAIRMAN put the resolutions, which were agreed to ; and they were afterwards signed by the Chairman on behalf of the meeting.

The usual complimentary vote brought the proceedings to a close.

NOTES.

THE SCILLY ISLANDS.—Telegraphic communication with the Scilly Islands is interrupted.

MEXICO.—The Mexican journals are agitating for the removal of overhead wires from the streets of the capital.

LUCERNE.—The electric light installation at Lucerne, of which we have already given a description, has now commenced active operations.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 27th ult. amounted to £3,368.

CABLE DIVIDEND.—The Directors of the West Coast of America Telegraph Company have declared an interim dividend of 2s. per share.

POST OFFICE TELEGRAPHS.—Mr. G. O. Davies, sorting clerk and telegraphist at Birmingham, has been appointed postmaster of Ruabon.

THE NEW EDISON FACTORY.—The new factory which is being built for the Edison Company of New York will, when complete, afford accommodation for 1,200 mechanics.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August amounted to £44,091, against £47,968 in the corresponding period of last year.

THE ELECTRIC LIGHT IN BOURNEMOUTH.—Messrs. Mortimer, Shepherd, and Co. announce an exhibition of the electric light (arc and incandescent lamps) in the Arcade, Bournemouth.

LIGHTING FERRY BOATS BY ELECTRICITY.—The *Dundee Advertiser* says :—"The Tay Ferries Committee have under consideration the matter of fitting up the two ferry steamers with the electric light."

RHEIMS.—During a severe thunderstorm the great rose-window at the cathedral of Rheims, one of the most magnificent specimens of the art of the mediæval glass worker, was last week entirely destroyed.

SPANISH TENDERS.—Tenders for the supply of 20,000 bottles of blue ink for the Spanish Telegraph Service will be allotted on the 24th inst. Specifications and conditions are on view at the Madrid office.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August amounted to £34,687, and to £41,987 in the corresponding period of 1885.

BRUSSELS.—The General Post Office at Brussels is now lit by electric light. Four arc lamps, two *lampes soleil*, and a large number of incandescent lamps are hung. The dynamo is driven by an engine of 46 horse-power.

THE TELEPHONE IN AFRICA.—The Portuguese settlement at St. Paul, Loanda, possesses a telephone exchange. The number of subscribers is at present sixty-one, and the annual rate is extremely low, being only £6 per annum.

PATENT LAW IN THE UNITED STATES.—The Congress of the United States has under consideration a proposal for extending patent rights in certain cases, at the discretion of the Commissioners, for an additional period of eight years.

ELECTRIC LIGHT AT CHERBOURG.—It is proposed to strengthen the defences of Cherbourg by providing two fixed electric lights which shall illuminate the channels upon either side of the breakwater within which the arsenal is situated.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 21st ult. were £2,479, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

EXHIBITION AT THE PALAIS DE L'INDUSTRIE.—Although Paris is reserving its energy for the great Exhibition of 1889, yet a very interesting "Exhibition of Arts and Sciences" is now being held at the Palais de l'Industrie. Electricity, of course, plays a very prominent part.

TELEGRAPHIC MONEY ORDERS.—In the House of Commons on Tuesday, the Postmaster-General, replying to Mr. Shirley, stated that he had not yet had time to consider the suggestion for establishing a telegraphic money order system, but that it should receive his attention during the recess.

ELECTRIC TRICYCLE.—We hear of another tricycle to be driven by accumulators. This machine has been brought out in the States. We fear, however, that it is scarcely possible to achieve any real success in this direction until the storage capacity of accumulators has been greatly increased.

THE INDIAN TELEGRAPHS.—It is feared that the concessions reported by telegraph to have been made by the Secretary of State as to reorganising the telegraph department will not satisfy the desires of the Indian Government servants. The subject, it is anticipated, will have to be again considered at the India Office.

REDUCTION OF TELEPHONE TARIFFS. — The Western Counties and South Wales Telephone Company have reduced the tariffs for connections with the private residences of the subscribers to their exchange to the following rates :—Under quarter of a mile, £5 ; under half a mile, £6. 5s. ; under one mile, £8. 15s.

SIGNALLING BY INCANDESCENT LAMPS.—M. O. Kalezowski, of Berlin, has suggested that when incandescent lamps are used for signalling at night for military or naval purposes the switches should be actuated by means of a modified Wheatstone transmitter, so that the punched tape may be retained as a record of the message.

"L'INGENIEUR ELECTRICIEN."—We have received a copy of a new weekly electrical journal published at Paris under the above title. The contents of the first two numbers are varied and interesting. We note that in the next issue it is proposed to give a *resumé* of all the criticisms upon the recent experiments of M. Deprez which have hitherto appeared.

NEW TELEGRAPHIC CABLE.—A new telegraphic cable is now being laid between Ireland and England to connect Dublin and London by a fresh route. The ss. "Monarch" has already laid the Welsh shore end, which starts from Nevin in Pembrokeshire. In connection with this line a special copper wire is being run between Nevin and London.

THE LISBON TELEPHONE SERVICE.—Strong complaints are made in one of the Portuguese papers as to the extremely unsatisfactory nature of the telephone service in Lisbon. It is alleged that the utmost difficulty is experienced in obtaining communication through the central office; and that many subscribers have decided not to renew their subscriptions.

THE BOSTON STREET RAILWAY.—The directors of the Boston Street Railways have determined to adopt either electric or cable traction for the whole of their extensive lines, and have appointed a committee to visit various towns in the States to investigate the practical working of each system. It is probably a foregone conclusion in favour of electricity.

NEWCASTLE-ON-TYNE INTERNATIONAL EXHIBITION, 1887.—We have received a copy of the prospectus of the Newcastle-on-Tyne Mining Engineering and Industrial Exhibition,

Digitized by Google

which is to be held next year. Electric lighting is entered in Division 10, under the head of Hygiene, and electric appliances in Division 14, under the head of Science and Education.

PRESS TELEGRAMS IN GERMANY.—There has recently been a good deal of grumbling in Germany over the revised press tariffs. Nevertheless, the use of the telegraph by the more important journals continues to increase. A recent number of the *Frankfurter Zeitung* contained no less than 23,900 words of telegraphic intelligence. Of this, 13,700 words were parliamentary, and the remainder general news.

THE INSTITUTE OF MECHANICAL ENGINEERS.—During the recent summer meeting of this body, at which a large number of Belgian engineers were present, among the places of interest which were visited were the works of Messrs. Crompton and Co. at Chelmsford, the works of the Anglo-American Brush Corporation at Lambeth, and the electric light installations at the Holborn and the Criterion Restaurants and at the Princes Theatre.

A TELEPHONE RAID.—The whole of the departmental offices of the United States Government were recently required to make a return of the number of telephone instruments in their possession. A committee is investigating the matter, and has already ordered the number of telephones in the offices of the executive at Washington to be reduced by 50 per cent., and it is expected that a similar reduction will take place throughout the service.

ELECTRICITY ON THE FRENCH RAILWAYS.—The French Minister of Public Works has appointed a technical commission, consisting of State engineers, and presided over by M. Lucas, engineer of highways and bridges, to inquire into the practicability of applying electricity to the working of railways in the matter of signalling, announcing the arrival of trains by electric bells, intercommunication between trains in motion, and the working of continuous brakes.

THE REGENT PRIMARY BATTERY.—The prospectus is issued of the Regent Portable Electric Lamp and Lighting Company (Limited), with a capital of £85,000 in 17,000 shares of £5 each. The company is formed, among other things, to acquire the "exclusive licence to manufacture and sell in the United Kingdom and the Isle of Man" the Regent Primary Battery, particulars of which have from time to time appeared in our columns. The list of application for shares closes to-morrow (Saturday).

EDISON-SWAN COMPANY *v.* WOODHOUSE AND RAWSON.—We understand that pending the hearing of the appeal in this case, a mutual arrangement has been made by which Messrs. Woodhouse and Rawson have agreed to pay a royalty upon all lamps sold by them, the royalty to be returned in case the appeal is successful. The effect of this arrangement will be that if the appeal should be unsuccessful, the purchasers of Woodhouse and Rawson lamps will still be free from any claim on the part of the Edison-Swan Company.

TELEGRAPHS ON THE WEST AFRICAN COAST.—The West African Telegraph Company has received telegraphic information from the Gold Coast and West Africa, announcing the opening to the public service on the 28th ult. of this Company's stations at Accra, Grand Bassam, Porto Novo or Kotoonon, and on the island of St. Thomé. It is expected that the station of Principé will be opened on the 31st ult., and that shortly after that date Gaboon and St. Paul de Loando will be in telegraphic communication with Europe.

GUATEMALA.—The city of Guatemala is lit by 250 arc lights supplied by six Thomson-Houston dynamos, which are driven by water power. The total length of the five circuits (one machine being spare) is over sixty miles. The wires are carried along the fronts of the houses, under the eaves. Good insulation is thus secured. The city also possesses a telephone exchange, with over 200 subscribers. The charge for the exchange service is $5 per month. The country is well supplied with telegraph lines, which are effectively administered by the Government Department of Posts and Telegraphs.

ELECTRIC LIGHT AT THE BIRMINGHAM ART GALLERY.—The arrangements for illuminating the rotunda at the Art Gallery with the electric light are now complete. The illumination is accomplished by a large ring of Swan incandescent lights, backed by carved reflectors of silvered glass, so arranged as to direct the light towards the walls. The light is very brilliant, and the colours of the various paintings are seen even better than by daylight. The critics say the only disadvantage is that the brilliancy of the rotunda makes the other rooms dull by comparison. Messrs. Chamberlain and Hookham are the contractors.

HERMOSAND, SWEDEN.—It was announced some time since that this town was to be lit by a Thomson-Houston plant driven by water-power. The installation is now an accomplished fact. The machines are placed at a distance of 2½ miles from the town, and supply 27 arc lamps of 1,200 candles each. This is found to be amply sufficient to light the whole of the streets of the town, which has only 4,000 inhabitants. The cost of the whole installation has amounted to about £1,150, and the annual expenditure is estimated not to exceed £100; giving an economy of 25 per cent. over the method of illumination previously in use.

ELECTRIC TRAMWAY IN PARIS.—An electric tramcar, expressly constructed for service between the Palace de l'Industrie and the Place de la Concorde during the Exhibition of Sciences and Industrial Arts, has recently been sent from Brussels to the French capital. The car was built by the Société l'Electrique, and will be propelled by an electric motor, fed by a battery of accumulators of the Julien type. The line on which it is to be run has been finished some time, so that it will be put into immediate operation. After having done duty at the Exhibition the car will return to Brussels, where it will be employed on the line in the Leopold quarter.

AN OVERSIGHT.—At Appleton, Wisconsin, on the day of the first public trial of the electric tramway, which has just been completed in that town, the electrician in charge had a distinct *mauvaise quatre d'heure*. The car was crowded with passengers, the road was *en fête*, the dynamo was running full speed, but when the motor was switched on nothing further occurred. The more ill-bred Appletonians raised a shout of derision, and it was not until every possible fault had been searched for that it was finally discovered that the dynamo was running without any brushes. The incident suggests a lamentable ignorance of the use of ammeters and voltmeters.

THE MEMORIAL TO THE LATE POSTMASTER-GENERAL.—The clay model of a colossal statue of the late Mr. Fawcett has been completed by Mr. Pinker, of Kensington, ready for casting in bronze for the memorial at Salisbury. The figure is standing without any adjunct as a support, and is most easily and naturally posed. The likeness of the face is admirable, and the slight stoop and other familiar details of the figure have been most truthfully rendered. Around the bronze base of the statue there will be an incised inscription, "The Right Honourable Henry Fawcett, Professor of Political Economy at Cambridge." The casting will be performed by Mr. Moore, of Thames Ditton.

CURIOUS EFFECT OF LIGHTNING.—Although in this country we have had very few thunderstorms during the present summer, the Continental and American journals are full of accounts of severe storms and strange freaks played by lightning. Of this latter variety one of the most curious which we have met with is the following :—"During a thunderstorm at Plainfield, N.Y., a young lady lifted a lacquered metal tray which was lying on a table in front of the window. At this moment a blinding flash of lightning caused her to throw it hastily down. The next morning on examining the tray it was seen to bear an excellent profile likeness of the young lady apparently burned into the metal. The tray is to be placed in a public museum."

THE BRITISH MUSEUM.—The lighting of the Reading Room of the British Museum by electricity for the autumn and winter season began on Tuesday, the closing hour for readers being extended till 8 p.m. Mr. Barrett, the electrical engineer of the establishment, has been able to make considerable improvements on the lighting of previous years. It has been found that, from the great height of the dome and the large circumference of the room, four lights are not sufficient, and it has been considered necessary to add a fifth. Additional lights have also been placed in several of the galleries and in the new or "White" newspaper reading room, and the number of incandescent lamps throughout the building has been largely increased.

FINSBURY TECHNICAL COLLEGE.—We have received a copy of the programme of the Finsbury Technical College for the ensuing session. We would call the particular attention of those upon whose behalf the arrangements have been made to the special evening classes in electrical engineering "for apprentices and others engaged in electric lighting, telephony, electro-plating, and other branches of electric engineering." A student who diligently follows up this three years' course ought at the end of that period to find himself fairly on the way to becoming a thoroughly well equipped electrician. The fees for this course of instruction are extremely moderate, and a further reduction of 50 per cent. is made in the case of apprentices.

ELECTRICITY APPLIED TO FARRIERY.—General Boulanger has recently ordered the trial of a method of inducing vicious and restive horses to stand quietly while being shod. The method is due to the knowledge and ingenuity of M. le Capitaine Place, and is said to have proved eminently successful. We confess that such is our own ignorance of the electrical pathology of the noble quadruped that we should rather have expected the very opposite results to follow. The arrangement merely consists of an induction coil, a dry battery, and an arrangement for giving "a shock of graduated intensity" to the animal under treatment. The most vicious horses which could be found in the cavalry school at Saumur subsided into quietness upon the application of this device.

GAS V. ELECTRICITY.—The shareholders of the Eastbourne Gas Company are to be congratulated. Their Chairman (Dr. G. A. Jeffrey), in moving the adoption of the directors' report at the half yearly meeting last week, was able to announce an increase of 7¾ per cent. in the consumption of gas. The illuminating power of the gas now supplied stands at 16·1 candles, whereas the Act of Parliament does not require them to give more than 14 candles. This disinterested mark of generosity on the part of the gas company must be greatly appreciated by the inhabitants. The doctor explained that "the particular reason why this extra lighting power was given was to show the public the absence of any necessity to go to the Electric Light Company ; and he thought they had been paid for the experiment by having been called upon to make more and more gas every year."

EARTHQUAKES.—On August 27 a severe earthquake occurred in Greece by which several small towns and villages were destroyed. On August 31, about 10 p.m., an earthquake wave passed over the United States ; the shock was experienced with greater or less intensity over the whole of the country lying to the east of the Mississippi. The centre of the disturbance appears to have been situated in South Carolina, where the town of Charleston has been almost entirely destroyed. The Signal Service Bureau at Washington reports that four distinct shocks were felt at that place ; the first began at 9:54 p.m. and lasted 40 seconds, the second occurred at 10 p.m., the third at 10:10 p.m., and the fourth at 10:30 p.m. On the same night, between 10 p.m. and 12 p.m., several smart shocks were felt at Smyrna. A hill upon a small island lying off Sardinia is reported to have broken into volcanic eruption.

THE FIRST ELECTRIC LIGHT IN LONDON.—Mr. John Hollingshead, who has been identified with the management of the Gaiety Theatre since it was first opened about eighteen years ago, in severing his connection with that popular place of entertainment, concludes his farewell address by claiming to have achieved three things in the interests of the playgoing community, namely, the abolition of fees, the invention of *matinées*, and the introduction into London of the electric light. Our readers cannot fail to remember that it was at the door of the Gaiety where the first attempt to use electricity as an illuminant was made, nor can they forget with what varying opinions it was received by the public. It was an arc lamp installation on the Lontin system, and for a time, notwithstanding that it was remarkable chiefly for the unsteadiness of its light, it was regarded as one of the wonders of the metropolis.

THE PHONOPLEX SYSTEM OF TELEGRAPHY.—The system of duplex telegraphy which Edison has introduced under the title of "phonoplex" has met with much favour from the American telegraph companies, and has already received an extensive application. The Kansas and Southern Railway, the Sante Fé Railway, the Baltimore and Ohio Telegraph Company, and the Great North-Western Company of Canada, are all employing the system upon a large scale. Our readers are already aware that the system consists essentially in the employment of sounders, which are really Bell telephones of special construction, and which are connected upon the circuit through condensers, so that they only respond to induced currents. Currents of lower tension can therefore, at the same time and upon the same line, be employed for working ordinary Morse sounders. In fact, the system is developed upon precisely similar lines to that of the Rysselberghe system of working telephones and telegraphs simultaneously.

FATAL DISCHARGE OF GLOBULAR LIGHTING.—On the 9th inst. at Crawforth, Indiana, during the fall of a slight shower of rain, but in the absence of any indication of a thunderstorm, a ball of fire was seen to enter the window of a house occupied by one of the most prominent citizens of the town. Shortly afterwards, Mr. Riley was discovered lying upon the floor, his body, according to the American account from which we quote, burnt almost to a cinder and unrecognisable. A black streak was traced upon the carpet from the window to the fireplace, in which line the body was found. The family, who were sitting outside the house, witnessed the ball of fire enter the window and apparently disappear up the chimney. This is the second instance which we have recently recorded of a discharge of globular lighting having *ascended* a chimney. The fact would

Digitized by Google

seem to indicate the possibility that its course may be determined in part by the direction of a current of air. But if, as we recently suggested, the phenomena is due to a small quantity of vapour charged to an excessively high electric tension, it is difficult to understand how it could continue its course after having discharged sufficient electricity to carbonise a human body.

THE OLDEST INSTALLATION IN EXISTENCE.—It is said that the Paris Hippodrome claims the honour of having been lit by electricity for the longest consecutive period on record. The installation dates back to the year 1877, when four "Serrin regulators" were first permanently installed. Each of these lamps was supplied from a separate Gramme dynamo in the manner then practised. From time to time the number of arcs has been increased, but, strange to say, the primitive arrangements have not only been retained but positively extended, so that at the present time there are no less than *seventeen* "Serrin regulators," each with its separate and distinct Gramme machine! These arcs do not, however, by any means represent the entire installation. There are employed in addition 133 Jablochkoff candles and over 1,000 incandescents. The current for the Jablochkoffs is supplied by seven alternating Grammes, for which four exciters are employed. Three additional direct current Grammes supply a portion of the incandescents, and the remainder are provided for by two Edison machines, each supplying 400 8 c.-p. lamps at 110 volts. The total number of dynamos is thus no less than thirty-three. All these machines are driven from one counter-shaft by cotton belting; the counter-shaft is driven in turn by two engines running at 180 revolutions. The machines are mounted on sliding frames, provided with screw adjustment.

AN ELECTRIC TRAVELLING CRANE.—An electric travelling crane is now at work at the warehouses of the Compagnie des Entrepos et Magasins Généraux, at Roabuix, France. At these warehouses the cotton bales, arriving mostly from America and La Plata, are stored before being forwarded to the different cotton mills. On account of the great fire risk, no steam crane is allowed in the establishment, and the bales, which weigh about half a ton each, had until recently to be hoisted and handled generally by manual labour. This work is now accomplished by a travelling crane worked electrically. The crane post is placed on a trolly which runs on rails, and a rail fixed to the ceiling of the warehouse guides the upper end of the post. The jib of the crane has a derrick motion. A small Gramme 4 horse-power dynamo is fixed on the trolly. This is always kept running (900 revolutions per minute), and being connected with suitable gearing, it can be made to hoist the load, advance the crane on the rails, and operate the jib. The current of 15 amperes, with an electromotive force of 250 volts, is conveyed to the crane by overhead sliding contacts from the generator, which is a 6 horse-power Gramme dynamo, running at 1,200 revolutions per minute. The commercial efficiency of this arrangement is stated to be 60 per cent. It shows, however, an economy in working, for, whereas formerly 10 men were required to handle 150 bales in 18 or 20 hours, now with this electric crane 4 men can do the same amount of work in 3 hours.

ELECTRIC LIGHT BUILDING BURNED.—The *Electrical Review* of New York reports that the large Brush station at 202 to 210, Elizabeth-street, New York City, supplying over 800 arc lights, has been almost entirely destroyed by fire. The fire began on the second floor of the three-story building, and is supposed to have been caused by a shaft heated at the journal from friction. In four minutes from the time of the first alarm at 7:28 o'clock the entire three-story building was in flames. The ten boilers, engines of a capacity up to 180 horse-power, and the 40 dynamos or generators were the costly part of the plant, which was valued in the aggregate at $200,000, and the loss will amount probably to $150,000, all covered by insurance. The West Twenty-fifth-street Station was still serving 400 lights between Fifty Ninth and Fourteenth-streets when the firemen got to Elizabeth-street. At the outbreak of the fire the electric light men connected the eastern system with the western by a switch at the Bowery and Fifth-street, but the firemen feared that in their wet clothing they would be in danger at their work with the wires alive, and orders were telephoned up to Twenty-fifth-street to shut down altogether, and the 1,200 lights were extinct. At midnight all the lights were burning again except the west head lights in Madison and Union Squares. The chief engineer says that the company can supply all the light from the west side station alone. The offices of the parent company—the Brush-Swan Electric Light Company of New England—were in the building that was burned.

A FRAUD.—The following American story comes to us through the columns of the *Etoile Belge*. It appears that two citizens of New York, both well known in Wall-street, recently announced that they were in possession of a new long-distance telephone, capable of speaking over any required length of line, overhead, underground, or even submarine. As a mere preliminary demonstration they were already prepared to exhibit its performance upon a line between New York and Chicago, and they had commenced negotiations for laying down a cable to be worked by their apparatus between San Francisco, Melbourne, and Pekin. This announcement created great excitement amongst *les gogos* (Anglicé, the greenhorns). They all rushed to the office in Broad-street to try the instrument. The articulation was found to be perfectly distinct and clear. Moreover, the information obtained from Chicago was verified by the telegraph lines. A large proportion of the proposed capital of $200,000 was rapidly subscribed, and the 10 per cent. due on application was promptly paid up. It then became necessary for the two promoters to visit Chicago in person. As they did not return so soon as was anticipated, it occurred to some curious individual to follow up the wire from the Broad-street office. It was then discovered that the line had not been quite completed through to Chicago, in fact, its total length did not exceed 98ft. At this end arrangements had been made to place the operator in rapid telegraphic communication with Chicago. Hence the accuracy of the intellegence, the excellence of the articulation, and the dismay of the gulls.

THE VAN DEPOELE ELECTRIC RAILWAY.—The following details concerning the Van Depoele system of electric railway are taken from an article in the *Electrical World*:—The system was first brought into practical operation at Chicago at the end of 1882. The current was conveyed by an overhead wire. No further details are given with regard to this early attempt. Two years later a line was opened at Toronto to connect the extremity of the street railway with the grounds of the exhibition there being held. On this occasion underground conductors were employed in the first instance, but afterwards these were replaced by an overhead cable. The line proved a decided success; three cars, carrying about 230 passengers, were drawn by each motor, at a speed of 30 miles an hour. A forty arc light dynamo was used, driven by a Doty engine, for which rather less than half a ton of coal was burnt per day. Experiments have since been made upon the South Bend Railway in the vicinity of Toronto, and it is in contemplation to work this line entirely by electric

Digitized by Google

power. At the New Orleans Exhibition a train consisting of three cars was run with great success. At Minneapolis the Lydale and Minnetonka Railway Company have adopted the Van Depoele system for that portion of their line which runs into the city of Minneapolis. Forty-eight trains are run each way daily. A total weight of 91 tons has been hauled up an incline of 1 in 30 without difficulty. An old slide valve engine, 12 by 18 cylinder, making 125 revolutions per minute, is employed, and the consumption of coal is about 3,000lb. for seventeen hours run. The current is conveyed to the conductors by an overhead cable. Installations of very similar character are at work at Montgomery, Alaska, and at Windsor, Ontario. At three other towns in the States the system will very shortly be in operation, and further contracts are in the hands of the company.

VOTING BY ELECTRICITY.—At the mechanical exhibition at the Palais de l'Industrie in Paris there is exhibited a machine for registering votes which will, it is said, be shortly installed in the Senate and the Chamber of Deputies. Its object is to obviate mistakes, the loss of time, and the necessity of the members leaving their desks to record their votes. The machine, which is the invention of M. Debayeux, is worked by electricity, and the vote of a full house, it is said, may be made known by this means in less than five minutes. The arrangement of the apparatus is as follows :—In front of each seat three contact makers are placed, the knobs being marked respectively "Yes," "No," and "Abstention." Only one of the pushes can be depressed at one time, and neither of them can be used more than once until they have been released by the action of another part of the apparatus, which is under the control of the president. The voting is recorded by means of three sets of cylinders, upon which are inscribed in relief the names of the members in alphabetical order, and also the series of figures from 1 up to the total number of members. These cylinders rotate under inking pads, and after the voting, an impression being taken on a band of paper, against the name of each member present is found a number in one or other of the three columns "Yes," "No," or "Abstention." These numbers appear perpendicularly in numerical order. Hence the total number in each division is read at the foot of the three columns. The apparatus is necessarily somewhat complicated, but it is said to work with great facility. It will be noticed, however, that it can only be employed under the condition that each member always occupies the same seat. But for this difficulty it would be well worthy of the attention of our own Parliament, where a division seldom takes less than 20 minutes. We fear, however, that the facilities for "personation" which would necessarily result would sometimes prove a great temptation to some of our more frivolous legislators.

NEW METHOD FOR DETERMINING THE VERTICAL INTENSITY OF A MAGNETIC FIELD.—In the last number of *Wiedemann's Annalen* Herr Krüger describes a new method for determining the vertical intensity of a magnetic field. He points out that the methods hitherto used for measuring the vertical intensity of a magnetic field depend on the electromotive action which it exerts on a spiral which rotates about a horizontal axis. If, moreover, the spiral turns about a vertical axis, the ratio of the currents induced in the two rotations gives the inclination of the magnetic lines of force to the horizon. If, again, the current induced by a rotation about a horizontal axis be determined in absolute measure by a galvanometer, the vertical intensity of the field is determined from the contents of the surface enclosed by the windings of the spiral, and from the absolute resistance of the circuit formed by the spiral and the galvanometer. In a field of small extent the rotation must be replaced by a parallel displacement of the spiral in its plane. In any case the determination of a vertical intensity by these means is a difficult and tedious operation. In contrast with this, the deflection which a disc suspended horizontally by means of a vertical wire in a solution of copper sulphate experiences when traversed in a radial direction by a current, forms a very convenient means of determining the vertical magnetic force which produces that deflection. In order to test the capability of this method, it was used to determine the vertical intensity of the terrestrial magnetism, or rather the magnetic inclination. The value of the vertical intensity was thus found to be $V = 2{\cdot}2903 \times T$, in which T is the horizontal intensity. Simultaneous observations with the terrestrial inductor gave $V = 2{\cdot}2899 \times T$; while the vertical intensity deduced from the formula for variations given by Prof. Schering would be $V = 2{\cdot}2895\ T$. Taking as a mean $V = 2{\cdot}2899\ T$, it will be seen that the divergence obtained by this method does not exceed $\frac{1}{5700}$. The rest of the paper contains the establishment of the formula, and the experimental details and data.

A NEW SPEED COUNTER WITHOUT MECHANICAL CONNECTION.—We recently described a method by which M. Marcel Deprez proposed to count the number of oscillations made by a pendulum during any given time without in any way interfering with the freedom of the vibration. At the last meeting of the Académie des Sciences M. Gustave Hermite presented a note upon a somewhat similar subject. He proposes to determine the speed of a revolving body without touching it. The method is highly ingenious and interesting; but we doubt whether it is capable of any practical application even as a laboratory process. M. Hermite proposed to illuminate a disc attached to the revolving body by light from a Geissler tube. The tube is placed in circuit with a Rhumkorff coil arranged so that the number of makes and breaks per second is absolutely constant. The method of determining the number of vibrations of the hammer will be described immediately; for the present consider this number to be known. The disc, which is attached to the revolving body, and which is preferably connected so as to rotate in its own plane, is covered with paper on which some words have been printed—any printed paper will do. Now, it will be evident that if the number of illuminations of the tube per second is exactly coincident with the number of revolutions of the disc, the latter will appear to be at rest, and from some one position around the periphery of the disc the words upon the paper will be easily read; provided, however, that the speed of revolution is not less than about three turns per second. It is also evident that if the two motions be not absolutely synchronous the disc will appear to revolve more or less slowly in a direction, depending upon which of the two motions is the more rapid. Further, if the disc make precisely n times as many revolutions per second as the hammer makes vibrations, then a legible view of the printed surface will be attained, "right side up," at n different points around the circumference of the disc. It is thus necessary that the ratio between the rate of vibrations of the hammer and that of the revolutions of the disc should be represented by some integral number. On this point M. Hermite does not appear to have made any further suggestion. In any case it is necessary also to know the rate of vibration of the hammer. M. Hermite proposes to obtain this, as he says, "once for all," by comparison with a disc rotating at a known rate. The speed could no doubt be determined in this way; but from the considerations which we have just advanced we fail to see how this would serve the purpose "once for all."

CONTEMPORARY PROGRESS.*

ON THE LAW OF THE ELECTRO-MAGNET AND THE LAW OF THE DYNAMO.

By S. P. Thompson, in *Philosophical Magazine*, 5th Series, Vol. XXI., 1886.

The author comments on the want of agreement among physicists as to the true law of the electro-magnet, and points out that most of the mathematical formulæ which have been given are not at all in accord with experiment, and are mostly based on no consistent theory. The relations determined by Weber ("Electrodynamische Maasbestimmungen," p. 572) between the magnetising force and the induced magnetism are an exception to this, but his expressions are very unmanageable.

The expressions generally given in treatises on physics are

Lenz and Jacobi's formula, $M = K S i$,

where i is the strength of the current in the coil, S the number of turns in it, K a constant depending on shape and quality of iron, and M the strength of the pole;

and *Müller's formula*, $m = b \tan^{-1} \frac{S i}{a}$,

where a and b are constants depending on the form, quantity, and quality of the core, and the form and disposition of the coils.

Both of these are empirical, and do not agree with experimental results. The discovery of the true law and its expression in a simple form is of great importance, as upon it the determination of the law of the dynamo depends.

A law which agrees well with experiment is now known, chiefly as the result of Frölich's researches, published mostly in the *Electrotechnische Zeitschrift* (Vol. II., 1881), and subsequent volumes, with the exception of the first, which is published in the *Berl. Berichte*, 1880, p. 978. Following Faraday's law of induction, Frölich assumes that the induced electromotive force E will be proportional to the speed of the machine n, and to a quantity, M, which he calls the "effective magnetism," and which is itself proportional to the effective area of the armature coils and to the intensity of the magnetic field.

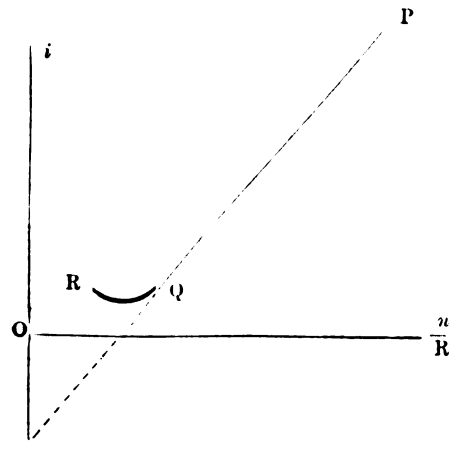
This gives $E = n M$;

but, by Ohm's law, $E = \frac{i}{R}$.

Therefore, $\frac{i}{M} = \frac{n}{R}$.

Since M is a function of i, and not primarily of n or R, it follows that i is a function of $\frac{n}{R}$, so we may write $n/R = \phi(i)$.

This function Frölich endeavoured to determine experimentally by observing the values of i for different values of n and R, and plotting the results as a curve obtained by taking the values of i as ordinates, and the values of n/R as abscissæ.



This curve, which he calls the "current curve," is found to be, with the exception of the part near the origin, sensibly a straight line not passing through the origin. The observations for the curved portion are difficult to make, as they depend either on values of n so small, or values of R so great, that the dynamo can scarcely excite its magnets. The straight line, therefore, is the only part of the curve applicable to practical conditions of use of the machine, so that we may write, where a and b are constants,

$$b i = \frac{n}{R} - a,$$

giving as the equation of the series dynamo

$$i = \frac{1}{b}\left(\frac{n}{R} - a\right).$$

The expression for M will therefore be,

$$M = \frac{i}{a + b i}.$$

In 1883 the author had been using the fundamental law

$$E = 4 n A H$$

to express the average value of the electromotive force developed by rotating an armature of total effective area A in a uniform magnetic field of intensity H, and requiring a formula to connect H with the exciting current he noticed that Frölich's formula gave what was needed, and finding it necessary for compound-wound machines to express the excitation in terms of ampere-turns rather than those of amperes, he wrote the formula

$$H = G S i \frac{k}{1 + \sigma S i},$$

where $S i$ is the number of ampere-turns, G a geometrical coefficient, k the coefficient of magnetic permeability in the initial stage, and σ a small saturation coefficient depending on the quantity, quality, and form of the core.

Writing $Z i_s$, the number of ampere-turns in a shunt-winding, in place of $S i$ in the above formula, we get the corresponding formula for shunt-wound machines, and for compound-wound machines we get

$$H = G (S i \pm Z i_s) \frac{k}{1 + \sigma (S i \pm Z i_s)}$$

Inserting these valves in the fundamental equation, and writing e for the difference of potentials at the terminals of the machine, and r_a, r_m, r_s, and R for the resistances of the armature, main circuit-coil, shunt-coil, and external circuit respectively, we get

For Series Dynamo—

$$E = \frac{1}{\sigma}\left\{4 n A G k - \frac{\Sigma R}{S}\right\}$$

For Shunt Dynamo—

$$E = \frac{1}{\sigma}\left\{4 n A G k - \frac{r_a r_s + R r_s + R r_a}{Z R}\right\}$$

For Compound Dynamos (at critical speed for regulation)—

$$e = \frac{1}{\sigma}\left\{\frac{r_s (r_a + r_m)}{S (r_s + r_a)} - \frac{r_s}{Z}\right\} \text{ (short shunt.)}$$

$$e = \frac{1}{\sigma}\left\{\frac{r_s (r_a + r_m)}{S (r_s + r_a + r_m)} - \frac{r_s}{Z + S}\right\} \text{ (long shunt.)}$$

These formulæ are given in the author's volume on "Dynamo-Electric Machinery," where he also shows that $\frac{1}{\sigma}$, which he calls the *determinant* of the working power of the dynamo, is that number of ampere turns which will reduce the effective permeability of the electro-magnet, or rather of the magnetic circuit, to half its initial value.

The preceding table gives the result of some experimental comparisons made by Frölich of results obtained from his formula with those obtained experimentally.

Now, Lamont, in his "Handbuch von dem Magnetismus" (1867), p. 41, gave the equation

$$m = \frac{a\,\mathrm{M}\,x}{\mathrm{M} + a\,x}$$

(when x = magnetising force, m = induced magnetism, M = maximum value of m) as a convenient first approximation to another equation, based on a new theory of induced magnetism.

Writing G k for a, S i for x, and σ for a/M, we get

$$m = \frac{\mathrm{G}\,k\,\mathrm{S}\,i}{1 + \sigma\,\mathrm{S}\,i},$$

the author's way of uniting Frölich's equation.

Lamont's physical theory has since been revived independently in a more elaborate form by Bosanquet (*Phil. Mag.*, Series V., Vol. XIX., p. 85, 1885)—Lamont's theory assumes that for any bar there is a maximum value of the magnetisation, and that at every stage of the magnetisation the permeability is proportional to the deficit from this maximum, which gives for the permeability $d\,m/d\,x$,

$$\frac{d\,m}{d\,x} = k\,(\mathrm{M} - m)$$

which gives, since m and x vanish together,

$$m = \mathrm{M}\,(1 - \Sigma^{-k\,x}),$$

which may be developed in the form

$$m = \mathrm{M}\,k\,x\left(1 - \frac{k\,x}{1\cdot 2} + \frac{k^2 x^2}{1\cdot 2\cdot 3} - \ldots\right),$$

which Lamont remarks may be approximately represented by the simple but empirical expression,

$$m = \frac{a\,\mathrm{M}\,x}{\mathrm{M} + a\,x},$$

for writing $k = a/\mathrm{M}$, and developing in ascending powers of $k\,x$, we get

$$m = \mathrm{M}\,k\,x\,(1 - k\,x + k^2 x^2 - \ldots),$$

so that the two expressions give nearly the same result for small values of $k\,x$.

None of these formulæ take account of the concavity often found in the early part of the curve of magnetisation, due to an increase in the permeability after a certain stage of magnetisation has been reached; but this is of no practical importance, since the apparent maximum of permeability is attained in most cases at a much lower degree of magnetisation than that at which the dynamo is actually worked.

The experimental comparisons show that Frölich's formula may be taken as something more than a first approximation to the true law of the electro-magnet within the limits of saturation occurring in practice, and it may be taken as a first approximation for all degrees of saturation beyond those usually attained.

ON THE BEHAVIOUR OF ROCK-CRYSTAL IN A MAGNETIC FIELD.

By O. Tumlirz, in *Wiedemann's Annalen*, Vol. XXVII., 1886.

The behaviour of quartz in the magnetic field was studied by Plücker in several researches (*Pogg. Ann.*, Vols. LXXII., 1847; LXXVIII., 1849; and LXXXI., 1850), but the results obtained were so discordant that he came to the conclusion that the action observed was due entirely to particles of iron accidentally present. The subject was also taken up by Knoblauch and Tyndall (*Pogg. Ann.*, Vol. LXXXI., 1850), who at first got nothing but contradictory results; but finally, by taking special precautions to ensure purity in the crystal, and suspending it with extreme care, they succeeded in obtaining a series of ten observations which all agreed in showing a tendency in the crystal to set itself with its axis at right angles to the lines of force.

The author used in his experiments two plates of quartz cut perpendicularly to the optical axis, one left-handed and the other right-handed, about 4mm. in thickness, and about 25mm. long. The plates were carefully cleaned, washed repeatedly in alcohol, and finally soaked for 30 hours in weak hydrochloric acid. They were suspended by silk fibres, attached by knotted loops, and the greatest care was taken while attaching the fibres to ensure perfect cleanliness of the hands and of the material on which the plates rested.

In the first experiment a single pointed pole-piece was made to act on one or other of the plates placed equatorially, with the result that the part nearest to the pole was repelled in each case, showing that quartz, whether right-handed or left-handed, is diamagnetic.

Immediately after this the plates were successively suspended between the two poles, perpendicularly to the line joining them. On closing the circuit, the principal axis in each case moved from an axial to an equatorial position, and came to rest in a position making an angle of about 20deg. with the line joining the poles. On reversing the current the principal axis assumed a symmetrical position with respect to this line.

The last result can be observed still better in a uniform magnetic field. In order that the plate should take up its position of equilibrium with the circuit open, more rapidly, a bifilar suspension with a small restoring moment was used, and it was suspended with its principal axis perpendicular to the direction of the magnetic force. On closing the circuit the axis came to rest at an angle of about 60deg. with this direction, and on reversing the current it assumed a symmetrical position with regard to it.

These experiments were frequently repeated, always with the same results. The plates were found to have a permanent polarity due to induction, and if left suspended for several days with no iron near, the principal axes were found to take up a position perpendicular to the lines of force, as observed by Tyndall and Knoblauch, and by Plücker in his first research.

When the plate was subjected to magnetic action, either parallel or perpendicular to its axis, and was then suspended in a field of force, it was found to deviate more or less according to the intensity of its magnetisation and of the field.

Contrary to what would have been expected, since quartz is diamagnetic, the side opposite to the North Pole during the magnetisation was in each case attracted by it, and repelled by the South Pole. This result is in agreement with Becquerel's theory, according to which all bodies are magnetic, and diamagnetism is due simply to the greater magnetic permeability of the surrounding medium.

ON THE DOUBLE REFRACTION OF LIGHT IN METALLIC FILMS, Obtained by the Pulverisation of a Cathode.

By A. Kundt, *in Wiedemann's Annalen*, Vol. XXVII, 1886.

In his researches on the electro-magnetic rotation of the plane of polarisation of light the author had previously obtained thin transparent metallic films of iron, cobalt, and nickel, by electro-deposition on a thin layer of platinum burnt into plate glass. A difficulty was found in getting a perfectly uniform and coherent film of platinum, and another objection to the use of the platinum film was that it absorbed a sensible portion of the light which traversed the glass.

Now, Wright found (*Silliman's Journal*, January and September, 1877) that if strong electric discharges be passed through a Geissler tube, the metal forming the negative electrode becomes pulverised, and is deposited as a reflecting film upon the inside of the tube, and in this way he succeeded in obtaining thin films of different metals upon glass plates.

Kundt made use of the same apparatus as that employed by Wright. It consisted of a vertical cylinder about 10cm. in diameter, open at both ends, which could be closed when requisite by glass plates, to which vertical tubes were cemented. An aluminium electrode was fused into the lower of these, and the cathode, formed of the metal to be pulverised, was placed in the upper one. The latter was, for convenience of removal, fused into a narrower tube, and fixed in position by means of an india rubber cork. The glass plate on which a film was to be deposited was supported horizontally under the cathode by

Digitized by Google

means of a glass tripod. The exhaustion was effected by means of a mercury air pump, and the electric discharges were obtained from a large induction coil worked by three to six Bunsen cells. Films, even of easily oxidisable metals, such as iron, could be obtained without difficulty by taking special precautions to exclude every trace of oxygen and water vapour, as Wright had already shown. The pulverisation was found to take place most rapidly and thoroughly when the cathode was at a red heat, but the best degree of exhaustion and strength of the discharge had to be determined for each metal. When examined under the microscope by transmitted light the films were found to be perfectly coherent and homogeneous. Newton's rings were generally seen, even when the films were apparently quite free from oxide. On placing them between two crossed Nicol's prisms the author was surprised to find that they were doubly refracting.

The phenomenon was observed with films of platinum, palladium, gold, silver, copper, and iron. When the cathode consisted of a straight wire perpendicular to the plate on which the film was to be formed, the metal was deposited in the form of a cone, with its vertex perpendicularly below the wire. When the conical film was placed between two crossed Nicol's prisms and observed by means of a beam of parallel light, a black cross was seen on a bright ground, having its arms in the planes of polarisation of the polariser and analyser respectively, and its middle point coinciding with the vertex of the cone.

It was shown that this appearance was not due to the conical form of the film by allowing polarised light to pass through the glass so as to fall nearly perpendicularly upon the plane surface of the film, and examining the reflected light by means of a second Nicol's prism placed crosswise to the first, when the same appearance was observed as before, even when the film was so thick as to be opaque. Experiments were also made which proved that the effect was not due to the glass, as it might have been supposed to be caused by a state of strain in the glass set up by cooling after being heated by the hot electrode just over the vertex of the cone.

It was also proved by various experiments that the double refraction was not due to a state of tension in the metallic film on cooling after being unequally heated.

The appearance even then might be due to a radial crystalline disposition of the particles of metal, provided each crystal were itself double refracting; but silver, gold, and copper crystallise according to the cubical system, and, as far as is known, are not dimorphous. The author therefore believes that the double refraction must be due to a special arrangement of the particles of metal under the action of electrical forces, which with the vertical wire cathode used would necessarily be symmetrical with regard to the point immediately below it, and therefore if double refraction were produced in that way it would be of the kind observed.

It was found that in the case of an easily oxidisable metal all traces of double refraction disappeared when the film was heated in contact with air. The author found no trace of double refraction in electrolytically-deposited films.

In the case of silver a variation was observed in the colour of different films when viewed by transmitted light, the colours varying from blue to reddish violet. How far these variations depend on the strength of the electrical discharge and the consequent variation in the temperature of the electrode, and on the nature of the gas in the tube, has not yet been determined.

ON THE DEFLECTION OF THE EQUIPOTENTIAL LINES AND The Variation in the Resistance of Bismuth in the Magnetic Field.

By A. Leduc (*Comptes Rendus*, Vol. CII., p. 358, Feb., 1886).

Variations in the Resistance of Bismuth.

The author used for his experiments a plate of bismuth 5·5cm. in length, 3·2cm. in breadth, and with a mean thickness, calculated from its resistance, of ·0233mm. The changes were studied both for variation in the temperature t, and the intensity M of the magnetic field. The results of a number of experiments were well represented by parabolic formulæ of the form—

$$\rho M = \rho_0 (1 + a M + b M^2 - c M^3) \quad (t \text{ constant}),$$
$$\rho t = \rho_0 (1 - p t + q t^2) \quad (M \text{ constant}),$$

where ρ_0 is the resistance of the plate per centimetre of its length when t and M are both zero.

The coefficients, a, b, c, p, q, were found to have the mean values—

$$a = 277 \times 10^{-8} \quad p = 303 \times 10^{-5}$$
$$b = 228 \times 10^{-11} \quad q = 188 \times 10^{-7}$$
$$c \times 105 \times 10^{-15}$$

and the value of ρ_0 was found to be ·0183.

Hall's Phenomenon.

Let A, B, G, H represent the middle points of the sides of the plate. Binding screws, fixed at A and B, served as electrodes for a current which traversed the plate longitudinally. Two other binding screws, fixed at G and H, but insulated from the metal by means of mica, carried small springs with rounded ends, which pressed upon the plates at two points, E and F, of the line G H.

Let D be the deflection of the equipotential line passing through the point E in a magnetic field of intensity M at the temperature t, ρ the resistance of the plate per centrimetre of its length under the same conditions, I the strength of the current, d the distance E F.

Between these two points a difference of potential will be maintained, given by the formula

$$e = I \rho d \tan D.$$

The angle D was found to be never greater than 5° in the experiments, and therefore D may be written for tan D.

If we assume that the variations in the resistance with M and t respectively are independent, and writing

$$\phi(M, t) = (1 + a M + b M^2 - c M^3)(1 - p t + q t^2) = \delta = \frac{e}{I \rho_0 d};$$

we shall therefore have

$$D = \frac{e}{I \rho d} = \frac{e}{I \rho_0 d \phi(M, t)} = \frac{\delta}{\phi(M, t)}$$

It only remains then to investigate the function.

Three sets of experiments were made to determine the effect of M, t, and I respectively. The relation between e/I and M were found to be given by the equation

$$\frac{e}{I} = \mu M (1 - \alpha M + \beta M^2)$$

where
$$\alpha = 91 \times 10^{-6}$$
$$\beta = 316 \times 10^{-11}$$

When M and t were maintained constant as far as possible, D was found to be independent of I.

The temperature was made to vary between 0° and 70°, and the change in δ was found to be given by the formula

$$\delta = \delta_0 (1 + m t - n t^2),$$

where
$$m = ·00541$$
$$n = ·000093.$$

We get then

$$\delta = K M (1 - \alpha M + \beta M^2)(1 + m t - n t^2),$$

and therefore

$$D = K M (1 - A M + B M^2 + C M^3)(1 + P t - Q t^2),$$

where
$$K = 158 \times 10^{-7}$$
$$A = a + \alpha = 882 \times 10^{-7}$$
$$B = \beta - b + a A = 112 \times 10^{-11}$$
$$C = c + b A - a B = 303 \times 10^{-15}$$
$$P = m + p = 844 \times 10^{-5}$$
$$Q = n + q - p P = 862 \times 10^{-7}$$

It is easily seen that D reaches about 5° in a field of intensity 10,000 C.-G.-S. D is a maximum at the temperature 49°. As the resistance of bismuth increases more than 15 per cent. in a magnetic field of 10,000 C.-G.-S., the author intends to make use of this variation, when fully investigated, to measure magnetic intensities.

This increase in the resistance is partly due to the deflection of the equipotential lines, in fact the resistance must be multi-

Digitized by Google

plied by 1/cos D; this coefficient, however, will not exceed 1·005, and therefore the explanation must be sought in the change in structure of the metal produced by the alteration in the electric field of the plate.

THE ELECTRO-MAGNETIC ROTATION OF ORDINARY LIGHT.

By L. Sohncke, in *Wiedemann's Annalen*, Vol. XXVII., 1886.

The object of the research was to endeavour to determine whether or not ordinary unpolarised light could be acted on by magnetic force.

It is known that two beams of plane-polarised light from the same source interfere more or less completely when they meet at a sufficiently acute angle, the interference being most complete when the planes of polarisation of the two beams are parallel, and ceasing entirely when the planes of polarisation are at right angles.

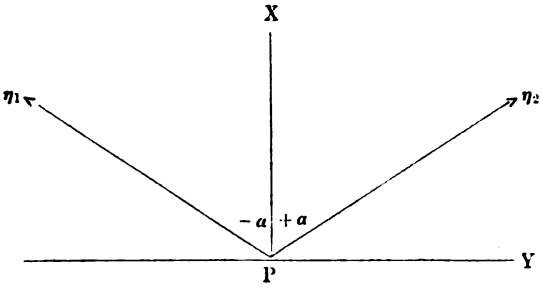
Pencils of ordinary unpolarised light proceeding from the same source interfere in exactly the same way as polarised pencils with their planes of polarisation parallel.

Now, ordinary light may be regarded as plane polarised light, in which the plane of polarisation passes through all possible positions within a very short period, and the interfering rays which cannot differ much in the length of their path may be regarded as polarised in parallel planes. If it be represented more generally as light polarised elliptically, with the major axis of the ellipse continually changing in position, the corresponding rectangular components of two interfering rays may still be regarded as being polarised in parallel planes.

It is clear, therefore, that if the direction of vibration with the first representation, or the major axis of the ellipse, with the second, of one of two mutually interfering rays, be rotated through an angle of 90° with regard to that of the other ray, the two rays will behave as though they were polarised in perpendicular planes. This gives a means of determining whether ordinary light is subject to the same electro-magnetic action as polarised light. The investigation was greatly facilitated by the results of some experiments of Prof. Abbe hitherto unpublished, which he communicated to the author.

Prof. Abbe found that when a slice of right-handed quartz, of such a thickness (1·88mm.) as to rotate the plane of polarisation of sodium light through 45°, was interposed in the path of one of two interfering rays, and a slice of left-handed quartz of equal thickness in the path of the other ray, the interference fringes disappear, not only in the case of polarised light, but also when ordinary light was used. When the experiment was repeated with slices of quartz of twice this thickness, so as to produce a rotation in each case of 90°, the fringes were again seen.

These results were important in connection with the author's investigations, as it enabled him, instead of endeavouring to produce an electro-magnetic rotation sufficient to cause a disappearance of the fringes, to cause the fringes to disappear by the introduction of slices of quartz, as in Prof. Abbe's experiments, and then to endeavour to produce their reappearance by electro-magnetic action, and therefore the experiments could be made with weaker currents and with thinner slices of the substance in which the electro-magnetic rotation was produced. The attention of the author was, therefore, in the first place directed to the further consideration of the phenomenon observed by Prof. Abbe.



Consider two rays of plane polarised light with their planes of polarisation rotated in opposite directions through angles $+\alpha$ and $-\alpha$ respectively, making so small an angle with each other that they may be treated as parallel, and meeting at the point P. Then they may both be supposed perpendicular to the plane of the paper, and the axis of X may be taken as the original direction of vibration. Let δ be the difference between the paths of the two rays measured from the screen to the point P, T the time of a complete oscillation, and λ the wave length of the light used. Then, if the amplitude of vibration be taken as unity, the distance η of a vibrating molecule at the time t from its position of rest P will be given in the case of the two rays respectively by the equations.

$$\eta_1 = \cos 2\pi \frac{t}{T};$$

$$\eta_2 = \cos 2\pi \left(\frac{t}{T} - \frac{\delta}{\lambda} \right),$$

and resolving along the axes these give the components

$$x_1 = \cos\alpha \cos 2\pi \frac{t}{T}$$

$$y_1 = -\sin\alpha \cos 2\pi \frac{t}{T}$$

and

$$x_2 = \cos\alpha \cos 2\pi \left(\frac{t}{T} - \frac{\delta}{\lambda} \right)$$

$$y_2 = \sin\alpha \cos 2\pi \left(\frac{t}{T} - \frac{\delta}{\lambda} \right)$$

giving a resultant vibration

$$x_1 + x_2 = \cos\alpha \left\{ \cos 2\pi \frac{t}{T} + \cos 2\pi \left(\frac{t}{T} - \frac{\delta}{\lambda} \right) \right\}$$

along the axis of x_1, and

$$y_1 + y_2 = \sin\alpha \left\{ -\cos 2\pi \frac{t}{T} + \cos 2\pi \left(\frac{t}{T} - \frac{\delta}{\lambda} \right) \right\}$$

along the axis of y, which may be written

$$x_1 + x_2 = X = 2\cos\alpha \cos\frac{\delta\pi}{\lambda} \cos 2\pi \left(\frac{t}{T} - \frac{\delta}{\lambda} \right)$$

$$y_1 + y_2 = Y = 2\sin\alpha \sin\frac{\delta\pi}{\lambda} \cos 2\pi \left(\frac{t}{T} - \frac{\delta - \frac{\lambda}{2}}{2\lambda} \right)$$

Now if a and b be the amplitudes of vibration of two rays, whose directions of vibrations are at right angles to each other, the resultant intensity T is given by the equation

$$J = \frac{2\pi^2}{T^2}(a^2 + b^2)$$

and therefore if J be the intensity at the point P

$$J = \frac{8\pi^2}{T^2} \left\{ \cos^2\alpha \cos^2\frac{\delta\pi}{\lambda} + \sin^2\alpha \sin^2\frac{\delta\pi}{\lambda} \right\}$$

If J_m be the intensity at the centre (where $\delta = 0$) and J_s the intensity at a distance from the centre, equal to half the distance between the fringes (where $\delta = \lambda/2$)

$$J_m = \frac{8\pi^2}{T^2} \cos^2\alpha;$$

$$J_s = \frac{8\pi^2}{T^2} \sin^2\alpha.$$

Then for $\alpha = 45°$,

$$J_m = J_s = \frac{4\pi^2}{T^2},$$

and the general expression for J gives the same value at every part of the field, which is therefore uniformly bright.

For $\alpha < 45°$, $J_m > J_s$, or the centre is the brightest portion, and fringes appear, which become more disturbed as α approaches 0, when $J_m = 8\pi^2/T^2$, and $J_s = 0$, so that the centre is as bright as possible, and the adjacent fringes are perfectly dark.

For $45° < \alpha < 135°$.

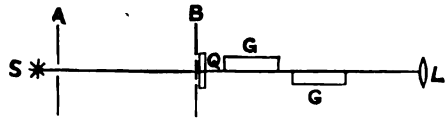
$J_m < J_s$, and therefore the centre is the darkest portion, and for $\alpha = 90°$ $J_m = 0$ and $J_s = 8\pi^2/T^2$, so that the centre is perfectly dark, and the adjacent fringes are as bright as possible. On either of the hypotheses already given for the constitution of ordinary light, these should be obtained with it, as well as with polarised light, and this was fully confirmed

Digitized by Google

by experiment. The phenomena were observed almost as distinctly with white light as with homogeneous light, owing to the fact that in white light the other colours are of feeble intensity compared with the yellow.

Electro-magnetic Rotation Experiments.

The general management of the apparatus, without details of adjustment, is shown in the diagram.



The source of light was a gas flame, S, placed immediately behind a screen, A, through a narrow slit in which the light passed. The pencil of light so obtained fell upon a second screen, B, provided with two small slits, passed through the quartz Q, 1·88 mm. in thickness, which could be placed so that one slice should be in front of each slit, or the same slice in front of both slits, as required. The pencils then passed through two exactly equal and similar pieces of heavy glass G, consisting of pure silicate of lead, cut in such a manner from the same block, and so placed, that if one of the pieces was made to slide along the line S L, until the sides in contact with this line coincided, the two pieces would occupy the same relative position as in the original block. They were supported in such a way that they could be surrounded by coils of wire without disturbing their position. The interference fringes were observed by means of the lens L.

In making an observation, one slice of quartz was first made to cover both the slits in the screen B, and the apparatus adjusted so that the fringes were clearly defined.

The coils of wire were then placed in position round the pieces of glass G, G, and the separate slices of quartz were placed before the two slits, causing a complete disappearance of the fringes. A current of 20 amperes or upwards from a Shuckert compound dynamo was then sent through the coils in such a way as to cause opposite rotations in the two pieces of glass when the fringes again became visible, showing that ordinary light is subject to the same electro-magnetic action as polarised light. When the direction of the current was such as would have caused rotation in the opposite direction to that produced by the quartz in the case of polarised light, the fringes reappeared in their original position. When the direction of the current was reversed the fringes were displaced through half the distance between them, so that the dark bands were replaced by light ones, and *vice versâ*.

It is therefore clear from the analysis previously given that the electro-magnetic rotation of the direction of vibration of a ray of ordinary light is in the same direction as the current round the pieces of glass, as is the case for polarised light.

The observations had to be made quickly, and could not be frequently repeated without allowing some time to elapse, as the glass soon became heated owing to the heat developed in the coils by the passage of the currents, which therefore acquired temporarily the property of double refraction.

CORRESPONDENCE.

THE PROSPECTUS OF THE REGENT PORTABLE LAMP AND LIGHTING COMPANY (LIMITED).

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is to the general interest of the public and the electric community that more capital should be invested in electric industry. We all know that it is possible to employ large amounts of capital, and at a profit, in electric work, but after the immense and needless retardation suffered by electric lighting a few years back through the careless knocking together of companies and bad management, all who have been identified with electric lighting from its commencement in this country have a right to jealously guard the interests of the public in this matter, and consequently their own, and I am sure that the technical journals devoted to electric work are earnestly determined to safeguard these interests so far as possible.

I should be sorry to say anything that would cause grievance to any inventor who may have worked long and hard, and be on the point of seeing his hopes and wishes realised, but the above prospectus involves the following observations:—

1st. Dr. Fleming, Mr. Sydney F. Walker, and Messrs. Ingrey, Poore, and Latham, all, of course, by having their names, reports, &c., in the prospectus, as they are, pledge themselves to the public on the points claimed by the prospectus.

2nd. It is claimed that the battery is "the invention of the century."

3rd. That numerous primary batteries have lately been introduced to the public, but none of them have been of any practical commercial use." Now, is this statement correct or not? What have Messrs. Johnson and Phillips to say to this? as it affects the battery which they largely advertise as a practical success. Would not Messrs. Woodhouse and Rawson dispute this statement, and Mr. Upland have something to say? Would not the Volta-Pavin battery, which is meeting, I believe, with considerable success in America, and is now being introduced here on a commercial footing, controvert this statement?

4th. One paragraph says: "The following are some of the *special* features in connection with electric lighting by means of this battery."

The public would surely understand this to mean features *peculiar* to the battery in question. The points mentioned under this heading are that "it is self-contained"; "that no machinery is required"; "the battery being very small and portable can be removed from house to house, &c."; "atmosphere not vitiated, &c."; "a steady and constant light is maintained 8 to 13 hours without attention."

If this latter point meets the view of the technical gentlemen concerned, they are very easy to please. The length of time a battery will run depends on the liquids used and the quantity, to a great extent; but batteries are now being made for house lighting that go from six to ten times the number of hours here mentioned without alteration. As regards Dr. Fleming's report, in his preliminary letter it is not clear whether he means that there is no local action in the battery or whether it is only got rid of to a remarkable degree. However, in his detailed report he says that the average loss by local action is $\frac{1}{4}$ per cent. per hour, but in one of his concluding paragraphs he says:—"One thing that greatly recommends such a primary battery as this for such domestic lighting is that it can be used occasionally whenever required. Now, no arrangement in which secondary cells are used can be employed intermittently." Now, if the battery is to be used intermittently (in practice for house lighting a battery will be idle, say, 18 hours out of 24 on an average), what will become of the plates which vanish at the rate of $\frac{1}{4}$ per cent. per hour, say, in one month?

How in this respect will the battery be superior to accumulators?

Does Dr. Fleming consider that the second clause of his table of requirements is met by this $\frac{1}{4}$ per cent. per hour? As regards the local action, which Dr. Fleming puts at $\frac{1}{4}$ per cent. per hour, in this same prospectus Messrs. Ingrey, Poore, and Latham state that "*entire* absence of local action is one of the astounding features of the invention."

Mr. Sydney F. Walker states that "this invention has rendered a practicable portable electrical miner's lamp possible for the first time."

He also says that the materials used are the cheapest known to science for this purpose. I think these statements are more glowing than easily supported. On the solution question, if he refers to the mixture described, but now claimed by Mr. Macquay, Mr. O. C. D. Ross could enlighten him.

We are all glad to see a New York electrical appliance to the fore, but would not the labours of those concerned in this matter have been more sure of reward if they had been dealt with on a different basis—as to points claimed, &c.?

What is it that Dr. Fleming, Mr. Sydney F. Walker, and Messrs. Ingrey, Poore, and Latham, by their position in this affair, as representing electrical experts, recommend the public to pay £45,000 for—£17,500 in cash?

Digitized by Google

No particular solution is claimed in the battery. There are four claims :—

1st. Is for the alloy of mercury, tin, and lead (in the proportion stated) with zinc.

2nd. For a method of amalgamating.

3rd. Is for treating the carbon electrode with sulphur (painting the upper part, as I understand it).

4th. Is the arrangement of letting all the liquids intermix when filling the cells.

I must apologise for the length of these reviewing remarks, but I hope you will see there is ground for criticism in the real interest of electric work.—Yours, &c.,

RADCLIFFE WARD.

P.S.—I know a set of Volta-Pavin cells that run 240 hours. They had one solution changed about every 60 hours (four times).

10A, Great Queen-street, Westminster,
September 1, 1886.

DOMESTIC ELECTRIC LIGHTING.—A PROTEST.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : We beg to refer to the prospectus of the Regent Portable Electric Lamp and Lighting Company (Limited) which is now being advertised, and subscriptions for shares in which are now being sought.

We beg to state that we are the owners of patents for domestic electric lighting produced by primary batteries which are both extensively in use and a great commercial success.

The statement in the prospectus of the Regent Portable Electric Lamp and Lighting Company (Limited) "that numerous primary batteries have lately been introduced to the public, but *none* of them have been of any practical or commercial use" is incorrect. For instance, we guarantee to run our batteries without discharging or any alteration whatever ten times the number of hours claimed for the Regent.

As the above statement in the Regent prospectus is calculated to do us great damage we shall be obliged if you will give publicity to this letter.—Yours, &c.,

JAMES S. BURROUGHES, Chairman.

The Loeb Chemical Electric Light Company (Limited),
19, Soho-square, W.

ABSOLUTE NEGATIVE CHARGES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : I am pleased to gather from Mr. Caine's letter published last week that in his opinion the number is small of those who are ready to come forward to answer for the absolute negative charge, and that there are not many who believe in their heart and soul that the earth carries a negative charge, and that the corresponding positive charge is banished out of all localised existence in the universe, or, as it is expressed by mathematicians with their more refined conceptions, situated "at an infinite distance."

However, the chief bearing of your correspondent's remarks seems to be an objection to the use of the word "static" in connection with those electrical phenomena to which it is generally applied, and more particularly to the quoted expression "electrostatic circuit." Whilst I agree that the term "inductive circuit" is very appropriate, I do not feel that "electrostatic" is an unsuitable epithet. Electrostatics and static electricity, are these ill-chosen expressions? To me the statical phenomena of electricity seem quite the counterpart of the phenomena of mechanical statics.

I should be sorry if any of your readers were misled by Mr. Caine's reflections on what I said about strain and yielding, as well as about the action of a dielectric medium. Mental abstractions are the very essence of science, and we are constantly obliged to use the words "so far as" to indicate that we are considering one feature alone, and neglecting for the moment other aspects of the case before us. Thus, as a matter of fact, every dielectric does conduct a little and slowly; nevertheless, *qua* dielectric it does not conduct. The gradual leakage which a dielectric permits is not its principal and essential action, but an accident. Conduction is no part of induction so far as it is induction. And although Mr. Caine may often have heard the cracks and squeaks of a rope on the capstan, it is nevertheless true that strain, as such, is incompatible with yielding. The stretching of a rope is, I certainly think, a temporary hindrance to our setting up in it the desired tension.—Yours, &c.,

E. ALDRED WILLIAMS.

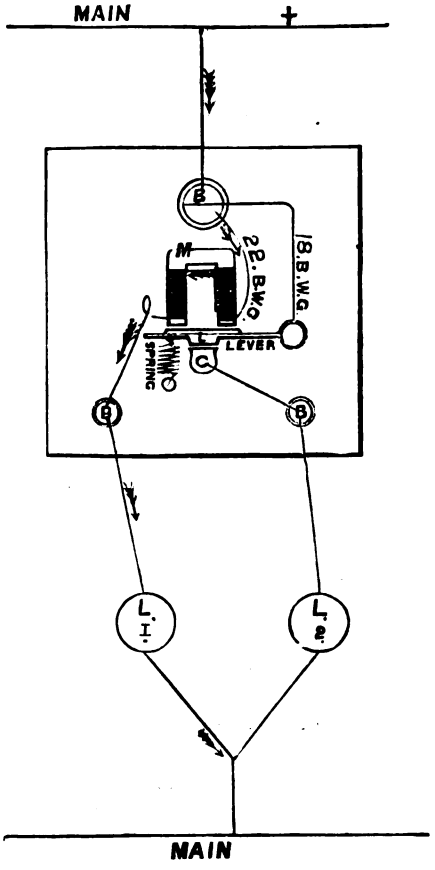
ELECTRICAL TRAIN LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : In your last week's issue I notice a paragraph relating to my "Improvements in Electrical Train Lighting" which states that there is only one lamp in each compartment.

There are two 16 candle-power 50-volt lamps in each compartment, but only one is lit at a time. By the introduction, however, of a special contact maker, the second lamp lights up on the first one giving way. I devised this so as to have another lamp ready in event of the first one breaking, and find it works very well when constructed and coupled up as shown on enclosed sketch.

As stated, the lamps are 50-volt ones, and are coupled in parallel. There is nothing special about the contact maker, except *arrangement of connections*, and I do not remember seeing anything so simple before.



B B B Binding screws ; C Contact maker ; L L Lamps ; M Electromagnet wound with eight layers of No. 22 B.W.G. wire.

If not new to you, perhaps its application may be so to some of your readers.

My name was wrongly spelt in the *Scotsman*.—Yours, &c.,

THOS. P. CARSWELL.

THE BRITISH ASSOCIATION.

The meeting of the British Association this year at the centre of British industry bids fair to be as important and as interesting as that which was held there twenty-one years ago, under the presidency of JOHN PHILLIPS, one of the founders of the Association. In its choice of president for the coming year it has been peculiarly happy. Sir WILLIAM DAWSON is a man of world-wide reputation in the special branch of science to which he has devoted a lifetime; but he is also a Canadian; and at a time when greater Britain is being entertained in the metropolis, and when the desire for closer unity among her children is taking definite and practical shape in the mother country, the selection is naturally regarded as having some significance. Two years ago the Association held its meeting for the first time outside the British Isles; and in 1888 Australia will follow the example of Canada. No wonder that the present representative of Colonial science, from the presidential chair on Wednesday evening, referred to these striking facts as proof of the Imperial character of the Association, and the consolidation of the scientific interests of Her Majesty's dominions. The industrial gathering at South Kensington and the scientific union at Birmingham are pledges of a moral federation of the Empire which may perhaps be more enduring than any political federation we could devise, and is certainly beset with fewer practical difficulties.

Sir WILLIAM DAWSON'S presidential address, which we print elsewhere, was almost exclusively confined to a geological survey of the North Atlantic ocean, a subject with which as a specialist he was peculiarly competent to deal, and which he contrived to make as attractive as any special subject of the kind could possibly be. Setting himself the seemingly impossible task of answering such questions as, What has at first determined the position and form of the Atlantic? What changes has it experienced in the lapse of geological time? What relations have these changes borne to the development of life on the land and in the water? and What is its probable future? the President astonished his audience by the array of cosmographical facts and inferences which geologists have already accumulated, and which go far to enable us to speak with some confidence on these vast operations of nature in the remote past. The bottom of the Atlantic has now been almost as carefully explored and mapped out as the two continents which bound it, and the evidence collected by the "Challenger," in deep sea, as well as by land exploration on either shore, shows the processes of change which are ever going on, and which have been doubtless going on for ages. To say nothing of volcanic disturbances on a vast scale—of which the speaker no doubt would have had more to say had he been aware of the terrestrial convulsions to which even at that moment his native continent was being subjected—boulders from the Arctic seas are being constantly carried by ice drift, and imbedded in the mud which forms the normal bottom of the Atlantic; and of living objects almost every stage of their evolution and development may be traced on both sides of the ocean separating the old and new worlds. The only thing that seems not to have changed is the oyster. The oyster is precisely what it was in the carboniferous age, a fact consoling to posterity, who may reckon on the conservative instincts of this delectable mollusc to preserve it unimpaired through the revolutionary ages in store for its human admirers.

Although the presidential address on this occasion had less to do with electrical science than any similar discourse for many years past, the subject was not without interest to the practical telegraph engineer in relation to the operations of submarine cable-laying; and we have reason to believe that some valuable contributions will be made to theoretical and applied electrical science in the course of the meeting. Ample reports of all papers likely to be of interest to readers of *The Electrician* will be supplied by our representative on the spot, and printed in these pages. Meantime we have only to congratulate the Association on the signs of continued vitality which attends its progress from year to year. Its finances appear to be in a prosperous condition, and the interest taken in its proceedings by the newspaper press shows this year no sign of abatement. One thing surprises us. Of the brilliant assembly which on Wednesday evening listened to the presidential address in the Town Hall, at Birmingham, more than half were ladies; yet the report of the Council declared that they had negatived the admission of ladies as officers of the Association, or as members of the General or Sectional Committees. We do not see how this exclusion can be maintained much longer, seeing that the Association freely admits the weaker sex to its membership—assuming, of course, that they desire to have a share in the management of its affairs. Possibly the spirit which prevails in the Council may be that of the Treasurer, who, if correctly reported, announced at the conclusion of the opening meeting, that "the total number of members enrolled was 2,222, and that among these there were

Digitized by Google

412 ladies and a considerable number of foreigners." Ladies appear to be classed with foreigners, whose numbers need not be specified. This reminds us of a famous siege which took place a couple of centuries or so ago, and of which the historian has left record, that "thus was the city carried by fire and sword, when 5,000 souls were slain, *besides women and Jews.*"

THE THREATENED INCANDESCENT LAMP MONOPOLY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The more one thinks over the above subject the more important does the matter become, and it is one which makers of engines and dynamo machines should not lose sight of now that they have a fair chance before it is too late—that is, *if they wish to frustrate a monopoly of the lamp trade*, which should be prevented if possible, because if not, it may tend to check an important industry just now on the turning point of success.

The question is, as Mr. Shippey stated at the meeting held at the Cannon-street Hotel on the 26th ult., of national importance. On this point I quite agree with him, for what is the use of a good engine or dynamo machine without a really good and cheap lamp to produce the light at a reasonable price? The paper read by him certainly contained much interesting information. If only one-half of the facts stated by him can be proved, the outcome of this meeting may do more good than the engineering trade at present dreams of, and to my mind every support should be accorded to Messrs. Shippey's firm to assist them in carrying out their objects. If a monopoly can be frustrated, by all means let it be done. Mr. Shippey clearly stated that it was not his object to upset the Edison patents, but to keep them within the limits of the specification. I have had considerable experience in patents and patent law, and I am already of opinion that the Edison and Swan Company will not, nor can they in the face of fact adduced at the meeting, secure a monopoly of the trade if the company's patents are properly attacked.

The question of the resistance of lamps made by each maker is a point which appears to have been lost sight of. Edison claims by his specification a filament of high resistance—say 100 ohms and upwards—and has specified such a claim in his patent. He is therefore undoubtedly entitled to it, but that is all. Then, again, Shippey Brothers candidly state that their process is not suitable for incandescent lamps of high resistance, or do they, or can they, make such a lamp, their process, which is a secret one, being only suitable for glow lamps of low resistance—say from 6 to 40 or 50 ohms resistance at the outside—suitable for battery work and single domestic installations. Their specification clearly states low resistance and 50 ohms; Edison's says 100 ohms and upwards, and makes a point of this, which is one that should not be lost sight of.

Now, if the law upholds Mr. Edison's patent for a lamp of high resistance, made as described in his specification, surely the law will also protect Messrs. Shippey Brothers for their speciality of a glow lamp of low resistance. Further, even if it has been decided that Woodhouse and Rawson were making lamps which were proved to be an infringement of Edison's rights, it does not for one moment prove that the other lamp, such as the Victoria lamp, made by the Brush Corporation, or the Standard lamps sold by Messrs. Shippey's firm, or the Bernstein type, are also infringements of the Edison system, and to my mind, if the company are pinned down to the details of their specification pure and simple, such as the mode of manufacture, and materials used, and resistance claimed, that is all that can be upheld, and they have not a leg to stand upon against any patent which describes its process as entirely different, especially against such a patent as that of Shippey Brothers, who appear to have successfully made a lamp of low resistance, which Mr. Edison said was impossible. Consequently, the Edison and Swan Company will have some hard work before them, and will have many battles to fight, before they will secure a monopoly for that which they, on the face of facts, do not appear to be entitled to; and this appears to be the general opinion of those who understand the art of incandescent lamp making.—Yours, &c.,

WM. H. LE FEVRE, C.E,
Past President of the Society of Engineers.

St. Antholin's Chambers, Budge-row,
Cannon-street, E.C., Sept. 2, 1886.

THE BRITISH ASSOCIATION MEETING AT BIRMINGHAM.

(FROM OUR SPECIAL CORRESPONDENT.)

BIRMINGHAM, Thursday Evening.

The Sections opened to-day with the various Presidental addresses. The only address touching even indirectly on electrical subjects, was that of Prof. Crookes in the Chemical Section. The address of Prof. Darwin, in the Physical Section, discussed the question of a unit for geologic time. In this Section, Dr. MacAlister reported the success of the Grenada Eclipse Expedition; and among other papers read was one by Prof. Bottomley "On An Improved Mercurial Air Pump." Prof. J. Blyth also read a paper "On a New Form of Current Weigher for the Absolute Measurement of an Electric Current," and Prof. Poynting a paper "On the Proof of Cavendish's Method as to the Law of Inverse Squares." Prof. Bottomley also described experiments carried out in the Glasgow University laboratory "On the Application of Electrolysis to the Standardising of Electrical Instruments."

Prof. Poynting, in his paper, said that the proof of the law of electrical action depending on the fact that there is no electrification within a charged conductor was first given by Cavendish. His proof was made more general by Laptall, who has been followed by other writers, including Maxwell. Maxwell and MacAlister have also verified the experimental fact, repeating an investigation of Cavendish only recently published in Maxwell's edition of his researches. The proof may be analysed in the following way:—Take the case of a uniformly charged sphere. The action at a point within it may be considered as the resultant of the actions of the pairs of sections of the surfaces of all the elementary cones, with the point as vector. If, then, the resultant action is zero for all points and for all sizes of the sphere, it follows that by the action of the pair of sections each elementary cone is zero; and, since the sections of the surfaces are directly as the squares of the distances, the two sections neutralise each other. A proof was given by the author in the *Memoirs* of the Manchester Philosophical Society, 1876-7. There appears to be two objections to this proof. (1) That it takes no account of the always existing opposite charges when the sphere, for instance, is positively charged. An equal and opposite negative charge is on the walls of the room, and the action of this should be considered. Probably this objection could be removed. (2) There is a solution still simpler than the inverse square law—viz., that no element of the surface has any action within the closed conductor. If we suppose that a conductor is a complete screen to electrical action, then, whatever the law of the force exerted across an insulator, there will be no action within the conductor. In any null proof it is not sufficient merely to show that there is no action in the null arrangement, but it is also necessary to show that on disturbing the null arrangement some action is manifested. Now, in the case here considered it is impossible to obtain any action within the conductor in any statical arrangement; it is only during changes of the system while charging or discharging that we can get a disturbance of the null arrangement. But here new phenomena come in, for we have currents, and therefore electro-magnetic action. But, even disregarding the different kind of action occurring, the only experiment which I know of on this point, was that of Faraday with his electrified cube. While the most violent charges and discharges were taking place on the outside of the cube, so that the null arrangement was probably disturbed, he found no

Digitized by Google
REESE LIBRARY OF THE UNIVERSITY

action on his electroscope within. Possibly the actions were alternating and so rapid that no electroscope of ordinary construction would reveal them. But he himself went into the cube, and he would probably be sensitive to rapidly alternating electromotive forces. It appears to me, then, that we cannot accept this proof, and must fall back upon the more direct proof of Coulomb. I do not know whether Maxwell was aware of this objection; but it is worthy of note that in the remarkable fragment published since his death, as "An Elementary Treatise on Electricity," he returned to Coulomb's proof, and was apparently building upon the mathematical theory of electricity in a way quite different from that followed in his larger work.

ALTERNATING AND INDUCED ELECTROMOTIVE FORCES.—V.

BY W. H. SNELL.

We have already seen that the current traversing any circuit of resistance R under an alternating E.M.F., E, of periodic time T, is numerically equal at any moment to the quotient of this E.M.F. divided by S, where S is put for

$$\left\{ R^2 + \left(\frac{2\pi L}{T}\right)^2 \right\}^{\frac{1}{2}},$$

Let us also put $\frac{2\pi}{T} = p$ for brevity, then

$$S = (R^2 + p^2 L^2)^{\frac{1}{2}}.$$

It is convenient to call S the "virtual resistance" of the circuit, or of any part of it, such as a single coil, only we have to remember that this virtual resistance is not merely a function of the constants R and L of the coil, but also of the periodic time of the alternations; so that the coil does not itself possess any one definite value of S. And further although S is always necessarily larger than R it cannot be expressed in the form $(R + a)$, but is in general a quantity incommensurable with R. If these points are borne in mind it will be found useful to employ the term "virtual resistance," and we shall not then be liable to be misled thereby.

The recent appearance of a paper by MM. Vaschy and De la Touanne "On the Numerical Values of Certain Coefficients of Self-Induction," which has been presented to the *Société Internationale des Electriciens*, and a translation of which appeared in the last number of this journal, enables me to illustrate this part of the subject by means of values taken from actual examples such as have scarcely been hitherto attainable.

From this paper we take the following values for L and R, for the cases specified:—

(A.)	Coil without core	R = 242; L = 0·233.
(B.)	Same coil with soft iron core	R = 242; L = 1·66.
(C.)	Coil with hard steel core	R = 200; L = 0·15.
(D.)	Coil with soft iron core	R = 200; L = 1·00.

The first two cases relate to the same coil, but the two latter are each distinct coils. It will be seen that the several values of L do not lie far apart; nevertheless the difference which results in the values of S, especially where T is small, are enormous. In Fig. 11, the values of S are plotted for successive values of T from 0·05 down to 0·005; that is from 20 up to 200 alternations per second.

Comparing A and B, the enormous increase in the virtual resistance of the coil when a soft iron core is introduced is at once apparent, although the second curve cannot be shown in full upon the scale of the figure. Coils C and D, again, which have each a resistance of 200 ohms for continuous currents, are seen to have a resistance of 220 ohms and 660 ohms respectively for a current with 100 alternations per second. If the periodic time be made still smaller, so as to obtain 200 alternations per second, we get a virtual resistance of 274 ohms in the first case, and 1,290 ohms in the second. The difference mainly results from the presence of soft iron in the latter coil and hard steel in the former; but as the coils are not the same, and we do not know in what way either of them is wound, we cannot tell how much of this effect is due to the winding, or how much to the the nature of the core. The bearing of these facts upon the theory of the telephone, and especially upon the resulting loss upon long lines of the higher over-tones which are essential to distinct articulation, and the curious way in which these effects may be counterbalanced by the static capacity of the line, has been thoroughly worked out by Mr. Blakesley in his papers upon Alternating Currents, although the matter still seems to be but little understood.

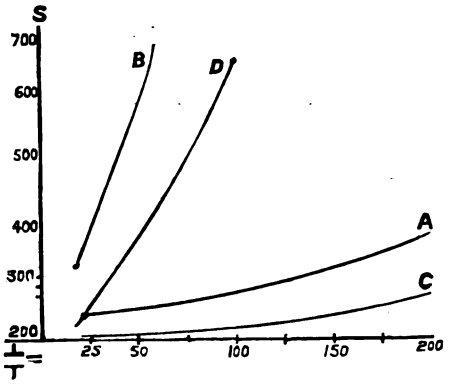

FIG. 11.

Before proceeding to the subject of mutual induction, it will be desirable to make some reference to the general problem of an alternating E.M.F. acting in a compound circuit. In the most elementary case let there be two coils connected in parallel, with resistances R_1, R_2 and self-induction coefficients L_1, L_2 respectively; let an alternating *impressed* E.M.F. act in the other part of the circuit (for which we may suppose the resistance and self-induction to be negligible). It is required to determine the current, and the angle of retardation in each part of the circuit.

Now, if at first we consider only the main branch, in which the E.M.F. is placed, it is obvious that the problem is equivalent to finding the values R_0 and L_0 for a coil such that the total current and the resultant lag shall remain unaltered when this single coil is substituted for the two in parallel. We may then say that these two sets of coils have "equivalent" resistances. It is however obvious that, just as in the case of the virtual resistance of one coil, there is no definite value of R_0 and L_0 for any two coils, except as a function of the periodic time.

The solution of this problem has been given by Lord Rayleigh in a form which is particularly convenient, because it readily permits of extension to the case of a circuit with three or more parallel branches. But for permission to make use of the following simplified method of arriving at this form of the solution the writer is indebted to the courtesy of Mr. (now Dr.) R. M. Walmsley.

In the first place, making use of equation (10) and writing p for $\frac{2\pi}{T}$, we may put down the expressions for the three currents in the circuit at any moment, thus

$$\left.\begin{aligned} I_1 &= \frac{E}{S_1}\sin(pt - \phi_1) \\ I_2 &= \frac{E}{S_2}\sin(pt - \phi_2) \\ I_0 &= \frac{E}{S_0}\sin(pt - \phi_0) \end{aligned}\right\} \quad . \quad . \quad . \qquad (15)$$

and we know also that

$$\left.\begin{aligned} \tan\phi_0 &= \frac{pL_1}{R_1} \\ \tan\phi_2 &= \frac{pL_2}{R_2} \\ \tan\phi_0 &= \frac{pL_0}{R_0} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \qquad (16)$$

First, put $t = 0$, then from (15) since also

$$I_0 = I_1 + I_2 \quad \text{(always)} \quad . \quad . \quad . \quad . \qquad (17)$$

Digitized by Google

we have $$\frac{\sin\phi_0}{S_0}=\frac{\sin\phi_1}{S_1}+\frac{\sin\phi_2}{S_2}.$$

But from equation (16)

$$\sin\phi_1=\frac{pL_1}{S_1}$$

$$\sin\phi_2=\frac{pL_2}{S_2}$$

$$\sin\phi_0=\frac{pL_0}{S_0}$$

$$\therefore\quad \frac{L_0}{S_0^2}=\frac{L_1}{S_1^2}+\frac{L_2}{S_2^2}=Q \text{ suppose} \quad . \quad . \quad (18)$$

Next, put $p\,t=\frac{\pi}{2}$. Then from (15) and (17)

$$\frac{\cos\phi_0}{S_0}=\frac{\cos\phi_1}{S_1}+\frac{\cos\phi_2}{S_2},$$

which gives, with the values of sin ϕ_0, &c., just obtained,

$$\frac{R_0}{S_0^2}=\frac{R_1}{S_1^2}+\frac{R_2}{S_2^2}=P \text{ (suppose)} \quad . \quad (19)$$

Re-writing (18) and (19)

$$Q=\frac{L_0}{R_0^2+p^2L_0^2}$$

$$P=\frac{R_0}{R_0^2+p^2L_0^2}$$

whence $$R_0^2+p^2L_0^2=\frac{1}{P^2+p^2Q^2}$$

and $$R_0=\frac{P}{P^2+p^2Q^2} \quad . \quad . \quad . \quad . \quad . \quad (20)$$

$$L_0=\frac{Q}{P^2+p^2Q^2} \quad . \quad . \quad . \quad . \quad . \quad (21)$$

But from (18) and (19) the values of P and Q are given in terms of R_1 L_1 and R_2 L_2, hence R_0 and L_0 are found in known terms. The extension to three or more branches is obtained by simply adding the successive terms to P and Q in (18) and (19), and using these values in (20) and (21).

The fact that the angle of retardation is not necessarily the same in the two branches shows that there may be a circular current around this part of the circuit alone. It is unfortunately difficult to show exactly how R_0 and L_0 vary with the constants of the two coils; if the above expressions are written out in full they become very unwieldy. The correctness of the formula may readily be inferred by making L_1 and L_2 vanish in the expression for R_0, when it will be found to result in the ordinary formula for the resistance of compound circuits.

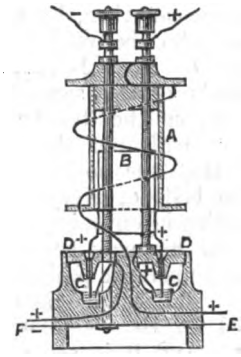
A NEW AUTOMATIC SWITCH.

In ordinary incandescent lighting it is often desirable, and on the multiple series system it is even necessary, to provide means by which a fresh lamp is substituted upon the breaking of a filament in one of those burning. A novel automatic switch designed for this purpose is that shown in section in the accompanying illustration. It is the design of M. L. Clerc. It consists of a vertical solenoid A included in the circuit of the active lamp. Within the solenoid there plays a core or tubular plunger B of thin sheet-iron, which carries two rods C at its lower end, arranged so as to dip into two mercury troughs D. When the active lamp (connected at E) burns, the current passing in the solenoid raises the cylinder, and the circuit of the reserve lamp is open. Should an accident occur to the first lamp, the cylinder drops, the rods plunge into the troughs of mercury, and the circuit of the reserve lamp connected at F is closed. The light is therefore interrupted only for an instant.

When the lamp is switched off in the regular way, the stoppage of the current allows the cylinder to fall. Thus, when the lamp in service is switched on again, the current for an instant passes through both lamps; but as the cylinder is almost instantly raised, the reserve lamp is cut out.

The mercury troughs are arranged so as to prevent spilling of the mercury, and have small conical openings at the top, to allow it to be conveniently poured in.

Since it requires power to keep the solenoid A energised, M. Clerc has sought to reduce that as much as possible by favourable construction, so that the electrical energy consumed in the solenoid does not exceed one watt.



New Automatic Switch.

If it is desired to have both lamps lit at the same time, this can be arranged by inserting an interrupter, which suppresses temporarily the function of the apparatus, and thus leaves both lamps in circuit.—*Electrical World.*

AN "AUTOMATIC DISTRIBUTOR" FOR TELEPHONE CIRCUITS.

The "automatic distributor" is the outcome of the combined labours of MM. Ericsson, Cedergren, Nyström, and Wennmann, the two latter being connected with the Swedish Telegraph Administration. By the employment of this apparatus it is possible to serve five different subscribers upon the same wire; if necessary, this number might easily be increased. We take the following description from the *Journal Télégraphique.* The automatic distributor, which is represented in Fig. 1, is intended for use upon telephone lines which are provided with magneto call signals. The apparatus, however, requires the use of a continuous current in addition to the magneto. Fig. 2 shows the connection of the various parts of the distributor with which each subscriber is provided. G is a polarised switch, which may be made to close the circuit of either of the magnets M or M_1, according to the direction of the battery current. A is the distributor proper, consisting of a needle moving over a dial. B, C, D, E, F is an "interruptor." The principal office of the latter instrument is (as its name does *not* very clearly imply) to enable any subscriber to connect his line with the exchange. The distributor A is actuated on the part of the exchange by means of a succession of positive currents, the number corresponding to the number of the subscriber. When the signal to switch off is given, the distributor is replaced in its normal position by means of *one* negative current.

Having given this general idea of the nature of the apparatus, we shall now proceed to follow its action in detail, and to trace the path of the currents by means of Fig. 2.

1st. The apparatus being at rest in the position indicated by the figure, the exchange wishes to establish communication with subscriber No. 1.—The exchange first sends one positive current to the line. The current passes first through the polarised relay, thence through the upper stops of the armatures of M and M_1, and divides among the five contact springs a_1.....a_5, and through the five electromagnets E, the springs D, and the contacts *e* of the "interruptors." It has already been mentioned that only one of these five interruptors is shown in the figure. A moment later the polarised armature (*m*) of the magnet G closes the contact *a*, and puts the coil M to earth. Consequently the current now divides at the point *f*, one part passes through the electromagnet M, and thence through the tongue *m* to earth. The armature of M being thus attracted interrupts the circuit first described by which the current passes to

Digitized by Google

the five lines L_1.....L_5. Now the armature of M is in mechanical connection with a pallet, not indicated in the figure, which acts upon an escapement wheel fixed upon the same axis as the needle *v*. Thus the positive current sent from the exchange causes the needle to advance one step, where it makes contact with a pin joined directly to the line L_1. By the same movement of the needle in question, the connection of the springs a_1.....a_5 with the needle *v* has been interrupted. The exchange can then, by means of its magneto-inductor, call up the subscriber on line L_1 without interfering with the subscribers on lines L_2 ..... L_5; and by reason of the rapid reversals of the signalling current no effect will be produced upon the tongue of the relay G, and the needle *v* will not be again disturbed. It must be admitted that the positive current first sent to line may sound the bells of every one of the subscribers; but this is a very trifling inconvenience, as only a single stroke can be given, and even this may be avoided by causing the hammer to rest always upon the positive side.

It is unnecessary to add that the same intermediate contacts which are established for the signalling circuit serve also for the speaking circuit. And it is also evident that the conversation cannot be overheard by those subscribers who have not been called. The employment of the distributors does not introduce any deviation from the main circuit, and the only additional resistance is that of the relay G, which is about 30 ohms.

When the conversation has ended the exchange sends one negative current upon the line, which follows at first the same path as the telephonic currents. But the next instant the tongue *m* closes the lower contact *b*, and the current again divides at the point *f*. A part of the current now traverses the coils of the electro-magnet M, and the movement of the armature releases the pallet of the escapement wheel, and also the needle *v*. The latter is then brought back to its original position by means of a spiral spring, to which it is attached.

2nd. The apparatus being at rest, subscriber No. 1 calls the exchange.—The magneto current passes through the distributor by the following path :—Lever B, contact point *e*, spring D, electro-magnet E, spring *a*. From this point the current is momentarily divided amongst the other four lines; but this circuit is immediately interrupted. In fact, all the electro-magnets of the interruptors E_1.....E_5 are provided with polarised armatures. Consequently, the armature E, which alone receives the full current, is at once pulled over, and so interrupts the circuit of the lines L_2.....L_5. The upper end F of the pin projecting from this armature turns to the left, and the left-hand extremity of the lever B, which rested upon this pin, falls, and so makes contact at *c* between B and F. The right-hand extremity of the same lever B then presses against and lifts the insulated end of the screw *s*, and turns the elbow lever C so that the screw *h*, which is also insulated at its extremity, *d*, is moved to the left, and presses back the spring D. The five bent levers C_1.....C_5 are all placed upon a common axis. Consequently, when any one of these levers opens its spring contact D, all the similar contacts are opened, and these circuits are simultaneously interrupted. The circuit of the magnets is now maintained through the point of contact *c*, between F and B, thence through the needle *v*, directly to the exchange. The only additional resistance is that of the relay G. The telephone current follows the same route.

The conversation being ended, the central station again sends a negative current, bringing the electro-magnet M_1 into action. This current does not produce any effect at this time upon needle *v*, which is already at zero. But the armature of M_1 is also in mechanical connection with the extremity *s* of the bent lever C, which, in consequence, follows the movement of the armature as it falls. The lever B of the line L, which had been disconnected, is then replaced in its normal position, resting upon the top of the pin of the armature F, from which it is, however, insulated by a piece of ebonite as already intimated. The whole apparatus has now returned to its normal condition.

3rd. The apparatus being at rest, subscriber No. 1 wishes to speak to No. 5.—The subscriber first calls the exchange in the manner already described, and asks to be connected with L_5. The exchange then sends nine positive currents to line, the first contact being held down rather longer than the others in order to give the polarised switch time to fall over. The needle *v* is thus led to the contact-piece marked "1—5" upon the dial. In this position the needle makes contact at one end with L_5, and upon an inner circle the other end makes contact with L_1 upon the disc *n*. The line L to the exchange is at the same time maintained in contact with the needle *v*. It follows that the telephone currents which pass between L_1 and L_5 are tapped through the exchange, which is thus able to discover whether the two

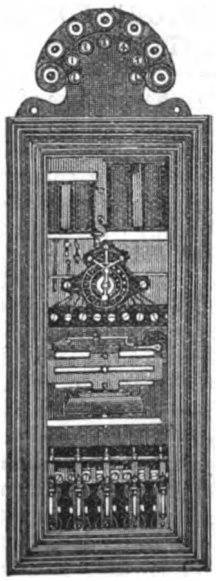


FIG. 1.

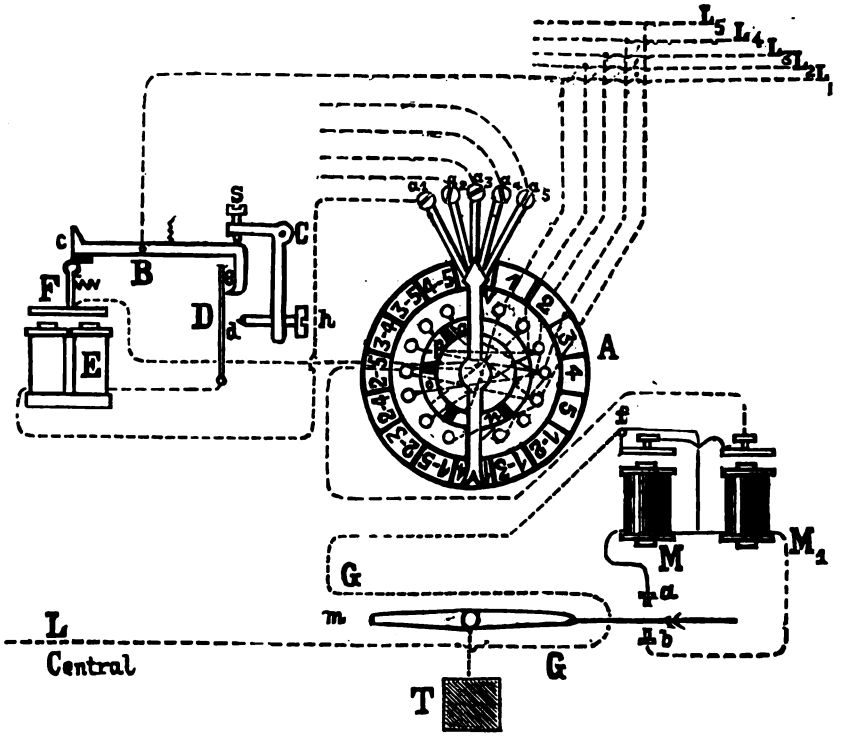

FIG. 2.

Digitized by Google

subscribers are in communication, and also to know when they have finished their conversation. In order that this shunt circuit may not interfere with the distinctness of the conversation between L_1 and L_5, an additional resistance is at the same time inserted in the line between L and earth.

The dial of the distributor in the same way possesses a separate contact piece for every distinct pair of lines. Thus, for five subscribers we require altogether 16 sections, including one for the zero position. The apparatus has been found to act well, and does not easily get out of order. If an error should be made in the signals, the needle can immediately be restored to the zero position. It has generally been found that the introduction of this apparatus permits a reduction to be made in the tariff for the exchange service.

ON THE MAGNETIC TORSION OF IRON AND NICKEL WIRES.

BY SHELFORD BIDWELL, M.A., F.R.S.*

In a paper published in the *Phil. Mag.* for July, 1886, p. 50, Prof. G. Wiedemann refers to his well-known experimental researches into relations between the torsion and magnetisation of iron wires. Let a longitudinally magnetised wire, NS, befixed at the south end of S, the other end N being free, and let a battery current be passed through it from S to N, then the free end will be observed to twist in the direction of the hands of a clock as seen from the fixed end.

Maxwell† explains the phenomenon thus. The wire being magnetised both circularly and longitudinally, the resultant magnetisation is in the direction of a right-handed screw round the wire. Now Joule found that an iron bar when longitudinally magnetised was increased in length, its tranverse dimensions being at the same time contracted. We should expect, therefore, that a spirally magnetised wire would expand in the direction of the magnetisation and contract in directions at right angles to the magnetisation. And thus the twisting would be produced.

This explanation assumes that the torsional effect is simply secondary to and dependent upon the phenomena observed by Joule, and Prof. Wiedemann, for reasons given in his paper, appears not to be satisfied with it.

Some additional light may perhaps be thrown on the subject by a few experiments which I made at the beginning of the present year. They were intended to be merely of a preliminary nature, and I had hoped to be able to carry them further; but so far as they go they appear to be conclusive, and a short account of them may be of interest at the present time in connection with the recent publication of Prof. Wiedemann.

In two papers communicated to the Royal Society,‡ I have pointed out that the effect of magnetisation upon the dimensions of an iron rod is not so simple as it had previously been believed to be. Joule enunciated the law that the elongation in a given bar is at first proportional to the magnetic intensity, and that it ceases to increase after the iron is fully "saturated." My own experiments show that if the magnetisation is carried beyond the point at which the elongation reaches a maximum, the length of the rod, instead of remaining unchanged, steadily diminishes, until, when the magnetising current has attained a certain strength, the original length of the rod is unaffected, and if this strength be exceeded actual *retraction* is produced. From some further experiments, details of which are not yet published, it appears that effects of the same character occur when rings are used instead of straight rods. The diameter of an iron ring surrounded by a coil of wire was found to be increased when a comparatively small current was passed through the coil and diminished when the current was strong.

I have also carried further Joule's experiments regarding the effects of magnetisation upon the length of iron wires under tension, and ascertained, among other things, that a wire when stretched by a weight attains its maximum elongation with a smaller external magnetising force than when it is free, retraction apparently beginning at an earlier stage of magnetisation.

Lastly, I have repeated and confirmed the experiments of Barrett* upon nickel. Barrett discovered that the length of a nickel bar when longitudinally magnetised was diminished. So far as appears from his published papers on the subject, which are very brief, he worked only with comparatively strong magnetising currents, and it seemed to me possible that, as in the case of iron, weaker currents might cause elongation. But on trying the experiment I found that this was not so. Magnetising forces which were so small as to produce no sensible effect whatever upon iron caused considerable diminution in the length of the nickel bar, and the curve of retraction given in my paper clearly passes through the intersection of the axes, and shows quite conclusively that elongation cannot occur at any early stage of the magnetisation.

Here, then, we have three classes of phenomena, which, if Maxwell's explanation were correct, would enable us to predict certain variations in the torsional effects observed by Wiedemann.

Let us consider the first case of nickel. According to Maxwell, a spirally magnetised iron wire is twisted in a certain manner, because the iron expands in the direction of the magnetisation. Since, then, nickel contracts in the direction of the magnetisation, we should expect a nickel wire to twist oppositely to an iron wire under similar conditions. This I found to be so. Whether the magnetising currents were strong or weak, the twist of the nickel wire was always in the direction opposite to that given by Wiedemann for iron.

I was not aware until I read Wiedemann's recent paper that this experiment had been performed previously.† Wiedemann discusses it fully and admits that the facts accord with Maxwell's explanation. But he appears to consider that it is a case of merely accidental coincidence: it is true that when longitudinally magnetised, iron expands while nickel contracts, and it is true that, when spirally magnetised, iron and nickel twist oppositely; but the two sets of phenomena are quite independent and are not related to one another as cause and effect. The torsion is to be explained, he thinks, by supposing that "the obliquely spiral direction which the molecules take up in consequence of the two magnetisations at right angles to each other" is, owing to intermolecular friction, "accompanied by a displacement of the longitudinal fibres and [of the] sections of the wires." In iron the friction of the longitudinal fibres is the greatest, and thus the torsion in the observed direction is accounted for. In nickel the friction of the sections predominates; a nickel wire is therefore twisted oppositely to an iron wire. For a more complete statement of Wiedemann's views reference must be made to the paper.‡

The behaviour of nickel, then, though in agreement with Maxwell's hypothesis, is not accepted by Wiedemann as affording confirmation of it.

But we have further means of testing the hypothesis. It has been said that an iron rod when very strongly magnetised is contracted instead of being elongated. Moreover, when the rod is stretched by a weight contraction occurs with smaller magnetising forces than when it is unstretched. In accordance with Maxwell's explanation, therefore, an iron wire spirally magnetised by very strong currents should twist (just as if it were a nickel wire) in the opposite direction to that indicated by Wiedemann for iron; and this reversal of the

* From the *Phil. Mag.* for September. † "Electricity" II., §448.
‡ *Proceedings*, Royal Society, XL., pp. 109,257.

* *Nature*, XXVI. 585, and British Association Report, 1882.
† Knott, *Proc.* Roy. Soc. Edin. 1882-3. Quoted by Wiedemann.
‡ I confess that I do not find it easy to follow the suggested explanation. Passing over preliminary difficulties, and assuming that the friction between the polar ends of adjoining molecules is different from that between their sides, it seems to me that the observed torsions could only be accounted for by assuming that in iron the friction of the ends is greater than the lateral friction, while in nickel the lateral friction is greatest. This appears to be directly opposed to Wiedemann's statement; but though I have considered the question carefully, and from several points of view, I can arrive at no other conclusion. It is, however, possible that I may have altogether misunderstood the argument, the more so as the paper referred to is a translation.

Digitized by Google

twist should take place at an earlier stage of the magnetisation if the wire were stretched. Now this is exactly what I have found to be the case. The free end of an iron wire, through which a constant current is passing, can be made to twist in either direction by varying the current through the surrounding helix, while with a certain medium strength of current there is no movement at all. And again, when the wire is loaded with a weight, the current which produces no torsion is considerably diminished, the reversal of the torsion also, of course, occurring with smaller currents.

It is not easy to see how Wiedemann's theory could fairly be made to explain these phenomena. He would be compelled to assume that when the iron is more intensely magnetised, that is, when the molecules are more completely turned in the same direction, the excess of longitudinal over transverse molecular friction, instead of becoming more marked, as might naturally be expected, would be decreased, and, with a sufficient degree of magnetisation, even converted into a deficiency. It would also be necessary to assume that when the molecules of a wire are drawn apart by stretching, the friction between their ends is nevertheless greater. Such assumptions would, I think, be highly unscientific.

On the other hand, Maxwell's explanation, which does not seek to go behind the magnetic elongations and retractions detected by Joule and others, fits the newly observed facts easily and naturally.

Note on the Experiments.—It seems desirable to give a few details of the experiments above referred to, though too much importance must not be attached to the quantitative results :—

The iron wire used was ·7mm. in diameter and 20cm. long. It was suspended in an upright position from a fixed clamp, and passed through a helix consisting of 876 turns of copper wire in 12 layers. To the lower end of the supended wire was fixed a small plane mirror which reflected an indicating beam of light upon an ordinary galvanometer scale 127cm. distant from it. Each scale division was equal to ·64mm. A steady current of about 1 ampere was passed through the iron wire from the clamp to the free end, which dipped into a mercury cup. The magnetising coil was in circuit with a battery of 7 Grove cells, a box of resistance coils, a tangent galvanometer, and a contact key.

The deflections of the spot of light when various currents were passed through the coil are given below :—

Iron wire unstretched.

Current.	Deflection.
0·36 ampere.	+ 7 divisions.
1·2 „	0 „
3·7 „	− 4 „

Same wire loaded with 6·3 kilos.

0·33 ampere.	+ 2 divisions.
0·59 „	0 „
3·68 „	− 3 „

The current which produced no deflection was obtained tentatively by varying the resistance ; a current slightly stronger or weaker than that indicated caused a perceptible deflection in one direction or the other It will be seen that when the wire was loaded with a weight of 6·3 kilogrammes the current causing no deflection was reduced to one half of its former value. The deflections given above are those produced by the second and subsequent currents of the strength denoted. That due to the first current was uncertain, depending probably upon the previously existing permanent magnetism of the wire. This point, amongst others, requires further investigation.

PHOTOMETRY.

Herr Strecker has given a review of the whole question of photometric measurements, and of the various kinds of photometers invented at various times. Since the lights which we have to measure are only perceived by the eye, it is to the eye that we must appeal for the final test of the equality of lights ; and it is not desirable to make use of some other effect of light than that produced on the retina, such, for instance, as the action of light on selenium or on some chemical compounds. The eye being the ultimate test, it remains to be seen which is the best instrument to assist the eye in its decision, and this appears undoubtedly to be the form of photometer due to Bunsen, in which a screen of paper with a grease spot in the centre serves to show when the illuminating powers of two sources of light have equal effect on it. In some cases it is preferable to use, in place of the single sheet of paper with the grease spot, three thicknesses of paper, the middle one having a geometric figure of some kind, generally a star, cut out of it With regard to the standard with which the light is to be compared, the standard candle cannot be recommended, except in the hands of very skilled and competent observers. The normal unit lamp proposed by v. Hefner-Alteneck, in which amyl acetate is burned, can be depended upon with far greater certainty to produce always the same light for the same height of flame ; the standard candles, on the average, being about 3 per cent. out. It is desirable, however, when measuring lights of great intensity, to have an intermediate standard, which is first compared with the standard unit, and then in turn used for comparison with the experimental light. For such a purpose a petroleum lamp of good construction, or a gas flame burning under constant pressure, may be used. A ready method of comparing a batch of glow lamps is the following :—In the circuit of a battery are introduced two branch circuits in parallel : the one contains a standard glow lamp of the same type as those to be tested, a resistance, and one coil of a differential galvanometer ; the other branch circuit contains the lamp to be tested, a resistance, and the second coil of the differential galvanometer. From one terminal of the standard lamp to one terminal of the experimental lamp is a circuit of very high known resistance containing a galvanometer ; this latter serves to show the difference of potential between the two lamps, while the differential galvanometer shows the difference in current, and the photometer the difference in light, and the whole of the measurements can conveniently be taken at once.—*Journal of Telegraph-Engineers.*

THE BRITISH ASSOCIATION MEETING.

The following is the Presidential address of Sir William Dawson. C.M.G., M.A., LL.D., F.R.S., F.G.S., Principal and Vice-Chancellor of M'Gill University, Montreal, Canada :—

Twenty-one years have passed away since the last meeting of the British Association in this great central city of England. At the third Birmingham meeting—that of 1865—I had the pleasure of being present, and had the honour of being one of the Vice-Presidents of Section C. At that meeting my friend John Phillips, one of the founders of the Association, occupied the Presidential chair, and I cannot better introduce what I have to say this evening than by the eloquent words in which he then addressed you :—"Assembled for the third time in this busy centre of industrious England, amid the roar of engines and clang of hammers, where the strongest powers of nature are trained to work in the fairy chains of art, how softly and fittingly falls upon the ear the accent of science, the friend of that art, and the guide of that industry ! Here where Priestley analysed the air, and Watt obtained the mastery over steam, it well becomes the students of nature to gather round the standard which they carried so far into the fields of knowledge. And when on other occasions we meet in quiet colleges and academic halls, how gladly welcome is the union of fresh discoveries and new inventions with the solid and venerable truths which are there treasured and taught. Long may such union last ; the fair alliance of cultivated thought and practical skill ; for by it labour is dignified and science fertilised, and the condition of human society exalted." These were the words of a man who, while earnest in the pursuit of science, was full of broad and kindly sympathy for his fellow men, and of hopeful confidence in the future. We have but to turn to the twenty reports of this Association, issued since 1865, to see the realisation of that union of science and art to which he so confidently looked forward, and to appreciate the stupendous results which it has achieved. In one department alone—that to which my predecessor in this chair so eloquently adverted in Aberdeen, the department of education in science—how much has been accomplished since 1865. Phillips himself lived to see a great revolution in this respect at Oxford. But no one in 1865 could have anticipated that immense development of local schools of science of which your own Mason College and your admirable technical, industrial, and art schools are eminent examples. Based on the general education given by the new system of Board schools, with which the name of the late W. E. Forster will ever be honourably connected, and extending its influence upward to special training and to the highest university examinations, this new scientific culture is opening paths of honourable ambition to the men and women of England scarcely dreamed of in 1865. I sympathise with the earnest appeal of Sir Lyon Playfair, in his Aberdeen address, in favour of scientific education ; but visiting England at rare intervals, I am more impressed with the progress that has been made than with the vexatious delays which have occurred.

Digitized by Google

No one could have anticipated twenty years ago that a Birmingham manufacturer, in whose youthful days there were no schools of science for the people, was about to endow a college, not only worthy of this great city, but one of its brightest ornaments.* Nor could anyone have foreseen the great development of local scientific societies, like your Midland Institute and Philosophical Society, which are now flourishing in every large town and in many of those of less magnitude. The period of twenty-one years that has elapsed since the last Birmingham meeting has also been an era of public museums and laboratories for the teaching of science, from the magnificent national institutions at South Kensington and those of the great universities and their colleges down to those of the schools and field clubs in country towns. It has besides been an era of gigantic progress in original work and in publication—a progress so rapid that workers in every branch of study have been reluctantly obliged to narrow in more and more their range of reading and of effort to keep abreast of the advance in their several departments. Lastly, these twenty-one years have been characterised as the "coming of age" of that great system of philosophy with which the names of three Englishmen—Darwin, Spencer, and Wallace—are associated as its founders Whatever opinions one may entertain as to the sufficiency and finality of this philosophy there can be no question as to its influence on scientific thought. On the one hand it is inaccurate to compare it with so entirely different things as the discovery of the chemical elements and of the law of gravitation; on the other, it is scarcely fair to characterise it as a mere "confused development" of the mind of the age. It is indeed a new attempt of science in its maturer years to grapple with those mysterious questions of origins which occupied it in the days of its infancy, and it is to be hoped that it may not, like the Titans of the ancient fable, be hurled back from heaven, or like the first mother find the knowledge to which it aspires a bitter thing. In any case we should fully understand the responsibility which we incur when in these times of full-grown science we venture to deal with the great problem of origins, and should be prepared to find that in this field the new philosophy, like those which have preceded it, may meet with very imperfect success. The agitation of these subjects has already brought science into close relations, sometimes friendly, sometimes hostile, it is to be hoped in the end helpful, with those great and awful questions of the ultimate destiny of humanity, and its relations to its Creator, which must always be nearer to the human heart than any of the achievements of science on its own ground. In entering on such questions we should proceed with caution and reverence, feeling that we are on holy ground, and that though, like Moses of old, we may be armed with all the learning of our time, we are in the presence of that which while it burns is not consumed; of a mystery which neither observation, experiment, nor induction can ever fully solve.

In a recent address, the late President of the Royal Society called attention to the fact that within the lifetime of the older men of science of the present day the greater part of the vast body of knowledge included in the modern sciences of physics, chemistry, biology, and geology has been accumulated, and the most important advances made in its application to such common and familar things as the railway, ocean navigation, the electric telegraph, electric lighting, the telephone, the germ theory of disease, the use of anæsthetics, the processes of metallurgy, and the dyeing of fabrics. Even since the last meeting in this city, much of this great work has been done, and has led to general results of the most marvellous kind. What at that time could have appeared more chimerical than the opening up by the enterprise of one British colony of a shorter road to the East by way of the extreme west, realising what was happily called by Milton and Cheadle "the new North-west Passage," making Japan the next neighbour of Canada on the west, and offering to Britain a new way to her Eastern possessions; or than the possibility of this Association holding a successful meeting on the other side of the Atlantic? To have ventured to predict such things in 1865, would have appeared quite visionary, yet we are now invited to meet in Australia, and may proceed thither by the Canadian Pacific Railway, and its new lines of steamers, returning by the Suez Canal.† To-day this is quite as feasible as the Canadian visit would have been in 1885. It is science that has thus brought the once widely separated parts of the world nearer to each other, and is breaking down those geographical barriers which have separated the different portions of our widely extended British race. Its work in this is not yet complete. Its goal to-day is its starting point to-morrow. It is as far as at any previous time from seeing the limit of its conquests, and every victory gained is but the opening of the way for a further advance.

By its visit to Canada the British Association has asserted its imperial character, and has consolidated the scientific interests of Her Majesty's dominions, in advance of that great gathering of the industrial products of all parts of the empire now on exhibition in London, and in advance of any political plans of Imperial federation.‡ There has even been a project before us for an international scientific convention, in which the great English republic of America shall take part, a project, the realisation of which was to some extent anticipated in the fusion of the members of the British and American Associations at Montreal and Philadelphia in 1884. As a Canadian, as a past President of the American Association, and now honoured with the Presidency of this Association, I may be held to represent in my own person this scientific union of the British Islands, of the various Colonies, and of the great Republic, which, whatever the difficulties attending its formal accomplishment at present, is certain to lead to an actual and real union for scientific work. In furtherance of this I am glad to see here to-day influential representatives of most of the British Colonies, of India, and of the United States. We welcome here also delegates from other countries, and though the barrier of language may at present prevent a larger union, we may entertain the hope that Britain, America, India, and the Colonies, working together in the interests of science, may ultimately render our English tongue the most general vehicle of scientific thought and discovery, a consummation of which, I think, there are, at present, many indications.

But, while science marches on from victory to victory, its path is marked by the resting-places of those who have fought its battles and assured its advance. In looking back to 1865 there rise before me the once familiar countenances of Phillips, Murchison, Lyell, Forbes, Jeffreys, Jukes, Rolleston, Millar, Spottiswoode, Fairbairn, Gassiot, Carpenter, and a host of others, present in full vigour at that meeting, but no more with us. These were veterans of science; but, alas! many then young and rising in fame are also numbered with the dead. It may be that before another Birmingham meeting many of us, the older members now, will also have passed away. But these men have left behind them ineffaceable monuments of their work, in which they still survive, and we rejoice to believe that, though dead to us, they live in that company of the great and good of all ages who have entered into that unseen universe where all that is high and holy and beautiful must go on accumulating till the time of the restitution of all things. Let us follow their example and carry on their work, as God may give us power and opportunity, gathering in precious stores of knowledge and of thought, in the belief that all truth is immortal, and must go on for ever bestowing blessings on mankind. Thus will the memory of the mighty dead remain to us as a power which—

Like a star
Beacons from the abode where the eternal are.

I do not wish, however, to occupy your time longer with general or personal matters, but rather to take the opportunity afforded by this address to invite your attention to some topics of scientific interest. In attempting to do this I must have before me the warning conveyed by Professor Huxley, in the address to which I have already referred, that in our time science, like Tarpeia, may be crushed with the weight of the rewards bestowed on her. In other words, it is impossible for any man to keep pace with the progress of more than one limited branch of science, and it is equally impossible to find an audience of scientific men of whom anything more than a mere fraction can be expected to take an interest in any one subject. There is, however, some consolation in the knowledge that a speaker who is sufficiently simple for those who are advanced specialists in other departments will of necessity be also sufficiently simple to be understood by the general public who are specialists in nothing. On this principle a geologist of the old school, accustomed to a great variety of work, may hope so to scatter his fire as to reach the greater part of his audience. In endeavouring to secure this end, I have sought inspiration from that ocean which connects rather than separates Britain and America, and may almost be said to be an English sea—the North Atlantic. The geological history of this depression of the earth's crust, and its relation to the continental masses which limit it, may furnish a theme at once generally intelligible and connected with great questions as to the structure and history of the earth, which have excited the attention alike of physicists, geologists, biologists, geographers, and ethnologists. Should I, in treating of these questions, appear to be somewhat abrupt and dogmatic, and to indicate rather than state the evidence of the general views announced, I trust you will kindly attribute this to the exigencies of a short address.

If we imagine an observer contemplating the earth from a convenient distance in space, and scrutinising its features as it rolls before him, we may suppose him to be struck with the fact that eleven-sixteenths of its surface are covered with water, and that the land is so unequally distributed that from one point of view he would see a hemisphere almost exclusively oceanic, while nearly the whole of the dry land is gathered in the opposite hemisphere. He might observe that the great oceanic area of the Pacific and Antarctic Oceans is dotted with islands—like a shallow pool with stones rising above its surface—as if its general depth were small in comparison with its area. He might also notice that a mass or belt of land surrounds each pole, and that the northern ring sends off to the southward three vast tongues of land and of mountain chains, terminating respectively in South America, South Africa, and Australia, towards which feebler and insular processes are given off by the Antarctic continental mass. This, as some geographers have observed,* gives a rudely three-ribbed aspect to the earth, though two of the three ribs are crowded together and form the Europ-asian mass or double continent, while the third is isolated in the single continent of America. He might also observe that the northern girdle is cut across, so that the Atlantic opens by a wide space into the Arctic sea, while the Pacific is contracted toward the north, but confluent with the Antarctic Ocean. The Atlantic is also relatively deeper and less cumbered with islands than the Pacific, which has the higher ridges near its shores, constituting what some visitors to the Pacific coast of America have not inaptly called the "back of the world," while the wider slopes face the narrower ocean, into which for this reason the greater part of the drainage of the land is poured.† The Pacific and Atlantic, though both depressions or flattenings of the earth, are, as we shall find, different in age, character, and conditions; and the Atlantic, though the smaller, is the older, and

* It was in 1865 that Sir Josiah Mason was, quietly and without any public note, beginning to lay the foundation of his orphanage at Erdington.

† It is expected that on the completion of the connections of the Canadian Pacific Railway the time from ocean to ocean may be reduced to 116 hours, and from London to Hong Kong to twenty-seven days.

‡ I should note here, in connection with this, the valuable volume of *Canadian Economics*, edited by Mr. D. A. P. Watt, which was one of the results of the Montreal meeting.

* Dana, "Manual of Geology," introductory part. Green, "Vestages of a Molten Globe," has summed up these facts.

† Mr. Millard Reade, in two Presidential addresses before the Geological Society of Liverpool, has well illustrated this point and its geological consequences.

Digitized by Google

from the geological point of view, in some respects, the more important of the two.

If our imaginary observer had the means of knowing anything of the rock formations of the continents, he would notice that those bounding the North Atlantic are in general of great age, some belonging to the Laurentian system. On the other hand, he would see that many of the mountain ranges along the Pacific are comparatively new, and that modern igneous action occurs in connection with them. Thus he might be led to believe that the Atlantic, though comparatively narrow, is an older feature of the earth's surface, while the Pacific belongs to more modern times. But he would note in connection with this that the oldest rocks of the great continental masses are mostly toward their northern ends, and that the borders of the northern ring of land and certain ridges extending southwards from it constitute the most ancient and permanent elevations of the earth's crust, though now greatly surpassed by mountains of more recent age nearer the equator. Before leaving this general survey we may make one further remark. An observer looking at the earth from without would notice that the margins of the Atlantic and the main lines of direction of its mountain chains are north-east and south-west, and north-west and south-east, as if some early causes had determined the occurrence of elevations along great circles of the earth's surface tangent to the polar circles.

We are invited by the preceding general glance at the surface of the earth to ask certain questions respecting the Atlantic. (1) What has at first determined its position and form? (2) What changes has it experienced in the lapse of geological time? (3) What relations have these changes borne to the development of life on the land and in the water? (4) What is its probable future?

Before attempting to answer these questions, which I shall not take up formally in succession, but, rather in connection with each other, it is necessary to state as briefly as possible certain general conclusions respecting the interior of the earth. It is popularly supposed that we know nothing of this beyond a superficial crust perhaps averaging 50,000 to 100,000 feet in thickness. It is true we have no means of exploration in the earth's interior, but the conjoined labours of physicists and geologists have now proceeded sufficiently far to throw much inferential light on the subject, and to enable us to make some general affirmations with certainty; and these it is the more necessary to state distinctly, since they are often treated as mere subjects of speculation and fruitless discussion.

(1) Since the dawn of geological science, it has been evident that the crust on which we live must be supported on a plastic or partially liquid mass of heated rock, approximately uniform in quality under the whole of its area. This is a legitimate conclusion from the wide distribution of volcanic phenomena, and from the fact that the ejections of volcanoes, while locally of various kinds, are similar in every part of the world. It led to the old idea of a fluid interior of the earth, but this is now generally abandoned, and this interior heated and plastic layer is regarded as merely an under-crust.

(2) We have reason to believe, as the result of astronomical investigations,* that, notwithstanding the plasticity or liquidity of the under-crust, the mass of the earth—its nucleus as we may call it—is practically solid and of great density and hardness. Thus we have the apparent paradox of a solid yet fluid earth; solid in its astronomical relations, liquid or plastic for the purposes of volcanic action and superficial movements.†

(3) The plastic sub-crust is not in a state of dry igneous fusion, but in that condition of aqueo-igneous or hydro-thermic fusion which arises from the action of heat on moist substances, and which may either be regarded as a fusion or as a species of solution at a very high temperature. This we learn from the phenomena of volcanic action, and from the composition of the volcanic and plutonic rocks, as well as from such chemical experiments as those of Daubré and of Tilden and Shenstone.‡

(4) The interior sub-crust is not perfectly homogeneous, but may be roughly divided into two layers or magmas, as they have been called; an upper, highly siliceous or acidic, of low specific gravity and light-coloured, and corresponding to such kinds of plutonic and volcanic rocks as granite and trachyte; and a lower, less siliceous, or more basic, more dense, and more highly charged with iron, and corresponding to such igneous rocks as the dolerites, basalts, and kindred lavas. It is interesting here to note that this conclusion, elaborated by Durocher and von Waltershausen, and usually connected with their names, appears to have been first announced by John Phillips, in his "Geological Manual," and as a mere common sense deduction from the observed phenomena of volcanic action and the probable results of the gradual cooling of the earth § It receives striking confirmation from the observed succession of acidic and basic volcanic rocks of all geological periods and in all localities. It would even seem, from recent spectroscopic investigations of Lockyer, that there is evidence of a similar succession of magmas in the heavenly bodies, and the discovery of Nordenskiöld of native iron in Greenland basalts, affords a probability that the inner magma is in part metallic.*

(5) Where rents or fissures form in the upper crust, the material of the lower crust is forced upward by the pressure of the less supported portions of the former, giving rise to volcanic phenomena either of an explosive or quiet character, as may be determined by contact with water. The underlying material may also be carried to the surface by the agency of heated water, producing those quiet discharges which Hunt has named crenitic. It is to be observed here that explosive volcanic phenomena, and the formation of cones, are, as Prestwich has well remarked, characteristic of an old and thickened crust; quiet ejection from fissures and hydro-thermal action may have been more common in earlier periods and with a thinner over-crust.

(6.) The contraction of the earth's interior by cooling and by the emission of material from below the over-crust has caused this crust to press downward, and therefore laterially, and so to effect great bends, folds, and plications; and these modified subsequently by surface denudation constitute mountain chains and continental plateaus. As Hall long ago pointed out,† such lines of folding have been produced more especially where thick sediments had been laid down on the sea bottom. Thus we have here another apparent paradox, namely, that the elevations of the earth's crust occur in the places where the greatest burden of detritus has been laid down upon it, and where consequently the crust has been softened and depressed. We must beware, in this connection, of exaggerated notions of the extent of contraction and of crumpling required to form mountains. Bonney has well shown, in lectures delivered at the London Institution, that an amount of contraction, almost inappreciable in comparison with the diameter of the earth, would be sufficient; and that as the greatest mountain chains are less than $\frac{1}{800}$th of the earth's radius in height, they would on an artificial globe a foot in diameter be no more important than the slight inequalities that might result from the paper gores overlapping each other at the edges.

(7.) The crushing and sliding of the over-crust implied in these movements raise some serious questions of a physical character. One of these relates to the rapidity or slowness of such movements, and the consequent degree of intensity of the heat developed, as a possible cause of metamorphism of rocks. Another has reference to the possibility of changes in the equilibrium of the earth itself as resulting from local collapse and ridging. These questions in connection with the present dissociation of the axis of rotation from the magnetic poles, and with changes of climate, have attracted some attention,‡ and probably deserve further consideration on the part of physicists. In so far as geological evidence is concerned, it would seem that the general association of crumpling with metamorphism indicates a certain rapidity in the process of mountain-making, and consequent development of heat, and the arrangement of the older rocks around the Arctic basin forbids us from assuming any extensive movement of the axis of rotation though it does not exclude changes to a limited extent. I hope that Professor Darwin will discuss these points in his address to the Physical Section.

I wish to formulate these principles as distinctly as possible, and as the result of all the long series of observations, calculations, and discussions since the time of Werner and Hutton, and in which a vast number of able physicists and naturalists have borne a part, because they may be considered as certain deductions from our actual knowledge, and because they lie at the foundation of a rational physical geology.

We may popularise these deductions by comparing the earth to a drupe or stone-fruit, such as a plum or peach, somewhat dried up. It has a large and intensely hard stone and kernal, a thin pulp made up of two layers, an inner more dense and dark-coloured, and an outer less dense and lighter-coloured. These constitute the under-crust. On the outside it has a thin membrane or over-crust. In the process of drying it has slightly shrunk, so as to produce ridges and hollows of the outer crust, and this outer crust has cracked in some places, allowing portions of the pulp to ooze out—in some of these its lower dark substance, in others its upper and lighter material. The analogy extends no further, for there is nothing in our withered fruit to represent the oceans occupying the lower parts of the surface or the deposits which they have laid down.

(To be continued.)

---

* Hopkins, Mallet, Sir William Thomson, and Prof. G. H. Darwin maintain the solidity and rigidity of the earth on astronomical grounds; but different conclusions have been reached by Hennesey, Delaunay, and Airy. In America Barnard and Crosby, Dutton, Le Conte, and Wadsworth have discussed these questions.

† An objection has been taken to the effect that the supposed ellipsoidal form of the equator is inconsistent with a plastic sub-crust. But this ellipsoidal form is not absolutely certain, or if it exists, is very minute. Bonney has in a recent lecture suggested the important consideration that a mass may be slowly mobile under long-continued pressure, while yet rigid with reference to more sudden movements.

‡ *Phil. Trans.*, 1884. Also Crosby in *Proc. Boston Soc. Nat. Hist.* 1883.

§ Phillips says("Manual of Geology," 1855, p. 493): "If we regard them (the internal crystalline rocks) as acquiring solidification by cooling in zones parallel to the surface, we should have sheets of granitic and basaltic rocks generated below, the first uppermost, the last undermost, while above the several strata were produced in a series beginning at the bottom. In this sense the rocks of fusion may be called with Lyell *hypogene*. Certainly under particular areas of country are found evidence of the liquefaction of one set of igneous products after the solidification of others. Many dykes of basalt traversing granite show themselves to have been in fusion after the solidification of the granite." In various forms Phillips returns to this idea, as at pp. 556 and 564, in that unpretending manner which was his wont. Dr. Sterry Hunt has kindly directed my attention to the fact of Phillips' right of priority in this matter. Durocher in 1857 elaborated the theory of magmas in the *Annales des Mines*, and we are indebted to Dutton, of the United States Geological Survey, for its detailed application to the remarkable volcanic outflows of Western America.

* These basalts occur at Ovifak, Greenland. Andrews has found small particles of iron in British basalts. Prestwich and Judd have referred to the bearing on general geology of these facts, and of Lockyer's suggestions.

ON ELECTROLYSIS.

BY PROF. OLIVER J. LODGE, D.SC.

(Continued from page 328.)

Modification of the above Table by the introduction of Kohlrausch's hypothesis that each ion has its own rate of travel.—Consider now what will happen if, instead of assuming that opposite corresponding ions must go at the same pace, we assume that each has its own pace; and that the sharing of the current between the ingredients of the fluid depends on these intrinsic ionic velocities and on the proportion of each substance present. Of the two compounds AC and A'C', we must affix a mass-velocity to each ion—say, α, γ, α', γ', respectively; so that

$\alpha+\gamma$ is what we formerly called λ,

and $\alpha'+\gamma'$,, ,, λ',

but no longer does $\alpha=\frac{1}{2}\lambda$. So the above table becomes :—

Results of Double Electrolysis, &c.

Substance.	Loss in cathode vessel.	Less in anode vessel.	Total loss.
A	α	$-\alpha$	0
A'	α'	$1-\alpha$	1
C	$1-\gamma$	γ	1
C'	$-\gamma$	γ'	0
AC	$1-\gamma$	γ	1
A'C'	α'	$1-\alpha'$	1
AC'	$-(\alpha'+\gamma')$	$-(\alpha+\gamma)$	-1

This gives the relative formation of free acid in the two vessels exactly the same as before, viz., $\frac{\alpha+\gamma}{\alpha'+\gamma'}=\frac{\lambda}{\lambda'}$

It is a trifle more general than the former hypothesis, in the non-equality of α and γ, and of α' and γ', and this fact may furnish a method of distinguishing between the two hypotheses.

From the table we see a way to find these values, thus :—

γ = loss of AC in the anode vessel,

α' = loss of A'C' in the cathode vessel,

$\alpha+\gamma$ = gain of AC' in the anode vessel,

and $\alpha+\gamma+\alpha'+\gamma'=1$.

In Kohlrausch's theory, indeed, ionic velocities are supposed to be pretty well known, and accordingly we may seek to compare the relative quantity of free acid, found in the two vessels, with the ratio $\frac{\alpha+\gamma}{\alpha'+\gamma'}$

But, then, Kohlrausch's velocity-numbers are founded on a strictly Hittorfian view of migration, and do not depend on the assumed conductivity of all the ingredients present in a fluid; they are intended to stand for the actual speed of moving salt atoms, and the water atoms are neglected. Kohlrausch's numbers are, in fact, totally different things from our α, γ, α', γ', which include along with the idea of velocity the idea of amount of substance available for conducting the current. In terms of a notation to be used later, $\frac{\alpha+\gamma}{\alpha'+\gamma'}=\frac{N_1 a_1}{N_2 a_2}$.

Generalisation of the above, to suit the case when a mixture of ions may be given off at each electrode.—If we now extend our view a little to cover cases (1), (2), and (3) at the same time—that is, to take account of a possible *mixture* of liberated ions, such as one frequently gets with intense currents, and may get at any time, we must write the actual amount of liberated cations c and c', and of anions a and a', where, of course, $c+c'=\alpha+\alpha'=1$; and the table becomes the following :—

Results of Double Electrolysis, &c.

Substance.	Amount of substance lost by cathode vessel.	Amount of substance lost by anode vessel.	Total loss.
A	a	$\alpha\ \alpha$	α
A'	α'	$\alpha'-\alpha'$	α'
C	$c-\gamma$	γ	c
C'	$c'-\gamma'$	γ'	c'
AC	$(c-\gamma)$ or (a)	(γ) or $(\alpha-a)$	(c) or (a)
A'C'	(a') or $(c'-\gamma')$	$(a'-\alpha')$ or (γ')	(α') or (c')
AC'	$(\alpha+\gamma)-c$	$a-(\alpha+\gamma)$	$(a-c)$
A'C	or $c-(\alpha+\gamma)$	or $(\alpha+\gamma)-a$	or $(c-a)$

This table looks more complex than the others because it contains alternatives; they are not ambiguities, and it is easy enough to know in any particular case which is the right alternative, but it cannot be expressed by the general symbols, because it is impossible to know whether $c-\gamma$ or a is going to be the bigger. The rule is that the bigger of the two alternatives about the loss of AC and A'C' is the true one; and the substance formed will be at the same time decided by the values which in the last two alternative lines come out negative. Or take it conversely. Suppose A'C is the substance formed in both vessels as the bye-product, then the second set of alternatives are the right ones all through; but if AC' is the substance formed in both vessels, the first set of alternatives are correct; while, if it should happen that AC' is formed in the anode vessel and A'C in the cathode, then the first set of alternatives are true for the anode vessel and the second set for the cathode vessel. With actual chemical substances it is usually easy to see whether the bye-product will be AC' or A'C, and thus to fix the alternatives. Thus, with a solution of copper sulphate, it is plain that the bye-product will be H_2SO_4 in both vessels, and not CuO.*

As an illustration of the possibility just mentioned, about the bye-products being different in the two vessels, consider the electrolysis of a salt of some metal more electropositive than hydrogen—for instance, Glauber's salts. Neither Na nor SO_4 can be liberated—the liberated ions must be H and O; but the water is not merely primarily decomposed, Na_2SO_4 shares in the conduction of the current, and accordingly secondary actions go on, forming acid at anode and alkali at cathode, as is perfectly well known. The last table gives every detail of the action, and points out that in order to determine experimentally how much of the current is conveyed by the salt and how much by the water, we have only to measure either the amount of acid or the amount of alkali produced. For in this case $\alpha'=c'=1$; $\alpha=c=0$; the production of acid is $\alpha+\gamma=\lambda$, the proportion of the current conveyed by the salt; and the production of alkali is precisely equivalent.

General Theory of Multiple Electrolysis.—It is now only a matter of writing to make a table for the most general case of electrolysis of a single liquid containing any number of substances. It is not much use now excluding double decomposition, and we will begin by letting the liberated ions be the most complicated mixture possible. Mix together the substances $A_1C_1+A_2C_2+\ldots+A_nC_n$; the result of the mixing is that each anion is liable to be combined with all the cations forming $A_1C_1+A_1C_2+\ldots$, and so on for the others; say, $A_1\Sigma C+A_2\Sigma C+\ldots$; or altogether $\Sigma A.\Sigma C$.

Let the liberated ions be $a_1, a_2 \ldots a_n$, equivalent of $A_1, A_2, \ldots$ &c. and $c_1, c_2, \ldots c_n$, equivalents of $C_1, C_2 \ldots$, &c., respectively. Let the mass-velocities of the independent ions be

$a_1, a_2, \ldots a_n$ for the anions,

and $\gamma_1, \gamma_2, \ldots \gamma_n$ for the cations.

Then the following equations hold among the quantities :—

$$\Sigma a=\Sigma c=1,$$

$$\Sigma a+\Sigma\gamma=1;$$

and, if it is worth while attempting to specify how much of the current each substance conveys,

$a_1+\gamma_1=\lambda_1$; $a_2+\gamma_2=\lambda_2$; . . ., &c.

[Further, if my notion is true that an electric current necessarily consists of equal positive and negative currents, $\Sigma a=\Sigma\gamma$. I even venture to think it *probable* that $a_1=\gamma_1$, $a_2=\gamma_2$, &c. See below.]

Now the portion of above table referring to the loss of elements is simple enough :—

Element.	Amount lost in cathode vessel.	Amount lost in anode vessel.
A_1	a_1	a_1-a_1
A_2	a_2	a_2-a_2
⋮	⋮	⋮
C_1	$c_1-\gamma_1$	γ_1
C_2	$c_2-\gamma_2$	γ_2
⋮	⋮	⋮

But when you come to the compounds there is no definiteness; by reason of the double decomposition which has gone on. Moreover, there are the apparent alternatives, just as in the last table. To get rid of alternatives, decide that the liberated ions are single, one anion A_k, and one cation C_l, where k and l may be equal as a special case. Then the proportion of the table referring to loss of compound is :—

Original substance.	Lost in cathode vessel.	Lost in anode vessel.	Total loss.
$A_1(\Sigma C-C_l)$	a_1	$-a_1$	0
$A_2(\Sigma C-C_l)$	a_2	$-a_2$	0
⋮	⋮	⋮	⋮
$A_k(\Sigma C-C_l)$	a_k	$1-a_k$	1
⋮	⋮	⋮	⋮
$A_n(\Sigma C-C_l)$	a_n	$-a_n$	0
$C_l(\Sigma A-A_k)$	$1-\gamma_l$	γ_l	1

If no double decomposition had gone on, the substances would have simply been A_1C_1, A_2C_2, &c. The meaning of $A_1(\Sigma C-C_l)$ is: all the compounds into which A_1 happens to enter, with the express exclusion of

* Remember that the electrodes are supposed to be platinum, so that oxygen is liberated; with a *copper* anode it is easy enough to form CuO as has already been said.

Digitized by Google

A_1C_l, this being considered separately, along with A_2C_l, A_3C_l, . . ., &c., in the last line of the table.

The remainder of the table, dealing with the secondary or bye-products formed, is too indeterminate to be instructive; for even if double decomposition had been excluded originally, it must be supposed to occur now, and the substances formed can only be written:—

Substance formed in cathode vessel.	Amount.	Substance formed in anode vessel.	Amount.
$A_1(\Sigma C - C_1 - C_l)$	$a_1+\gamma_1$	$C_1(\Sigma A - A_1 - A_k)$	$a_1+\gamma_1$
$A_2(\Sigma C - C_2 - C_l)$	$a_2+\gamma_2$	$C_2(\Sigma A - A_2 - A_k)$	$a_2+\gamma_2$
. . . . .	. . .	. . . . .	. . .
$A_l(\Sigma C - C_l)$	$1-(a_l+\gamma_l)$	$C_k(\Sigma A - A_k)$	$1-(a_k+\gamma_k)$
. . . . .	. . .	. . . . .	. . .
$A_n(\Sigma C - C_n)$	$a_n+\gamma_n$	$C_n(\Sigma A - A_n - A_k)$	$a_n+\gamma_n$

where A_1 ($\Sigma C - C_1 - C_3$) stands for $A_1C_2 + A_1C_4 + A_1C_5 + . . .$, or any of them—*i.e.*, for all the possible new combinations of A_1 with cations; the C_1 being excluded because A_1C_1 is certainly not a new compound; and C_l being excluded because, being the cation deposited on the electrode, there is bound to be a deficiency of it rather than an excess, unless, indeed, more is brought over by migration than is deposited. Cases of even this anomaly were discovered by Hittorf among the iodides and chlorides of zinc and cadmium, especially when dissolved in alcohol; more than one equivalent of iodine is carried over toward anode, as much indeed, in one case, as two equivalents. This, however, is regarded as exceptional by everybody, and is usually explained by supposing a sub-salt to travel bodily with the simple ion thus: $3CdI_2 = CD + (2CdI + 2I_2)$, where the quantity in brackets may be the true anion. The same idea has been extended to other and more ordinary cases.

Objections to the idea of unequal velocities of anions and cations.—The bare notion of unequal molecular velocity has received considerable and important development at the hands of Quincke, Wiedemann, and Kohlrausch; but they all accept the fact, and suggest modes for accounting for it. We will therefore defer consideration of their theories to a later head. What I wish to point out is that migration data afford no *proof* that ions travel at unequal rates, because the facts can be accounted for without any such assumption, as has been shown at length; but if I have to state what objection I feel towards considering the anion and cation velocity unequal, I can only answer in an unsatisfactory manner as follows:—1st. Electricity is known to obey the laws of an incompressible fluid; and whether for positive electricity or for negative electricity, this is equally true. It may well be that electricity is far from being such a fluid, or pair of fluids, but there must be some analogy or they would not obey so exactly the same equations. If one allows mental images of electric actions, the guise of an incompressible, indestructible, uncreatable fluid, always flowing in closed circuits, naturally suggests itself for either kind of electricity. Equal quantities of opposite kinds in coincidence do indeed neutralise all electrostatic effect, but one does not conceive of their annihilating each other. 2nd. In certain cases an electric current is *known* to consist of equal opposite streams of positive and negative electricity. In a simple binary (fused) electrolyte this is so (see above); and in the convection portion of the circuit of a Holtz machine it is so.

If provisionally these lemmas be granted, the argument is obvious. Include one or other such arrangement for insuring equal opposite flow in any circuit, along with many kinds of voltameters. Can one think of unequal rates of flow of opposite electricities in one part of a circuit and equal rates of flow in another? Not unless it is possible for equal streams of opposite electricities to meet and annihilate each other. And if we can thus control and make equal the electric streams without affecting phenomena in the slightest, must they not always be equal? And it is plain that equality of the electric streams renders necessary the equal speed of anion and cation, since by Faraday's laws atomic charge is constant. Not, indeed, that this rigidly requires that *each* anion should travel at the same rate as its corresponding cation, or that $a_1=\gamma_1$, $a_2=\gamma_2$, &c. All is satisfied if the anions *as a whole* travel as quick as the cations as a whole—*i.e.*, if $\Sigma a = \Sigma\gamma$; but it is difficult to think of the relations as being always satisfied unless each individual a equals each individual γ: the same kind of argument as that which leads one to "equate coefficients." But less rigorous! Granted. I do not pretend that any of this is a rigorous argument; it is little better than a statement of prejudice with an attempt at justification.

To see if any definite and unambiguous experimental answer can be obtained to the question, "At what rate do ions travel?" I propose to try a modification of those old experiments with electrolytes in series, where a precipitate is formed in the middle one of three vessels. For instance, use $BaCl_2$ in the anode vessel, Na_2SO_4 in the cathode vessel, and in the intermediate vessel, which is to be in the form of a long tube, dilute HCl. Then pass a current, and observe whereabouts, how soon, and with what appearances, the precipitate shows itself. Innumerable similar experiments suggest themselves, but it is needless to specify any more of them at present.

III.—Quantitative Laws of Electrolysis.

The main laws known at the present time concerning the passage of electricity through liquids may be denominated, (*a*) Ohm's or Kholrausch's (*b*) Faraday's two laws, (*c*) Joule's, or Helmholt's, or Thomson's laws.

(a) Ohm's Law of Electrolytic Conduction.—The researches of Kohlrausch and Nippoldt, and several others, give us very good grounds for asserting that, in all ordinary cases of electrolytic conjunction, Ohm's law is at least approximately obeyed; currents being proportional to E.M.F. actually applied to the liquid. It is exceedingly important to test this law in liquids with the utmost accuracy, as has been done for metals by a British Association Committee (Maxwell and Chrystal), but the research would be a very difficult one. We have seen reason for guessing that with violent currents the law may perhaps begin to fail, even if it be exact for weak currents; but on Maxwell's theory of light it can hardly be quite exact for any current, because the optical transparency of electrolytes shows that they behave as dielectrics to very rapidly alternating E.M.F.'s. But the law is very nearly true any way, and this fact of itself is important, as showing that infinitesimal E.M.F.'s can produce a current. Now, if there were any chemical cling between the atoms taking part in conduction this could not be—a finite E.M.F. would be needed to tear them asunder; and this is what physicists mean by using the term "dissociation" in this connection. The atoms are so free of one another that they must be either really or virtually dissociated. Not all the molecules of the compound need be in this condition, of course, only a certain percentage of them, and the conductivity of the liquid must depend upon the value of this percentage. It may be supposed nil in a perfectly pure homogeneous liquid like H_2O; it may be supposed to be caused by the presence of foreign molecules (*e.g.*, of salt or acid); and it may be supposed to increase with rise of temperature.

The transparency of an electrolyte may, however, be explained without assuming any violation of Ohm's law, by supposing that the percentage of dissociated atoms is too small to perceptibly affect the properties of the liquid in bulk. On this hypothesis, rise of temperature, or other mode of increasing conductivity, might perhaps cause some increase in opacity; moreover, it is to be remembered that the transparency of electrolytes for long waves is possibly very small.

(b) Faraday's Two Laws.—(1) The voltametric law. (2) The law of electro-chemical equivalence.

Law 1 asserts that the amount of electro-chemical decomposition is a precise measure of the amount of electricity conveyed; *i.e.*, that no electrolyte for which the law is true possesses a trace of metallic conductivity; or, that electrolytic conduction and chemical decomposition are precisely correlative. The law has been most exactly verified for nitrate of silver solution by Lord Rayleigh; for this substance, therefore, we know that it is true to a high degree of accuracy. For other substances our knowledge is at present only approximate, the main difficulty in its verification lying in the prevalence of secondary actions and the confusion they cause. So great is the influence of these actions that in some cases an electrolyte has been asserted to conduct only metallically, and not to be decomposed at all. This has been said, for instance, of the fused iodide and chloride of mercury. A strong current may be sent through these fused salts with carbon electrodes and no products of decomposition shall appear, because they dissolve and diffuse through the liquid with such suprising velocity. J. W. Clark* has proved this to be the explanation, and has succeeded in getting off a good supply of mercury, and of iodine and chlorine, by separating the electrodes by a sufficiency of intervening porous material, which, whether it retard true diffusion or not, certainly hinders convection. But, of course, such an experiment has not exact quantitative signification until every trace of recomposition is avoided, and the theoretical amount of free ions obtained. And this is just the difficulty; for even in simple acid water, if any air be dissolved in the water it is well known that an insufficient supply of hydrogen comes off, while if the water is *not* saturated with oxygen, the supply of oxygen must be deficient by reason of solution. If oxygen be estimated by *volume* it will be apparently deficient for another reason; but the better way of estimating it is by loss of weight, which gets over the ozone difficulty. Helmholtz has taught us how to get over the dissolved air difficulty, by making a most ingenious air-free cell, described in the Faraday Lecture, 1881; and he shows that in such a cell polarisation is produced by infinitesimal currents, and no permanent leak goes on through the cell until the applied E.M.F. attains a certain value. This is a perfectly valid proof that no trace of metallic conduction exists in air-free acid-water, and that accordingly for this substance Faraday's law 1 is true.

We have already expressed the law in several forms of words. Helmholtz expresses it as follows: "Through each section of an electrolytic conductor we have always equivalent electrical and chemical motion." And if this fact of equivalent electrical and chemical motion be expressed, as Ampère very naturally expressed it, by calling it a convection of electricity by the moving atoms of matter, we may state Faraday's law 1 thus: —*Electrolysis is a kind of electrical convection rather than conduction, each atom carrying a charge with it; and the charge conveyed by every atom of a given substance is the same.* Obviously a vitally important statement if the slight amount of hypothesis involved in it is legitimate, as I fully believe it to be; and it is the one virtually adopted by Clerk Maxwell in his treatise.

Law 2 asserts that when a current is sent through a series of different substances, the mass of each substance liberated (or decomposed, or dissolved, or whatever it is that happens to it) is proportional to its ordinary chemical equivalence: or, that the amount of any substance acted upon during the passage of a given quantity of electricity is equal to its molecular weight divided by its atomicity, or, more explicitly, its molecular weight divided by the number of bonds which under the particular circumstances happen to be loosed or joined, per molecule of that substance, be it element or be it compound. Evidence for the truth of this law has been accumulated by Daniell and Miller, by Wiedemann, Hittorf, Matteucci, Becquerel, Soret, and Buff. They all separate the anode from the cathode vessel by various devices, and it appears as if the more carefully secondary actions are prevented or allowed for, the more nearly is the law true. It may be sufficient to refer to Wiedemann's "Elecktricität" for an account of a mass of research. Further evidence may be

* *Phil. Mag.*, November, 1885.

Digitized by Google

suggested as given by the behaviour of certain electrolytes in series contact, without electrodes intervening, after the manner of Davy; for, if two meeting ions were not precisely equivalent, the one in excess would have to appear in a solitary state. Such a phenomenon might be well looked for, but it has never yet been certainly observed. The physical import of law 2 is that it extends the statement of law 1, about each atom in a single substance having the same definite electric charge, to all electrolytes, and enables us to conclude that a definite quantity of electricity belongs to each unit of affinity of every atom of whatever kind; in other words, that every monad atom or radicle (while being liberated on an electrode, at any rate) has associated with it a certain definite quantity of electricity, no matter from what compound it is being liberated, and no matter what the name of the radicle itself may be; that every dyad radicle has twice this quantity associated with it, every triad three times as much, and so on.

It is impossible to overlook the immense interest of such statements as these to any chemist wishing to grasp the real meaning of chemical combination and affinity. But the tremendous import of the law to physicists also may be more vividly indicated by pointing out that the electric charge of a nascent monad atom is a kind of natural unit of electric quantity, *and that fractional portions of such units are*, in electrolysis at least, *unknown*. One may have integral multiples of this natural unit, as in dyads and triads, but one cannot have submultiples, until chemists discover some quantivalence less than that of hydrogen, or rather until they see reason to abandon the idea that quantivalence proceeds by integers (the basis of their "atomic theory") altogether. Maxwell no doubt intends to call attention to the superlative interest of the fact that there appears to be a non-divisible electrical unit, when he calls it "a molecule (his customary cautious name, intended to include atoms also if they exist) of electricity." And Helmholtz does not shrink from staring the possibility in the face that electricity may turn out to be as "atomic" as matter.

Atomic Idea of Electricity; Electrostatic Theory of Chemistry.—Let us first consider what is really the evidence for such a view. Electricity is found to associate itself with the atoms of matter in multiples of one fundamental quantity, but never in fractions of it; it does not then follow that fractions of this quantity are impossible, but it may well be that we have never yet dwelt with them. The evidence for the atomic nature of electricity is pretty much of the same nature as that for the atomic nature of matter. Gains and losses of electricity are apparently continuous, but so they are of matter; all that is necessary to satisfy experience is for the atom of electricity to be smaller than any quantity hitherto measured. Whether the charge of a monad atom be indivisible or not, it is certainly a natural unit of electricity, and it becomes of great interest to calculate its value. This is easily possible to the same degree of approximation, as we know the size of an atom. The electrical charges in the atoms of a gramme of water are known accurately enough, from ordinary electro-chemical-equivalent determinations, viz., $1{\cdot}5\times10^{13}$ electrostatic units of each kind; the number of molecules in a gramme of water may be considered as something between 10^{24} and 10^{25}; and accordingly the charge of a monad atom is something like 10^{-11} 10^{-12} electrostatic units. Now this is very small, less than the hundred trillionth of a coulomb, and if it were really an ultimate atom of electricity, it is wholly unlikely that the fact would have been noticed. It is possible, however, to think of some phenomena which may afford an indication one way or the other, and I shall venture to suggest one or two later. The charge of an atom is so small that its potential cannot turn out high, on any customary hypothesis as to actual atomic magnitude, provided ordinary considerations of electrostatics apply to atoms. It is difficult to know whether they apply or not until it can be shown that absolute vacuum has a specific inductive capacity. The transparency of interstellar space, and the velocity of radiation in it, would seem respectively to answer the question in the affirmative, and to suggest unity as its value. At any rate, when one has no other mode of tackling atomic charges it would seem reasonable to try the ordinary electrostatic laws on them, and see how they fit and what happens. Consider, therefore, the following problem. A number of equal spheres, each charged with a definite quantity of electricity, are commingled with the same number of similar spheres, each charged with the same quantity of opposite electricity, the potentials of the spheres being so low that mutual discharge does not occur even during a collision, or so-called "contact," of the spheres, and some law of force being assumed between the spheres irrespective of their charges. I do not propose to attack the problem thus vaguely suggested, because many persons can do it far more easily and thoroughly than I; but certain facts are patent. The potential of each sphere must be lower in the "combined" state than in the isolated, and, unless an atom be assumed to be extravagantly small compared with the spaces between them in the liquid state, the potential of each isolated atom is but a few volts.

Facts are known which suggest sizes for the actual substance of the molecules, but, without pressing them, one may assume that whereas in the liquid state the distance of the atoms apart is about 10^{-8}, the radius of each of them is about 10^{-9} or even 10^{-10} centimetres; then, the charge of a monad atom being as aforesaid 10^{-11} or 10^{-12}, it follows that its potential, when isolated, is about 3 volts. If such an atom pair off with another of opposite sign, the potential of each will fall as they approach; becoming, when the distance between their nearest points is one-tenth the radius of either, about 1·2 volts,* and falling asymptotically to zero as the distance between them still further diminishes.† It is true that this fall of potential has not the result of postponing mutual discharge *ad infinitum* however near items may approach; but I feel constrained to believe that no such discharge ever in practice occurs, from the fact (if it be a fact) that the whole of a liquid can be electrolysed away, and from the assumption that any such discharged molecules would be wholly intractable to electrical influence. To explain non-discharge we can fall back on the rather dark fact of the enormous apparent dielectric strength of vacuum, combined with the very low potentials to which atoms are charged.

I have tried an experiment of electrifying two falling clouds of lycopodium oppositely, and allowing them to mix, or, so to speak, combine. The result has not yet been satisfactory, but lycopodium granules are coarse and weighty bodies, and are unwieldy representatives of atoms. To get anything like such a quantity of each kind of electricity into the grains of a cubic millimetre of lycopodium as exists in the atoms of a cubic millimetre of water, the charge, and therefore the potential, of each granule would have to be enormous, something like a billion volts: for I find the diameter of a lycopodium granule about ·004 centimetre. It is easy to see that a given quantity of both kinds of electricity, shared among a given bulk of equal and definitely arranged spheres, will raise the potential of each by an amount proportional to its superfices. It may be noted, as interestingly showing the enormous charges which, distributed among the atoms of a substance, produce such an insignificant potential, *i.e.*, as illustrating the prodigious electrical capacity of molecular arrangement, that if the opposite electricities were extracted from a milligramme of water, and given to two spheres one mile apart, those two spheres would attract each other with a force of ten tons!*—(Cf. Helmholtz, Faraday Lecture, 1881.)

A more hopeful substance than lycopodium, for constructing an artificial chemical compound with, is fine smoke, say of magnesia, which hovers in air for a long time. But, as Clark and I have observed, it is sufficient to electrify such smoke with only one kind of electricity in order to cause the particles to combine or coagulate together—doubtless because of minute differences of potential between them; the aggregations soon becoming very large and giving the appearance of snow. I now fancy that this same phenomenon of aggregation may go on among the atoms of a gas when it is electrified, and may account for the formation of ozone near an electric machine, for the formation of ammonia from nitrogen and hydrogen, and such like.

(c) Joule's or Helmholtz's or Thomson's law of the dependence of Decomposition E.M.F. on Chemical Combination-energy.—The deduction of this law from the first law of thermodynamics may be exhibited perhaps most clearly and briefly as follows:—

(i.) Definition of E.M.F. as—the work done in a circuit per unit of electricity conveyed, or $E=W/Q$.

(ii.) Definition of Electro-chemical Equivalent as—the mass of substance decomposed per unit of electricity conveyed, or $\epsilon=m/Q$

(iii.) Definition of Thermal Equivalent as—the heat set free during the formation of one gramme of the substance from the two radicles into which it has just been supposed to be decomposed, provided that none of the energy remains in some form other than that of heat, $\theta=H/m$.

(iv.) Statement of the first law of thermodynamics applied to the electrical decomposition of the said substance in the given way, on the assumption that the whole of the work done by a current is expended in decomposing the substance,

$$W=JH.$$

The simple algebraic consequence of these four equations is

$$E=J\epsilon\theta,$$

which is shorthand for the law, and may be read thus:—the E.M.F needed to decompose a substance into given constituents is calculable by simple energy considerations from purely thermo-chemical data.

If θ'' stands for the heat production per dyad gramme-equivalent of the substance (*e.g.*, per 18 grammes of water, 98 grammes of sulphuric acid, or 136 grammes of chloride of zinc), it is easy to see that

$$E=\frac{\theta''}{46{,}000}\text{ volts};$$

for $J=42\times10^6$, $\epsilon=\frac{\mu}{9{,}660\,k}$, $\theta''=\frac{2\mu\theta}{k}$, where μ is the molecular weight of the substance as compared with an atom of hydrogen, and k is the atomicity or number of bonds loosed in the decomposition supposed. Values of θ'' are tabulated direct by Julius Thomsen for a great variety of substances, and are quoted in Naumann's "Chemie," vol. i., and also

* See table by Sir William Thomson in "Electrostatics and Magnetism," sec. 142.

† Or one might work the argument conversely, and perhaps more plausibly, so as to obtain an estimate of atomic, as distinct from molecular, dimensions. Thus:—The total charge shared among the atoms of a gramme of water is perfectly well known, viz, 1,073 electro-magnetic units of each kind. The heat produced during the formation of a gramme of liquid water from its gaseous constituents is, according to J. Thomsen, 4,333 thermal units. If two bodies, or sets of bodies, each charged with that quantity of electricity (one set positive, the other set negative), approach each other so as to do this amount of work, their difference of potential must diminish, during the approach, by 1·7 volts. The fall may be from 1·7 to nearly 0, as the dissociation idea of electrolysis would suggest. Or it may be from 3 to 1·3, as the guess at atomic dimensions in the above text implies. Or atomic charge may be a thing acquired during the act of combination, as the hypothesis of zero charge in a molecular aggregate like HH or OO would imply; in which case the necessary fall of potential must be 3·4 volts. The first of these alternatives gives for the diameter of an oxgen atom $5{\cdot}6\times10^{15}x^3$; $1/x^3$ being the number of molecules in a gramme of water.

* If any cause could make the positive atoms in a drop of water group together and face the negative across a vacuum, a furious Leyden-jar, or "Globe-Lightning," would be produced.

Digitized by Google

partly in Watt's "Dictionary of Chemistry"; hence the obtaining of the volts needed to decompose a substance, by simply dividing $6''$ by 46,000, is extremely convenient.

(To be continued.)

VISIT TO THE WORKS OF THE ANGLO-AMERICAN BRUSH CORPORATION.

In connection with the summer meeting of the Institution of Mechanical Engineers a party of engineers, many of whom were from the Continent, visited the above works on the 18th August, and were shown the various operations and processes connected with the manufacture of electrical apparatus of various kinds.

In the fitting and erecting shop, amongst other things, they examined Brush and Victoria armature cores, of old and of recent designs, which were being made by special core winding and other machines.

The commutators and collectors of Brush and Victoria dynamos also engaged the attention of the visitors, who seemed much interested in the details and construction of these important parts of dynamo machines. Having inspected the very fine tools used in the fitting shop and the work of erecting the dynamos, a visit was made to the dynamo shed, where the machines used for lighting the shops and offices and for supplying current for various manufacturing operations were seen at work. Amongst these was running the old Brush No. 8 dynamo used so many years for the City lighting, which, it may be remembered, has always been operated from the Lambeth Works of the Brush Corporation. This dynamo has been fitted with one of the improved armatures, enabling it to supply about 60 arcs in series. Connected with it is a Brush automatic regulator for maintaing a constant current. The lamps in the shops and on the testing racks are all on the circuit of this machine, and are switched on and off as required, the power absorbed by the automatically-controlled dynamo being sensibly proportional to the number of lamps in operation.

In the winding shop were inspected the operation of winding armatures, field-magnets, electro-magnets, for arc lamps and for various instruments; and in the lamp-fitting shop the lighter operations of making arc lamps of various kinds, electric light fittings, electroliers, switches, switch-boards, and projectors.

In the testing room the visitors saw several projectors, with automatic and hand-fed lamps, Brush dynamos of various sizes, automatic regulators, arc lamps, including a Brush focussing or head-light lamp in an apparatus showing an image of the arc magnified about 100 times.

The multiple series or group lighting system for incandescent lamps was explained, and a safety device was seen in operation which placed spare lamps in circuit in case of breakage, and, if necessary, afterwards short-circuited the group.

Several Victoria dynamos were running, supplying power for projectors, for incandescent lamps, and for Victoria motors driving a circular saw and a ventilating fan.

The visitors seemed much interested in a Wimshurst machine giving a constant succession of vivid sparks.

NEWCASTLE-UPON-TYNE MINING, ENGINEERING, AND INDUSTRIAL EXHIBITION (INTERNATIONAL AND COLONIAL).

ROYAL JUBILEE YEAR, 1887.

PATRON—HIS GRACE THE DUKE OF NORTHUMBERLAND, K.G.
PRESIDENT—THE RIGHT HON. THE EARL OF RAVENSWORTH.
CHAIRMAN OF COUNCIL—JOHN DAGLISH, ESQ.

An International and Colonial EXHIBITION of INDUSTRIES, MANUFACTURES, and PRODUCTS will be opened in Newcastle-upon-Tyne on the 24th May, 1887.

Amongst other important Industries and Manufactures which will be represented are Coal and Mining, Shipbuilding, Ordnance, Marine, and other Engine works, Iron and Steel Works, Lead Works, Chemical Manufactures, and many others.

The attention of intending Exhibitors in the above Exhibition is drawn to the published Regulations of the Executive Council, which enact that all applications for space for Exhibits must be sent in on or before the 1st October, 1886.

It is important that this Regulation should be observed in order that the required spaces may be allotted.

By Order of the Executive Council,
JOHN H. AMOS, Honorary Secretary.

Exhibition, 23rd August, 1886.

JOURNAL OF THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

Edited by F. H. WEBB, Secretary.

No. 62, containing Papers on "LONG DISTANCE TELEPHONY," by W. H. PREECE, F.R.S.; "THE TELEPHONE as a RECEIVING INSTRUMENT in MILITARY TELEGRAPHY," by CAPTAIN P. CARDEW, R.E.; and "ON a PROBLEM relating to the ECONOMICAL ELECTROLYTIC DEPOSITION OF COPPER," by CAPTAIN H. R. SANKEY, R.E. With full report of the discussions arising thereon. Together with OTHER ORIGINAL COMMUNICATIONS and ABSTRACTS from various Scientific Periodicals, English and Foreign.
Price Three Shillings.

No. 63, containing "FURTHER HISTORICAL NOTES on the ELECTRIC LIGHT" (3rd article), by COLONEL SIR FRANCIS BOLTON.
Price Two Shillings.

E. and F. N. SPON, 125, Strand.

NALDER BROS.,
Instrument Makers, Electricians, and General Electrical and Mechanical Engineers,
Office: 8, Victoria Chambers, WESTMINSTER, S.W.

Steam Factory, Brent Electric Works, The Ham, Brentford.
Laboratory, The Butts, Brentford.

Manufacturers of Resistance Boxes, Wheatstone Bridges, Thomson and other Galvanometers, Lampstands and Scales, Electrometers, Condensers, Keys, and Electrical Standards of every description.

SOLE MAKERS OF PROF. GEORGE FORBES'S THERMO-GALVANOMETER.
VOLTMETERS and CURRENT INDICATORS.

Cathetometers, Micrometers, Bar Callipers, and all descriptions of Electrical, Physical, and Mathematical Instruments. Experimental work undertaken. Chloride of Silver and other Batteries. Switch Boards, Switches, and Electric Light Fittings.
Instrument Cabinet Work.

Complete Installations of Electric Light undertaken. Engines, Dynamos, Motors, and Lamps supplied.

DUNCAN WALLET & CO.,
BONDED STORE AND EXPORT PROVISION MERCHANTS,
15, BILLITER STREET, LONDON.

Special Arrangements made for Supply of Goods to Telegraph Stations.

Messrs. D. W. & Co. have supplied Provisions to the Stations of the Eastern and South African Telegraph Companies, and are prepared to execute orders on specially favourable terms at shortest notice

"THE ELECTRICIAN" SERIES.

NOW READY,

ELECTRO-CHEMISTRY. By G. GORE, F.R.S., Author of "The Art of Scientific Discovery," "The Art of Electro-Metallurgy," &c., &c.

This work possesses more of the character of a Dictionary than of a Text Book, in that it forms an almost complete reference to the original memoirs on this subject.
Only a very limited number of copies of this work can be supplied.
Price: Cloth, 2s.; post-free, 2s. 3d.

Publishing Office of "THE ELECTRICIAN" SERIES,
1, Salisbury-court, Fleet-street, London, E.C.

Digitized by Google

NOTES.

ELECTRIC LIGHT IN SPAIN.—At San Sebastian the bull ring has been provided with a Brush installation.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 3rd inst. amounted to £3,235.

ANOTHER ELECTRIC LIGHTING STATION DESTROYED.—The electric lighting station at Hannibal, Montana, has been destroyed by a cyclone.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending Aug. 31st were £3,105.

THE GAIETY THEATRE.—Messrs. E. L. Berry and Co. have received an order to light the Gaiety Theatre with 180 incandescent lamps three weeks from date of contract.

ELECTRICITY IN WARFARE.—The Russian Government has undertaken an extensive series of experiments on the employment of the telephone and also of the arc light for military purposes.

TELEPHONE TROUBLES.—A firm at Gresham House has issued a large type advertisement, notifying their withdrawal from the Telephone Exchange, "owing to the defective working of our telephone."

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of August amounted to £1,370, against £1,326 in the corresponding period of last year.

THEATRE LIGHTING.—It is a singular fact—assuming the statement to be correct—that up to the present time there is only one theatre in the States in which the stage is provided with electric foot-lights.

GREECE.—The Department of Posts and Telegraphs in this country is to be completely re-organised. The number of telegraph offices now open is 128, the total number of lines being—overland 4,667 kilometres; submarine 3,775 kilometres.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 3rd inst. were £2,535, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

QUERY.—The *Electrical World* says that Mobile, Alaska, "enjoys the distinction of being the only city in the world to go back to gas after having tried the electric light." Surely the London gas companies will not allow this statement to pass unchallenged.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for August were £22,400, and the receipts for the period from 1st January to 31st August, £169,960; for the corresponding months in 1885 and 1884, £192,040 and £182,680 respectively.

TELEGRAPH CABLES INTERRUPTED.—The cables between Madras and Penang and between Rangoon and Penang are interrupted. It is not expected that these interruptions will be of long duration. Telegraphic communication is also interrupted with the Island of Mull.

USE OF WATER POWER IN AMERICA.—It is estimated that up to the present time not less than 14,000 horse-power, derived from water falls, is in use in the United States and Canada for driving dynamo machines. Nearly the whole of this power is employed for arc lights.

TELEPHONES AND TELEGRAPHS IN NEW ZEALAND.—Telephone exchanges now exist in seven different towns in New Zealand, with a total of 1,114 subscribers. The number of telegrams forwarded in 1884 was 1,600,000, which is no less than three per head of the population.

ELECTRIC LIGHT AT BARCELONA.—Comparative trials of gas and electricity are being carried out in the Paseo de Colon by the Municipality of Barcelona. Ninety-six arc lamps are in use, and in addition to this about 150 incandescents are supplied to shops in the same locality.

TELEPHONES AT THE BIRMINGHAM INDUSTRIAL EXHIBITION.—The National Telephone Company fitted up a temporary exchange at this Exhibition, making connection with the Birmingham Exchange and also with the trunk lines to Wolverhampton, Walsall, and Wednesbury.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of August was 2,848, estimated to produce £2,200, against 2,833 messages, producing £2,262 in the corresponding month of last year. The traffic receipts for the month of May, estimated at £3,050, realised £3,103.

EDISON.—Edison has recently been interviewed by a New York reporter, to whom he made some observations upon the subject of earth currents. We are inclined to think, however, that it must have been the reporter and not Edison who has promised that before long earth currents will furnish the whole world with electricity for every required purpose.

CHURCH LIGHTING.—The problem of economically working a church lighting plant is solved in a very simple way at Oxford, Pa., where a storekeeper having put an installation of Thomson-Houston lights on his own premises, finds that it pays him very well to light the neighbouring church on Sunday evenings at a charge which is also considered satisfactory on the other side.

NEWCASTLE-ON-TYNE INTERNATIONAL EXHIBITION, 1887.—We would call the attention of electrical firms to the notice in our advertising columns which states that special attention will be given to electrical matters at this Exhibition, particularly with reference to the lighting and transmission of power in coal mines and ships. Applications for space must be made before 1st October.

PORTERAGE ON TELEGRAMS.—On Friday, September 3rd, Mr. Cochrane-Baillie asked the Postmaster-General whether he would take steps to reduce the porterage charged for telegrams delivered at a distance from a post office. The Postmaster-General replied that he did not see his way to make a less charge than 6d. per mile for a foot passenger, and 1s. per mile for a mounted messenger.

THE HASTINGS INSTALLATION.—At the last meeting of the Hastings Town Council it was resolved "That the existing contract with the Electric Light Company, for the lighting of the front from the Queen's Hotel to Warrior-square, by means of fifteen 2,000 nominal candle-power arc lamps, for the sum of £450 per annum, which expires on the 25th November, be renewed for another year."

MEDICAL ELECTRICITY.—The latest addition to appliances of this character consists of a small chloride of silver cell, measuring about 1½in. by 1in., and about the thickness of a shilling. It is intended to be worn inside the lining of a hat; two small silver plates connected with the terminals bear against the forehead. Thus equipped, we are assured that nervous headaches may be defied.

TELEPHONIC EXTENSION IN SCOTLAND.—The National Telephone Company have now completed the communication between Stirling, Alloa, and the Bridge of Allan. The lines between Stirling and Glasgow and between Stirling and

Digitized by Google

Edinburgh are now in course of construction. It is also intended shortly to open communication between the districts of Glasgow and of Dundee, *via* Stirling.

THE LODYGUINE FILAMENT.—M. Lodyguine's process for obtaining carbon filaments of great tensile strength, to which we recently made some reference, is now said to consist in the treatment of the raw material with boric fluoride (BF_3). The reaction which takes place (and which proceeds in the cold) has the effect of expelling hydrogen from the organic carbon, whether it exists in a state of combination or otherwise.

MADRID TELEPHONE COMPANY.—A new telephone company for Madrid, the *Sociedad de Teléfonos de Madrid*, has been formed in Paris, under the auspices of the French Credit Mobilier and the International Telephone Company of Brussels. At the first general meeting recently held in Paris it was reported that 2,400 shares of 500f. each had been subscribed for, giving a share capital of 1,200,000f., say, £48,000, of which 125f. per share had been paid.

THE "VOLTA."—The electric launch "Volta," which has recently been completed at the works of Messrs. Stephens, Smith, and Co., Millwall, to the designs of Mr. A. Reckenzaun, left the West India Docks on Wednesday afternoon for Dover. Weather permitting, it is proposed to cross the Channel in her on Saturday next. Arrangements have been made to re-charge the cells at Dover. We hope shortly to give a full account of this boat and of its performance.

DUNDEE UNIVERSITY COLLEGE.—We have received a copy of the "Calendar of the University College of Dundee for the Fourth Session, 1886-7." We have previously called attention to the prominence given to physical science in the Dundee College. A special course extending over two years has been arranged in electrical engineering. Profs. Ewing and Steggall deliver the lectures and superintend the laboratory work in connection with these classes.

THE NEW YORK CONDUIT.—The cost of the concrete conduit which is being constructed for the telegraph and telephone wires in New York is estimated at $80,000. This sum is to be provided by an assessment of $4 per mile upon the wires of all the companies concerned. The Commissioners having decided upon the material of which the conduit is to be made, are now engaged in testing the tensile and crushing strength of various samples which have been submitted to them.

A GELATINE BATTERY.—Mr. Cox, of Cincinnati, has invented a battery. The zinc carbon plates are separated by gelatine containing acid. The arrangement seems to have some merit. We therefore regret that Mr. Cox should in one sentence claim to be the original inventor of this battery, on the ground that he has had one in use for eight months already, and should in the next sentence express his conviction that the battery "will last about ten years *without any attention whatever.*" (Mr. Cox's italics.)

A NEW ELECTRICAL CLOCK SYSTEM.—The Synchronous Time Company of Boston has introduced a new method of regulating clocks by electricity. The clocks to be controlled are connected by wire with a standard clock, and once every hour the latter closes a contact, and sends a current through the circuit. Each clock is provided with a regulating apparatus, which when traversed by the standard current acts upon the pendulum suspension in such a way as to increase or decrease its length accordingly as the clock has been running fast or slow.

"SPECIAL DELIVERY" LETTERS.—At Philadelphia the Postal Department has tried the experiment of a "special and immediate delivery" post. The idea was to compete with the local telegraph companies by organising a system for the immediate despatch of letters within a certain area, and on payment of a small extra fee, direct to their destination. The system has had a trial of nearly twelve months, and is now pronounced to be a failure. In October last year, when it first came into operation, nearly 12,000 letters were so delivered, but in July the number had fallen to 3,800, which was not a remunerative figure.

THE ELECTRIC LIGHT FOR LIGHTSHIPS.—On and after October 15 an experiment of an important nature is to be made upon the bar lightship at Liverpool, the Mersey Docks and Harbour Board having decided to exhibit tentatively an electric light instead of the present oil light. The new light, which has been fitted by Messrs. Crompton and Co., is to be visible at a distance of ten miles, and will show flashes every half minute from sunset to sunrise. Should it be necessary to discontinue the electric light, the oil light will be substituted. After the same date at the same lightship a powerful fog siren will be substituted for the present fog horn.

INDUSTRIAL EXHIBITION.—At the Polytechnic Institute, Regent-street, an Industrial Exhibition of work executed by members and students, was opened on the 1st inst. by Sir J. Lubbock. The hall has been lit by 60 Edison-Swan 16 candle-power lamps, run off an Edison dynamo driven by a 12 horse-power gas engine. An arc lamp is also employed, which is run from an "A" type Gramme machine. This installation has been erected by the students themselves. The exhibition comprises an extensive and interesting display of electrical apparatus, either the property of the Institute or of the students, or in some cases lent by certain of the electric lighting companies.

THE LANCASHIRE AND CHESHIRE TELEPHONE COMPANY.—We have received a copy of the list of subscribers to this company's Manchester exchanges, dated August, 1886. The list is well printed and well indexed, and contains a map of the extensive trunk line connections of this company, showing also the connection with the trunk lines of the Yorkshire Company. In the matter of call offices, trunk lines, and all other telephonic facilities, this district is far ahead of the metropolis. The mileage of wire has increased during the past year from 4,570 miles to 6,230, and the transmission of messages has now arrived at 11,000,000, at a cost of a small decimal over a penny per message.

THE ELECTRIC LIGHT IN BANKS, &c.—A number of banks, insurance offices, and other large establishments in London are being fitted up with the electric light, but in a very private manner. No published accounts can be given of these installations, as in many cases the owners object to their places being described. We understand that several London contractors are busily engaged in carrying out work of the above nature, where the electric light seems to be gaining great favour. The East and West India Dock Company's installation at Billiter-street, carried out by Messrs. R. E. Crompton and Co., seems to have been the starting point for many of these installations. We hope shortly to see a still larger number adopt this means of illumination.

TELEGRAPH CLERKS.—A well attended meeting of telegraphists was held at the Foresters' Hall on Wednesday evening. The greatest unanimity prevailed, and resolutions were passed expressing disappointment at the silence of the Government towards their petition, presented in March last, for increased remuneration, and deciding to call the new Postmaster-General's attention to the matter. It was also resolved in the event of no re-arrangement of their position being forthcoming, to use their best endeavours to draw public and parliamentary

Digitized by Google

notice to their grievances, official agitation being declared hopeless. Every confidence in the committee was expressed, and a hearty vote of thanks was accorded to Mr. Pickersgill, M.P., for his attitude towards the telegraph clerks.

BOOKS RECEIVED.—We have received from Messrs. Mather and Platt a copy of their latest catalogue, containing full illustrated descriptions and price list of the well-known "Edison-Hopkinson" and "Manchester" dynamos, together with some well designed switch-boards and resistance frames.—Messrs. Goolden and Trotter send us a copy of their descriptive price list, which contains a very complete selection of requirements for installations of all kinds. We learn that this firm is about to introduce a new regulator for use in cases where it is necessary to run a dynamo from an unsteady engine.—From Messrs. Sampson Low and Co. we have received copies of "Analysis Tables for Chemical Students," by R. L. Taylor, and "Exercises in Mensuration," by T. W. Start.

ELECTRIC LIGHTING IN BOURNEMOUTH.—On Monday evening a number of the business men of the town met by invitation at the Tregonwell Arms Assembly Rooms to consider the introduction of electric lighting into Bournemouth, and to consider the advisability of forming a company for that purpose. Mr. Shepherd (of the firm of Mortimer, Shepherd, and Co., who have been giving electric lighting experiments in Bournemouth lately) stated the terms upon which he would undertake to light 500 incandescent lamps for shop purposes and also his terms for lighting 700 lamps. The following resolution was unanimously carried:—"That a sub-committee from the meeting be formed to canvass the town to see what support can be obtained for the purpose of using the electric light, and, secondly, in financing the experimental stage."

THE BEATTIE ELECTRO-MOTOR.—This motor possesses no special claim to novelty except in the method by which it is made self-regulating. The field-magnets, which are four in number, are each provided with several independent coils. The terminals of these coils are connected with a set of contact pieces, which are placed around the quadrant of a circle. An ordinary centrifugal governor is geared to the armature shaft, and this actuates a lever having a circular rack at its extremity. The latter moves a double contact switch, one end of which slides over the contact pieces connected with the field-magnet coils, and the other slides over a similar set connected to some resistance coils. In this way any increase of speed cuts out one or more of the field-magnet coils, and introduces resistance instead. The system is open to several very obvious objections.

THE LIGHTING OF MADRID.—We have several times referred to the conflict between the Madrid Gas Company and the trading community of Madrid with respect to the bad quality of the gas supplied and the high rates charged. The gas company has just issued its report for the past year, and it is somewhat surprising to find that while there has been a falling off of 12,000f. in the receipts, there has been an increase in the expenses of 60,000f. There was, consequently, a reduction in the dividend from 27½f. to 25f. The *Dia*, commenting upon the report, says "that the present year does not promise to be more satisfactory for the shareholders. The differences between the company and its customers is more pronounced, and in a short time we shall have part of Madrid illuminated by the electric light and a great number of the shops by petroleum."

THE EARTHQUAKE.—Earthquake shocks of diminished intensity continue to take place at frequent intervals in South Carolina, but not much additional damage has been done. The earthquake which inflicted so much injury in Greece upon the 27th ult. was also felt on the southern shore of the Mediterranean. In Lower Egypt three smart shocks were experienced, but little damage was done. Our French contemporary, the *Cosmos*, recently published a circumstantial account of an earthquake said to have been experienced in Normandy. The same issue in which this imaginary catastrophe is withdrawn from circulation contains the statement that earthquakes have "greatly multiplied" in England during the last few years. Whilst acknowledging that up to the present the inhabitants of this island have escaped lightly, the *Cosmos* fears that evil times are in store for us.

THE POSTMASTER-GENERAL AND THE TELEPHONE COMPANIES.—In the House of Commons on Wednesday evening, in reply to Mr. Gray, Mr. Raikes said, I have to state that I find the attention of the Department was called, in April last, to a statement of the managing director of the United Telephone Company that the company had made arrangements with certain railway companies to open telephone exchanges at all their stations. Thereupon, a letter was addressed to the United Telephone Company pointing out that such arrangements could not be carried out without the special consent of the Postmaster-General, the right of transacting telegraph business at the stations in question having been purchased by the State. The company replied that their chairman, vice-chairman, and managing director would come to the Post Office on an early date to discuss the matter. They have not yet done so, and, meanwhile, the Department has not allowed any call office to be established at railway stations.

PROPOSED INDUSTRIAL ELECTRICAL ASSOCIATION.—A circular has been issued signed by eight or nine of the leading electrical companies and firms, proposing the formation of an "Industrial Electrical Association for the Advancement of Electrical Engineering." The objects which this movement aims at will be gathered from the following extract:—"The duties of the association will be as follows—(1) To facilitate united action with regard to proceedings affecting the trade in Parliament and other public bodies. (2) To hold periodical meetings to discuss prices. (3) To collect and distribute information relating to the trade, its requirements, difficulties, and dangers. (4) To examine and report upon inventions and processes affecting the trade, and the supply and quality of the materials used. (5) To deal with labour questions. (6) If desired, and when requested by the parties, to arbitrate on and adjust trade disputes by competent and recognised authority. (7) To grant certificates of competence in the art to individuals." We shall be pleased to receive any expression of opinion from those of our readers who are interested in this matter.

UNIVERSITY COLLEGE, BRISTOL.—We would call attention to the following information which has reached us with respect to the Physical and Chemical courses at this college:—"In the chemical department lectures and classes are given in all branches of theoretical chemistry, and instruction in practical chemistry is given daily in the chemical laboratory. Excursions to some of the mines, manufactories, and chemical works of the neighbourhood are occasionally made. The department of experimental physics includes various courses of lectures arranged progressively, and practical instruction is given in the physical and electrical laboratory. The department of engineering and the constructive professions is designed to afford a thoroughly scientific education to students intending to become engineers, or to enter any of the allied professions, and to supplement the ordinary professional training by systematic

Digitized by Google

technical teaching. This department includes courses specially arranged for students intending to become civil, mechanical, electrical, or mining engineers, surveyors, or architects. Those who attend the mechanical engineering course enter engineering works during the six summer months, and, in accordance with this scheme, various manufacturing engineers in the neighbourhood have consented to receive students of the college into their offices and workshops as articled pupils. The engineering laboratory is provided with a powerful testing machine, and instruction in the use of tools is given in the workshop."

ELECTRICITY V. GAS.—The owners of large private houses in the country are beginning to find out that electric lighting offers immense advantages over private gas works such as was adopted when electric lighting by means of incandescent lamps was unknown. It will be remembered that Mr. O. E. Coope some two years or more ago gave his experience of fitting up the electric light, and compared it with the cost of erection of gas holders, &c. The difference in cost was very small (being about £140 out of £1,400) in favour of gas. The great improvements introduced in dynamo machinery and the reduction in prices which has since been made would, we believe, turn the scale largely in favour of the electric light. In any case, we believe that if owners of houses who are contemplating the erection of gasworks for their own use will send to the leading firms connected with the electric lighting industry they will get estimates for carrying out their work at as low a cost as it could be done by means of gas, with great additional comfort to themselves. In addition to this, the steam engine employed for driving the dynamo machinery could be utilised for many purposes during the day, such as pumping, &c. We should like to see some competitive tenders:—1st, For supplying a complete installation for a house, say, requiring 300 lights, including engines, dynamo, fittings, &c., complete by electric light. 2nd, Gas holder, furnaces, gas pipes, fittings, &c. This data would, we feel sure, be very useful to many. Perhaps some of our readers will supply us with copies of estimates they have received for the supply of gas plant, also what estimates they have given in competition for electric lighting.

THE ELECTRIC LIGHT AT THE BIRMINGHAM ART GALLERY.—We made some reference to this installation in our last issue, but the following extract from a local paper will be read with interest :—The *Birmingham Daily Post* says :—" The new electric lighting of the Art Gallery the Rotunda, has now had upwards of a week's trial, and, with some slight modifications upon the original arrangement, is found to give the fullest satisfaction. The heat from the gas-lighting on a damp day, and when a public gallery is full of people, has a most injurious effect on pictures, and Mr. Whitworth Wallis has been refused the loan of some desirable pictures on this account alone. In addition, however, to the heat, the products of combustion, principally of an acid character, have an even more injurious influence, and whatever devices the gas engineers have arrived at for confining and carrying these away, it is impossible to persuade the owners of valuable pictures that any system of gas-lighting will make them safe. The incandescent lamps are arranged in a circular frame attached to the structure of the central gas pendant; but a new departure is in the introduction of silvered-glass reflectors, constructed so as to throw the principal portion of the light upon the surrounding walls, while, at the same time, sufficiently illuminating the floor. An additional and important circumstance in connection with these reflectors is the economy effected, the pictures being better lighted by their employment than if double the number of lamps were employed. This means a saving on account of capital and cost of maintenance of about £500 original outlay and £100 per annum. The mirror arrangement is entirely new, and the results are such as were not expected by experts in the matter. There is no doubt that the principle will hereafter have a large field for its employment in the lighting of shops, club rooms, and large apartments generally. Mirrors of this kind can of course only be used with electric lamps, as gas smoke would at once dim the reflecting surface. The entire installation consists of a nine horse-power nominal Otto gas engine, of the latest type, and with special arrangements to secure steadiness, a result which is very perfectly attained. This drives a ten-unit Chamberlain and Hookham patent dynamo, specially designed for this installation. With its actual load it has an electrical efficiency of 95 per cent., the armature coils absorbing only 2 per cent. It is absolutely sparkless, and having an automatic brush arrangement, requires little attention. The leads are very heavy, absorbing only 2 per cent of the current which they convey from the dynamo to the lamps."

ELECTRIC LIGHTING IN ITALY.—An Italian correspondent of *Industries* says :—" Many of the smaller towns of Italy are about to follow the example set them by Milan in the matter of electric lighting. The success of the Edison Company in Milan has been so great that the municipal authorities are encouraged to become themselves undertakers for the electric light, and are inviting tenders for the supply of apparatus and material. One example is furnished by the town of Udine, which is about to provide itself with 5,000 glow lamps for house and street lighting. The motive power in this case is obtained from three waterfalls, the most distant of these being situated three miles away from the town, and the nearest 1¾ miles. At each of these three stations alternating current dynamos will be driven by turbines, but the exciting current for all these machines will be supplied by a continous current dynamo placed at the last-named station. The alternating current delivered by these machines will be used to work transformers, placed at convenient points. The peculiar configuration of the town, and the unequal distribution of the lighting, requires the use of a rather large number of transformers. Each of these sub-stations is surrounded by an Edison net work, which distributes the secondary currents to the lamps. The total loss of energy allowed in the main lines between the machines and the transformers is estimated at 20 per cent. This high figure has been chosen in order to save copper in the conductor. The loss in the secondary mains will be limited to 4 per cent. of the potential at the terminals of the secondary coils of the transformers. It is expected that the installation at Rome will be ready for work before the end of September. The peculiarity of this installation is that it has been undertaken by the gas company of Rome. Here also alternating currents and transformers are employed. The electric light in Turin is not in so good a position. It has been divided between two systems, and up to the present not much progress has been made with either of the installations. One of these is an Edison plant, which has given much trouble during the last few months on account of the careless way in which the underground conductors have been laid down. The cables were at first placed in soft and yielding soil without any mechanical protection. After this, naked overhead wires were tried, but great difficulties were again experienced with the insulation. The other system is that of alternating currents, and, curiously enough, this has again been divided. Gaulard and Gibbs are providing for the street lights, while the house and shop lighting is done by the Zipernowski-Déri Company. The small seaside town of San Remo will also be shortly supplied with electric light."

A PORTABLE ELECTRIC LAMP.*

BY W. H. PREECE, F.R.S.

The demand for a new safety lamp in mines has directed many minds to the application of electricity to this purpose. Some have proposed to use primary batteries; others utilise secondary batteries or accumulators. One of the most portable, compact, and convenient forms is that of Mr. Pitkin. It occupies a cubical space of 59 cubic inches for two cells, and 86½ cubic inches for three cells, weighing 5lb. 8oz. and 7lb. 3oz. respectively. The three-cell battery gives a light equal to 2·5 candles immediately after removal from the charging source, and lasts for nine or ten hours. I have also used it for other purposes. It is a most convenient portable lamp for going into a wine cellar or visiting our greenhouses, and it makes a very convenient reading lamp for railway travelling. I carry such a battery in my dressing bag, and by means of a flexible cord carrying two copper conductors I suspend by a hook to my waistcoat front a small candle-power Edison-Swan lamp that concentrates upon my book or my paper all the light I want. The lamp is fixed in the focus of a reflector whose surface is enamelled dead white, instead of being bright polished. The light is thus much more equably and uniformly distributed. It is, moreover, soft, absolutely steady, and free from smell or annoyance to my fellow passengers. It is lighted instantly without any match, and it can be rapidly replaced by a small coil of fine platinum wire, which, being raised to incandescence, enables me to light my cigarette.

IMPROVEMENTS IN ELECTRIC SAFETY LAMPS.*

BY J. WILSON SWAN, M.A.

I showed an electric safety lamp in this section last year. I have now improved the lamp in various ways, and I propose to describe and exhibit the improvements. The objects I had in view in altering the original design were :—

1st. To reduce the weight as much as possible, consistently with the giving of sufficient light.

2nd. To simplify the construction, with a view to minimising the cost of manufacture, and the cost of keeping in order.

3rd. To make the lamp better able to resist a blow.

4th. To seal in the liquid, so that the lamp could be held in any position.

5th. To add a fire-damp indicator.

The lamps on the table embody these improvements, and are here for the inspection of members. The details of construction and the record of experiments are given in the diagram. With regard to the first point—namely, the size and weight of the apparatus—that, of course, depends in a great degree, on the amount and duration of the light. Guided by the fact that the best of the oil safety lamps scarcely gives the light of one standard candle, and that most of those in common use give only a quarter or half a candle, I have assumed that an average light of one candle, over twelve hours for datal men, and 1¼ candle over nine hours for hewers, is sufficient, and I have fixed the size of the battery in the new lamps on this assumption. No alteration of the design is necessary when more or less light than this is required, but merely an increase or decrease of the size and weight of the battery contained within the lamp body.

In this respect the electric safety lamp has a marked advantage over all safety lamps of the ordinary kind which depend on the combustion of oil; *they* cannot be made to give a much larger light without radical alteration, if at all. If the electric safety lamp is required to give five or even 10 candle-light, it is only necessary to proportionally increase the size and weight of the battery. Safety is not in the slightest degree impaired. There is nothing easier than to be deceived as to the amount of light that can be obtained from a certain size and kind of battery applied to an incandescent lamp. If the lamp is constructed so as to allow such a large current to pass through the carbon filament as will heat it to the enormously high temperature at which disintegration rapidly takes place, ten times as much light is produced as when, by the use of a different lamp, the current is diminished, and the temperature of the filament thereby lowered to a degree which will prolong the life of the lamp to an economical point.

In the case of a miner's safety lamp, it is very desirable to get as much light as possible from a given weight of battery, and hence it is allowable to subject the lamp filament to what may be termed a rather high pressure, but not such a high pressure as will prevent the lamp from lasting about 700 hours. Subject to this condition I find I can obtain an average light of one standard candle during twelve hours, and 1¼ candle during nine hours from a battery which, with all the appurtenances of the lamp attached to it, weighs altogether 6¼lbs. The same battery, with a different lamp filament, will, of course, give either more light for a shorter time, or less light for a longer time than that I have mentioned. The battery cells are slightly different in construction from those in last year's lamp. They consist,

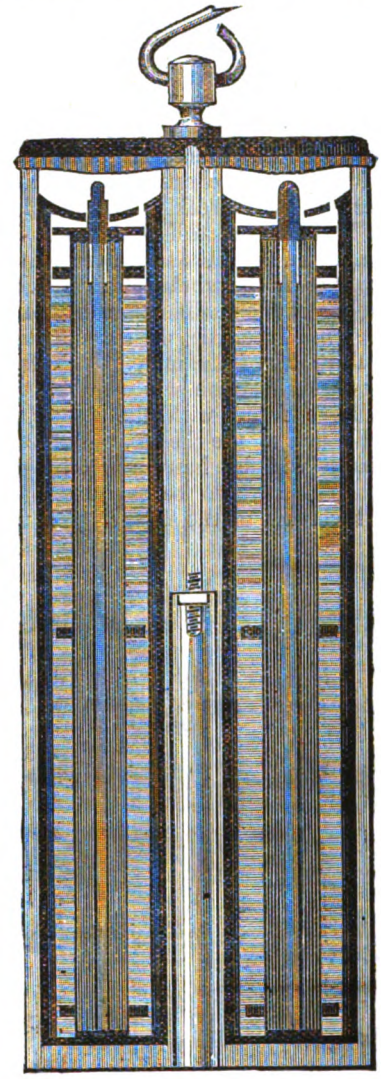

FIG. 1.—Sectional Elevation.

as before, of a central solid cylinder of peroxide of lead, with a conducting core of lead wire, fixed concentrically, by means of guide rings of india rubber, within a tube of lead, the internal surface of which is in the spongy state. The annular space between the peroxide of lead cylinder and the lead tube is filled with dilute sulphuric acid. Four such elements are fitted into four ebonite lined holes in a block of wood saturated with paraffin. The lead wire connections between cell and cell are covered with india rubber, and embedded in channels in the wood, and covered with Chatterton's compound. Over the buried connecting wires is fixed a veneer of ebonite, which further protects them, and also forms a level seat for the cushion of india rubber, which, when pressed down by the cover-disc, makes the cells liquid-tight, so that the whole block may be laid on its side, or inverted, without leakage.

* Paper read before the British Association at Birmingham.

Digitized by Google

In the form of lamp I showed last year, the cover of the case which contained the battery had to be screwed off to get at the battery terminals, for the purpose of putting them in connection with the charging circuit. In the new design, the removal of the cover is avoided by bringing down the battery terminals to the bottom. Access is given to these through two small holes, within which fit two pins connected with the positive and negative charging wires. Charging is effected by simply placing the lamp on a bench fitted with charging pins, in connection with wires from a dynamo, so that the charging pins enter the two holes at the bottom of the lamp case. The lamps remain on the dynamo circuit, receiving their charge during the time the men who have used the lamps are resting, and they become fully charged by the time these men return to work.

It is a point in favour of this kind of lamp that the operation of renewing the charge is effected with little trouble and cost—far less than is involved in replenishing and cleaning ordinary safety lamps. For example, one horse-power is sufficient to charge one hundred lamps at a time; that item of cost will, therefore, not exceed a farthing a lamp per week.

The total cost will not exceed fivepence per week, where several hundred lamps are in constant use. That amount will, I estimate, cover the total weekly cost per lamp, including renewal of lamp-bulbs, the cost of fuel, wages for keeping the lamp charged and in repair, and interest at 10 per cent. on the capital outlay for the whole plant including the lamps themselves. In one of the modifications of the lamp the light is fixed upon the top of the case, with a view to the illumination of the roof and sides of the mine. This form of lamp is intended for the use of overmen while travelling in the workings. The bullseye form, with the light on one side, is intended for the use of the hewer. While the hewer is at work the lamp will be hung up on a hook as usual. Where low workings have to be traversed the lamps can be fastened to the breast of the miner by a strap across the shoulder.

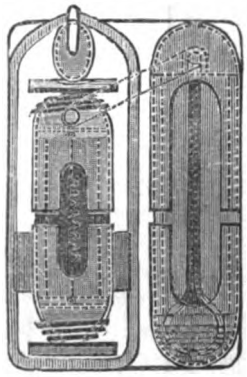

FIG. 2.—Fire Damp Indicator.

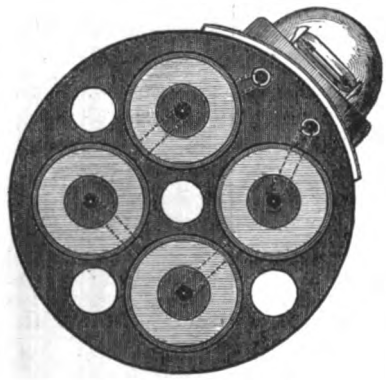

FIG. 3.—Sectional Plan.

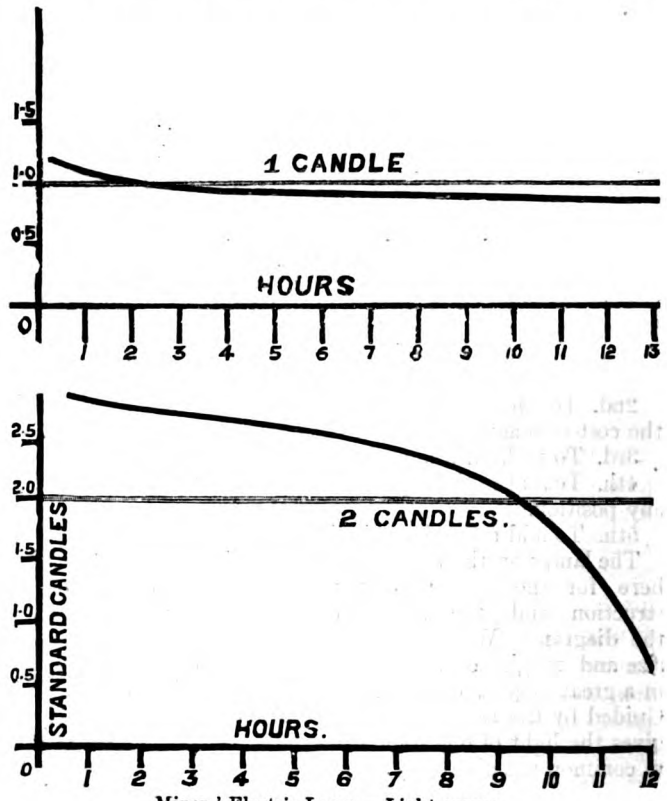
The only other point requiring explanation is the fire-damp indicator. The want in the lamp I showed last year, of the means of showing the presence of fire-damp, was urged as an objection to it. I have met the objection by adding an indicator. This will not be required on every lamp, but only on lamps used by overmen. I have made the indicator in three forms; two of these act on the same principle as Liveing's fire-damp indicator. A spiral coil of thin platinum wire is arranged so that it can be heated to a low red heat by switching through it the current generated by the lamp battery. If this takes place in an atmosphere in which fire-damp is present, the wire becomes hotter than when heated in pure atmospheric air, because combustion of the fire-damp with the oxygen of the air, brought about by the electrically heated wire, produces additional heat, and, consequently increases the temperature of the wire, so that it is sensibly brighter when heated in air containing fire-damp than when heated in air in which there is no fire-damp.

In one form of the indicator I have followed Mr. Liveing's idea of having a comparison wire, shut up, air-tight, in a glass tube containing pure air. In another, I have deviated from Liveing's construction in two ways, namely, by having only one wire (the test wire), and instead of this being in a wire gauze cage, always exposed to the atmosphere in which the lamp is placed, it is in a tube which, when the current is turned on to heat the wire, is completely closed. It is not easily conceivable, even if the test were made in an atmosphere of air and fire damp of maximum explosiveness, that flame would pass the four-fold lining of fine copper wire gauze of the Liveing indicator; still it is, perhaps, more consistent with the absolute safety of the lamp itself, to make the test in a closed vessel. With the double wire arrangement, when fire-damp is present in the air, even in so small a proportion as a half per cent., the *exposed* wire glows with perceptably greater brightness than the *enclosed* comparison wire. With the single wire arrangement, under the same atmospheric conditions, the wire would glow for an instant with extra brightness, and then, after the small quantity of enclosed fire-damp is consumed, would die down to normal redness.

The third form of indicator acts upon a different principle. In it there is a platinum wire within a small tube, and the means of turning on the current from the lamp battery to heat the wire, as before; but here the hot wire is employed only to



Miners' Electric Lamp.—Light curves.

effect the combustion of any fire-damp that may be present, with a view to the production of a partial vacuum resulting from the condensation of the watery vapour of the burnt gases. The degree of vacuum or shrinkage is shown by the rise of liquid in an adjacent gauge tube, and from this the exact per centage of fire-damp present in the air may be ascertained. This form of test is also, and necessarily, made in a closed vessel. The hot wire is completely cut off from contact with the outer air.

I think it will appear to the section that I have produced a miner's lamp having the advantage of absolute safety, and which is at once more efficient and more economical than any other miner's lamp yet constructed.

DISCUSSION.

Mr. SWAN, in answer to a question put by the Chairman as to what would happen in case the glass of the lamp should break, said that he had not had an accident of the kind, and it was not easy to conceive of such a contingency, because the glass was exceedingly thick—so much so, in fact, that if a lump of coal were to fall upon the glass the coal itself would break, and not the glass, which was about an eighth of an inch thick. But if for a moment it were supposed that the lamp was struck

with a hammer, so as to break the glass, the small lamp, which was held between two springs, would be knocked out of its place, and its electrical connections would be detached.

Prof. FORBES said that he had been very interested in the paper contributed by Mr. Swan, because it happened that he (the speaker) had occasion during a great number of years to try, in conjunction with others, to do as much as possible for procuring safety in the working of coal mines. The first thing that occurred to everyone in connection with such a lamp as that which Mr. Swan had exhibited was, what would happen if the lamp broke? The question had already been asked, and Mr. Swan had, to some extent, answered it. But Mr. Swan had not told them specifically if the lamp were broken in air containing an explosive mixture whether or not an explosion would take place. That might, perhaps, be beside the question, because Mr. Swan might say that such a thing would never happen, but he would like to know whether, if such a lamp were broken in an explosive mixture of fire damp, an explosion would take place. He did not know whether Mr. Swan in person had ever tested the lamp under such conditions, but if he had, considerable confidence might have been placed in his invention. That part in the paper which related to the detection of the presence of fire-damp and the measurement of it was exceedingly interesting and important. The miner's objection to an electric lamp of any kind was always what Mr. Swan had pointed out, namely, that it had not got the means of detecting fire-damp. An ordinary miner's lamp, when taken into a coal mine where the dangerous explosive might exist, showed by a blue tinge about the flame the presence of the fire-damp if it exceeded one per cent, and allowed him to approximate roughly the quantity of fire-damp which was present, so that one could determine whether it was large or small. That was the only apparatus used at present in coal mines for determining whether there was fire-damp in them or not. A great many years ago it seemed to him (Prof. Forbes), or rather it was urged upon him by people who had coal mines under their charge, that it was very important to introduce some independent and more scientific method of detecting fire-damp in mines. A device occurred to him which seemed to be very promising, and that was to determine the density of the gas by means of the velocity of sound through it, or by means of the sound of a resonator containing the air of the mine which would respond or resound to a tuning-fork of a definite pitch. He made a practical instrument with that object, which he believed was still in use in two collieries in Lanarkshire, but which was discarded by most of the miners because they liked their old safety lamp much better. Last year he met a gentleman, Mr. Blakeley, who had made numerous experiments on the velocity of sound, and who was associated with him (the speaker) in improving the apparatus, and they did improve it and made it practically perfect. But the same objection applied to it in that it did not overcome the conservative tendencies of the miners. Mr. Liveing had introduced a system which Mr. Swan had adopted in some of the indicators which had been shown, namely, to have two wires, which might be of platinum, and to heat them by the passage of an electric current through them, and to have one of the wires in pure air, and the other in the air of the mine. If the air of the mine contained a hydro-carbon gas—the fire-damp—the extra brilliancy of it was at once detected. The indicator was very sensitive. Mr. Liveing had put into it a photometric arrangement for enabling him to compare with accuracy the intensity of the brightness of the two platinum wires, and by that means was able to measure distinctly one-half per cent. of fire-damp mixed with the air. With Mr. Swan's arrangement the percentage required, as he imagined, would be rather greater in order to render the presence of the gas evident. He fancied that the arrangement which Mr. Swan had exhibited where there was only one wire—that exposed to the air of the mine—must be sensible to only 1½ or 2 per cent. He would like to hear Mr. Swan's opinion about the sensibility of the single wire in estimating the quantity of fire-damp in a mine. Mr. Swan had shown them another apparatus which struck him as being new in form and more scientific even than the other. It was devised for quantitatively estimating the hydro-carbon present, and seemed to be a very admirable system indeed. It reminded him of a system of the kind in use in some of the Belgian mines. It was the invention of M. Somzee, and was exhibited in the Paris Exhibition of 1881. It was the most remarkable fire-damp indicating apparatus he had ever seen. It was founded on the same principle of detecting the fire-damp, and measuring the quantity present by the rise of the mercurial tube. The apparatus was placed at the bottom of the mine, and periodically—every quarter of an hour—it took into its reservoir or receiver a supply of the air of the mine. It then analysed it by the same method, the most scientific method of analysis employed in the chemical laboratory. Having performed these functions automatically, it telegraphed the result to the mouth of the pit, and prepared itself to repeat the operation a quarter of an hour later. The same principle was adopted in Mr. Swan's latest invention. He heartily congratulated that gentleman on the advance he had made in this important direction, and on producing a lamp for miners which was necessary for their safety. But he could assure the inventor that miners, who were a most conservative class of men, would not adopt it if it was not to their own taste.

Mr. A. SOPWITH desired to know whether the lamp could be held in any position, as, for example, where the light was placed at the side of the lamp could it be used for examining the roof of the workings in a coal pit? If Mr. Swan could give them the assurance that the lamp could be put into the hands of the miners and they could turn the lamp so as to direct the light on the roof of the workings (and he considered that was one of the great defects of the ordinary miner's lamp), a great advantage would be gained by the invention.

Mr. SWAN replied that he could give that assurance. As a matter of fact, the lamp he now held in his hand had been more than once in a coal mine, and carried for very considerable distances in that position [holding the lamp horizontally], and, in fact, had been moved about in every position. He thought it was an exception to the general rule, but where every man at work was required to examine for gas in the roof of the mine he thought that the operation could be performed perfectly well without altering the form of the lamp. There would be no difficulty at all in using the lamp with the light on the side for examining the roof and ascertaining whether or not there was fire damp present.

In answer to Mr. JOSEPH STURGE, Birmingham, who asked whether the lamp exhibited fulfilled the conditions imposed upon the competitors for the prize offered by Mr. Ellis Lever for a safety lamp two years ago, Prof. SILVANUS THOMPSON explained the circumstances under which the committee appointed to adjudicate on the lamps on that occasion met at Woolwich week after week, and went on to say that they had in the course of their labours examined somewhere about eighty different kinds of lamps. A large number of those sent in were rejected at first sight because they obviously did not fulfil the conditions of the competition. For example, one lamp weighed about 1cwt., and another sent out a narrow beam of light very much like a magic lantern. In fact, a great many of the lamps, however meritorious they were in some respects, had to be rejected because they failed to fulfil one or other of the requirements. The beautiful little lamp sent by Mr. Swan on that occasion, and which was not a self-contained lamp, was not to be compared with that which had just been shown to the section. If some other benefactor would come forward and offer another prize of £500 or more for a perfect safety lamp, which would be portable, self-contained, and give a light of at least one candle for twelve hours, he fancied there would be a still more numerous array of lamps entered for the competition. But until then he must say that, as far as he knew at the present moment, the lamp now exhibited by Mr. Swan was the very best that existed.

Prof. SMITH said he was extremely interested when he saw the lamp shown by Mr. Swan at Aberdeen last year, and he ventured to express the hope on that occasion that Mr. Swan would be able to add to it an indicator. That hope seemed to be now realised in two distinct and very beautiful ways. Both Mr. Swan, and the mining community especially, were to be congratulated on the decided advance which had been made. One point which had not been noticed much by the section was worthy of attention. At Aberdeen last year the lamp exhibited weighed 6¾lb. As they had just been told the weight had been reduced to 5½lb. This might seem to some a small diminution; but when one came near the limit of possibilities even that small diminution represented great efforts, and it was one of the qualities of superiority in the lamp shown over that exhibited by Mr. Swan last year. Mr. Swan had partly explained what would happen if the glass of the lamp were broken, but he would like to ask one question in that connection, namely, whether the spark that must exist at the time of atmospheric contact would lead to any danger?

Mr. DESMOND FITZGERALD wished to draw the attention of the section to the fact that all secondary batteries, and particularly those batteries adapted for the production of small lights, might be greatly improved by the use of what was practically a new invention called lithanode. Drawing their attention to the diagrams exhibited, he desired to point out that the red lines represented peroxide of lead, the most highly electro-negative substance with which chemists were acquainted, and the blue line represented lead which was an extremely electro-positive body. He need not point out that those substances were in contact with each other, and also with the electrolyte in the cell. Those were the essential conditions of the production of a voltaic circuit which in the present instance was local. Electricity passed from the lead to the fluid, from the fluid to the peroxide, and from the peroxide back again to the lead. The result was extremely detrimental to the working of batteries, as was generally understood. It was detrimental in several ways. In the first place there was a continual loss of energy by this local action, and in the second place the element as represented would be gradually destroyed. The great objection in this case was the addition to the weight of the apparatus consequent upon the use of metallic lead, which he had already said was so detrimental. The question had long been asked, how was it possible to dispense with that metal? He ventured to express the hope that the question had been completely and satisfactorily answered by the introduction of a material which he termed lithanode. It was a peroxide of lead of high conductivity. It was comparable in that respect to carbon, and it constituted, he thought, the most perfect element for secondary batteries, and especially for batteries for small lights. He most heartily congratulated Mr Swan on the success of his endeavours to mitigate the awful sacrifice of life consequent upon the obtaining of coal, and the world owed him a debt of gratitude for his labours. Mr. Swan might, however, still further improve his lamp by greatly reducing its weight by the use of lithanode as a negative element. He must observe that as it stood Mr. Swan's battery was, comparatively speaking, a heavy one. The figures he had taken note of were 5½lb. as the weight, the current being ·14 ampere.

Mr. SWAN: I spoke of the current in amperes as being about ·4.

Mr. FITZGERALD, who was asked by the chairman to abbreviate his remarks as much as possible, said he would in that case content himself with pointing out that a horse-power was now obtainable very considerably within the weight of 100lb. His remarks might be summed up by saying that by using the improved conductor, and dispensing with the lead, the weight of the battery could be greatly reduced, or the illuminating power increased, or the number of hours during which the battery could be used would be increased.

Mr. SWAN, in reply, said that if Mr. FitzGerald had discovered any means of reducing the weight of a battery the discovery would be very welcome indeed. Mr. FitzGerald had called attention particularly to the weight involved by using a combination of metallic lead and peroxide of lead in the ordinary construction of anodes in secondary

batteries. No doubt there was a great deal of unnecessary lead used, and in the construction of his battery he had paid particular regard to that very point, with a view to the diminishing of the weight. He had got as little metallic lead as he possibly could make it with. He had also kept in view the point that Mr. FitzGerald had raised as to the undesirableness of the loss by local action. He had so designed the battery as to reduce the local action between the metallic lead which formed the core of the anode to the very smallest possible limits, and being in the centre it was removed very considerably out of the sphere of electrolytic action. From an examination of some cores after being a considerable time in use, he thought it was probable that there was no electrolytic action going on at all between the lead wire which formed the core of his anode, and the ingredients which formed the actual material of it.

The PRESIDENT (Sir James Douglass) said that they must all feel indebted to Mr. Swan for his very valuable paper. They could as yet scarcely realise its importance. They might not all remember, but they must all know historically, what an intense sensation was caused when Davy produced his first lamp for the use of miners. The lamp was, of course, a great improvement on the old one. But they all knew that miners had had to work with a very imperfect lamp. Everyone who had any knowledge of the subject knew how imperfect the instrument was. They could not, therefore, attach too much importance to the invention of Mr. Swan. There was every probability that they would now have a perfect instrument, and if it was a perfect instrument there was no doubt it was due to Mr. Swan. Whoever might follow it up with improvements, Mr. Swan had really produced the lamp. He concluded by moving a hearty vote of thanks to Mr. Swan and Mr. Preece for their valuable papers.

LITHANODE.*

BY DESMOND G. FITZ-GERALD.

The object of the present paper is to draw attention, as briefly as possible, to a substance for which it is claimed that it constitutes the negative element, *par excellence*, for voltaic batteries, primary or secondary, and also a perfect anode for the electrolytic separation of the most electro-negative elements, *e.g.*, chlorine.

It may be as well at once to specify the main desiderata in a negative voltaic element, and also the essential conditions in an anode applicable generally and commercially in electrolysis.

A negative voltaic element should be not only strongly electro-negative (inoxidisable) in itself, but also capable of retaining its electro-negative condition when constituting a cathode traversed by a (comparatively) strong current for a (comparatively) long period of time.

The electro-negative material of which it is constituted should not be associated with any relatively electro-positive substance, in contact with it and with the electrolyte; or, in other words, local voltaic action should be impossible. It should not be liable to disintegration or corrosion.

From an economic point of view it is essential, in order to render practicable the use of the element on an extended scale, that the abstract cost of the energy developed by means of the voltaic combination of which a given negative element forms part should not exceed one halfpenny per horse-power hour. It is most desirable, and it is also quite within the limits of practicability, that this cost should not exceed half this value. In other words, it is most desirable that we should be able to show in any given locality, that we can restore to a given battery, constructed with the given negative, the energy corresponding to an expenditure of 736 watts during one hour by means of the combustion of one farthing's worth of coal. From another economic point of view it is desirable in certain applications that the ratio of battery work to weight of negative element (inclusive of depolarising substances) necessary to develop this work should be relatively high. Lastly, an efficient negative voltaic element must possess a degree of conductivity such as will admit of a very low ratio between the quantity of energy converted into heat by the passage of electricity through its substance, and the quantity of energy converted into heat by the passage of electricity through the electrolyte under the best conditions obtainable.

Excepting the substance now presented to your notice, there is no negative voltaic element in which all these desiderata are fulfilled.

The essential conditions in an anode applicable generally for electrolytic decompositions on a large scale are that it must be chemically unattackable both by oxygen and by chlorine in the nascent state; it must not disintegrate by the action of the gases evolved from its surface; surfaces of any required area must be obtainable without any liability to augmented resistance and consequent sparking and heating at joints in the material; it must possess sufficient hardness to resist abrasion by contact with ores, &c.; and its cost must be small. The applications for an anode fulfilling all these requirements are practically unlimited; but with the exception of the substance I now bring before you, there is no material possessed of all these desiderata.

This substance termed lithanode, which for some time past has been known to a few electricians in this country and in France, is peroxide of lead in a dense, coherent, and highly conductive form, obtained, without any admixture of inert cementing or agglutinating material, and free from any contact with lead or other oxidisable body, by a process of which the original and essential features are described in my patent specification of April 15, 1885. But before adverting to the principle involved in its manufacture, it will be interesting to glance at the *raison d'être* of lithanode and to its position in the series of inventions by which the storage battery of the near future has gradually been evolved. Planté obtained peroxide of lead—almost identical in chemical composition with lithanode—in the form of very thin layers in contact with metallic lead.

The objections to Planté's negative were due to the difficulty of sensibly augumenting the thickness of the layer of peroxide initially obtained, and also to the local action between this layer of oxidant and the metallic lead beneath it. The former of these objections was overcome by Faure, whose inventions rendered it possible to obtain layers of active material of any required thickness. The objections to Faure's negative were threefold: first, the necessity for the use of parchment paper or felt to maintain the layer of active material in position; secondly, the liability to defective contact between this layer and its supporting lead plate; and, thirdly, the local action between the peroxide and the metal, limited, it is true, by the circumstance on which the preceding objection is based, but resulting, nevertheless, in a continuous waste of energy and in the ultimate destruction of the supporting plate. The first of these objections, and, to a great extent, the second also, have been obviated in the Faure Sellon-Volckmar accumulators manufactured by the Electrical Power Storage Company; but the third objection is still applicable to the negative element in this otherwise greatly-perfected form of secondary battery.

Obviously the next step in the process of development was to realise the condition I have referred to, under which local action is entirely precluded. This step almost necessarily involved a complete alteration in the form of the negative element, and a coherent plate of active material, independent of any surface support, afforded the most perfect solution of the problem; although in certain cases a support of non-conducting material might be useful. The question was, how to obtain a dense coherent plate of peroxide of lead without the use of any cementing or agglutinating substance of which the effect would be to augment fatally the resistance of the electrode? This question has received a practical solution only after many failures, some of which bore at first the appearance of success.

If we mix oxide of lead with water, and mould the plastic mass thus obtained into the form of a plate, this, as might be expected, will be very friable when dry; and, when immersed in a fluid, will resolve itself into the original pasty form. In order to obtain a coherent solid, without the use of an inert cementing body, it is necessary to produce a molecular change in the plastic mixture, so as to cause it to "set." Such a molecular change may most readily be brought about by a partial chemical change occurring in the moulded mass, provided such change be not too rapidly effected. If, for instance, we blend a certain proportion of finely-divided metallic lead with the oxide of lead and water, the re-arrangement of molecules due to the gradual oxidation of the lead in presence of air will have the effect of greatly increasing the cohesion of the mass so as to allow of its immersion in a fluid without disintegration. The resulting plate, when electrolytically peroxidised, will possess a considerable degree of cohesion and hardness constituting the product known to some electricians under the somewhat barbarous term of *petranode*. Better still—

and this is the invention to which I would draw your attention —if we mix our oxide of lead with a solution of a salt which will gradually be decomposed by the oxide—as, for instance, ammonic sulphate, from which ammonia is evolved whilst a certain proportion of the lead oxide is converted into plumbic sulphate—we may obtain a dense and coherent mass which, when electrolytically converted into peroxide of lead, constitutes *lithanode*.

From what has been said, it will be seen that this substance is in chemical composition almost, if not quite, identical with the active material in the anodes of the various forms of secondary battery which have been proposed for use on a large scale. The difference is one of molecular constitution, allowing of the use of an anode wholly composed of peroxide of lead, and consequently entirely free from the liability to local action. Moreover, the anode in question—unlike those which may be constructed with chemically-produced peroxide of lead—possesses in sufficient degree the quality of conductivity, and will withstand without deterioration and for an indefinite period the effects even of very rapid charge and discharge. When used in voltaic batteries, either primary or secondary, it offers a threefold advantage: first, it gives us a permanent element in lieu of one which contains the elements of its own destruction; secondly, it economises the energy elsewhere expended in local action; and, thirdly, it enables us to reduce the weight of the apparatus. The importance of this result does not need to be insisted upon in addressing electricians and electro-chemists. For the first time, we have it now in our power to construct an anode which with absolute impunity will withstand the test of a perfect voltaic negative—the electrolytic evolution of chlorine.

I have to apologise for the very imperfect manner in which I have been able to bring this material to your notice. Important improvements in its manufacture are in course of development; and I am unable, therefore, at the present moment to give more than a somewhat abstract view of the latest step that has been made in perfecting the secondary battery, and also the means for carrying out various processes of electrolysis on a commercial scale.

At the close of his paper, Mr. FitzGerald exhibited an experiment which, he observed, was not *primâ facie* of a very scientific character; but which, nevertheless, implied a great deal in favour of the lithanode element. A couple constituted by a strip of zinc, and between two and three square inches of platinum foil, immersed in dilute sulphuric acid, was circuited through an electric bell without producing any effect. The platinum was then replaced by a narrow strip of lithanode, which was slowly lowered until it came into contact with the electrolyte—a gentleman present being requested to clap his hands the moment the lithanode touched the acid. It was pointed out that the sound of the bell commencing to ring and the clapping of the hands were simultaneous.

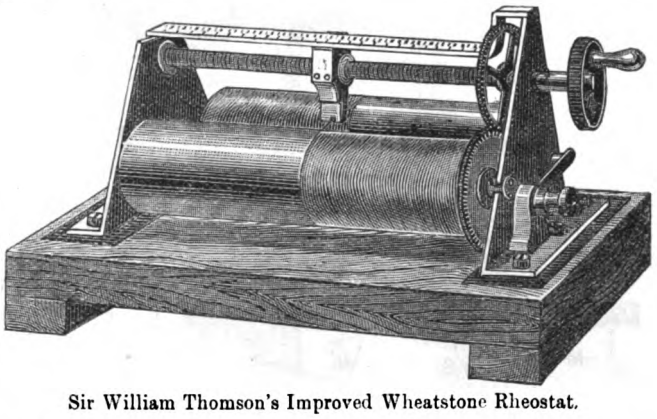
SIR WILLIAM THOMSON'S IMPROVED WHEATSTONE'S RHEOSTAT.*

Wheatstone's rheostat was invented over forty years ago; but, though admirable in conception, and commonly shown on the lecture table in illustrating and explaining the nature of electric resistance, it is scarcely, if at all, used in the laboratory. This is altogether owing to practical defects in the instruments as commonly constructed. The wire becomes loose, the contacts are uncertain, and, the current being incessantly broken and made again, the galvanometer needle is perpetually swinging about instead of showing a continuously increasing or diminishing deflection as the resistance is wound out of the circuit or wound into it.

Modifications of the original instrument have been made from time to time, and a very important improvement was recently introduced by Mr. Joulin, of Bristol. In Joulin's rheostat a toothed wheel fixed on one of the two cylinders gears into a toothed wheel on a shaft carrying the other cylinder, and a spring fixed to this shaft acts on the last-named cylinder, which surrounds it on the principle of the mainspring of a watch. By this arrangement the wire is kept tightly stretched, and the barrels can be turned both forwards and backwards by means of a handle attached to one of them, and the necessity of shifting the handle from one to the other when the motion is to be reversed is obviated.

In Sir William Thomson's improved rheostat the spiral groove in the non-conducting cylinder of previous instruments is dispensed with, and the wire is guided between the cylinders so as to be laid on them spirally by means of a travelling nut in a long screw. The screw is turned by the handle, and carries a toothed wheel which gears into two-toothed wheels, one of which turns one of the cylinders, and the other the aerial shaft of the other cylinder containing the watch spring. The guiding nut is also arranged to stop the motion of the screw-shaft at each end of the range, and so prevent the possibility of overwinding. It also carries an index, which moves along a graduated scale, and counts the turns of the wire on the insulating cylinder.

In Joulin's rheostat the two cylinders are geared together, as already described. The two cylinders are geared together directly, and turn in contrary directions, the wire passing from the upper side of one to the under side of the other. In Sir William Thomson's instrument, as is seen in the diagram, the toothed wheels of the two cylinders are turned in the same direction by the wheel on the screw-shaft, and the wire passes horizontally from the top of one cylinder to the top of the other.



Sir William Thomson's Improved Wheatstone Rheostat.

The conducting cylinder and the wire are both of platinoid, a metallic alloy specially suitable for the purpose. It has very high electric resistance, very small temperature variation of resistance, and it remains with its surface almost or altogether untarnished in the air. On account of the last-named property the contact between the wire and the conducting cylinder is as perfect as can be desired; and continuity of action, which was a great difficulty in the old form of the instrument, is absolutely complete.

A MAGNETIC EXPERIMENT.*

BY W. H. PREECE, F.R.S.

My daughter having finished a piece of needle-work, roughly smoothed it down on her lap, and, in doing so, drove a needle into the palm of her right hand, breaking it into several pieces. All these pieces were extracted but one, and this could not be found by probing. It remained in her hand for a fortnight, causing much pain and inconvenience. An examination by Prof. Hughes with his induction balance, though giving faint indications of its presence, failed to localise it. I tried several forms of this apparatus, but failed. I strongly magnetised a very fine needle, and suspended it to a light arm by a small paper stirrup and a single cocoon fibre. The damaged hand strongly deflected it, and by moving the hand about, the needle invariably pointed to one position, which was marked with a spot of ink. A free and deep incision was made in this spot, and the piece of needle—·4in. long—was found and extracted. The needle went through the opponens digiti minimi muscle, and was found deeply embedded under the deep palmae fascia. The operation was performed by Doctors Pocklington and Page, of Wimbledon.

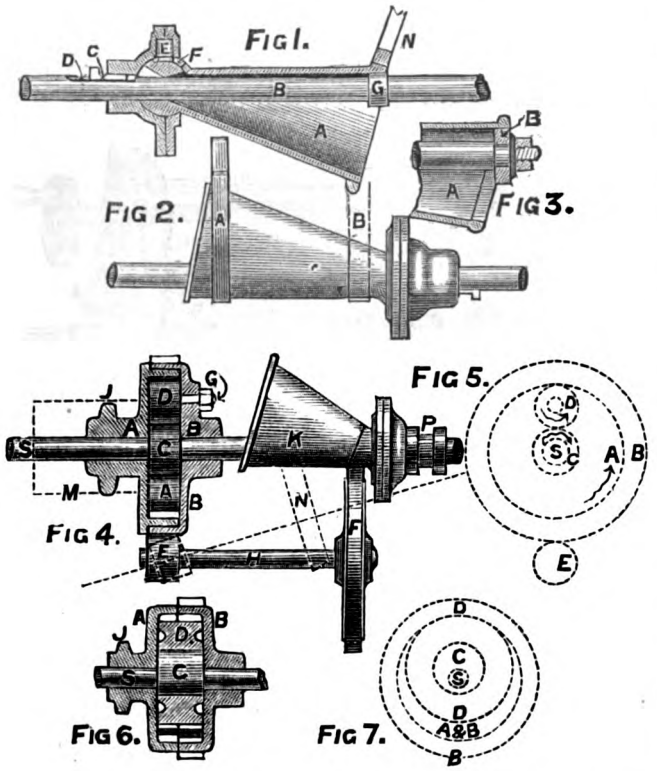
A NEW SYSTEM OF MECHANISM FOR IMPARTING AND RECORDING VARIABLE VELOCITY.*

BY W. WORBY BEAUMONT, M.I.C.E.

Engineers and mechanicians are so well acquainted with the difficulties that have attended the endeavours to obtain mechanism by means of which a determinately variable velocity may be imparted to rotating parts, that it is unnecessary to preface this description of a new system of mechanism by any account of those apparatus which have hitherto been placed before them.

The applications of such mechanism have been chiefly confined to small machinery or to instruments such as speed recorders or integrating machines. This restriction in application is not, however, due to restricted necessity for such mechanism, but to the insufficiency of the devices hitherto made for dealing with large powers.

The apparatus now to be described is, it is thought, applicable for instrumental purposes, or for varying the velocity of rotation of parts of light or heavy machinery.



A leading feature in it is the employment of a hollow cone, mounted concentrically, but ex-axially, upon a spindle with which it revolves, the axis of the cone being inclined from that of the spindle, the direction of the inclination and the plane of the two axes remaining the same while the cone and spindle revolve. This involves a continuous change in the relative positions of any point in the periphery of the cone and of the spindle, or of the distance between any such point and the axis of the spindle.

For this purpose the cone is mounted, so that while it is carried round by and rotates with the spindle, it is free to move in every direction transversely.

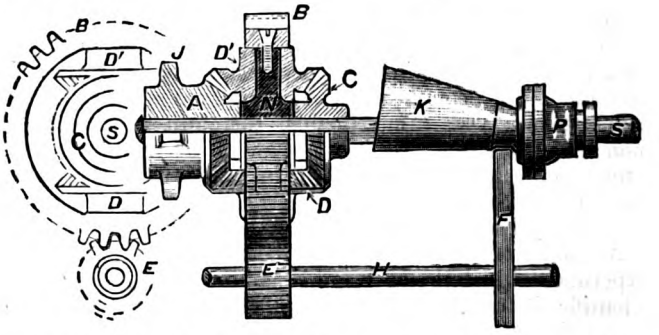
This will be readily seen from diagram Fig. 1, in which A is a section of cone mounted upon a shaft, B, by means of a ball and socket joint, the socket being shown as fixed, but in many cases it would be mounted so as to be capable of longitudinal movement upon the spindle B, and being carried round with it by means of a feather at C, moving in a groove or keyway, D. The cone is carried round by the key E, capable of axial movement, and engaging with the curved slot F, in the ball on the cone.

In the application of these cones for belt driving, the socket would in most cases be fixed upon the shaft, longitudinal movement not being necessary.

Fig. 2, with Fig. 1, shows a pair of such cones, connected by a belt, one cone driving the other, and the velocity of the driven cone depending upon the position of the belt anywhere between A and B, Fig 2. In some practical applications it would be necessary to steady the cone by running the end in a guide or bearing N, Fig. 1, or by guide rollers, but in many cases a roller, as shown at G, would be sufficient. A variable velocity could be communicated, for instance, to a dynamo-electric machine by one of these cones, as shown at Fig. 3, in which A is the cone and B a roller on the end of the spindle.

In the roller and disc devices, and in the known modifications of these for varying velocity and integrating differential velocities, it has been necessary that the area of contact between the roller and disc should be very small, in order that differential velocities in the area of contact should be a minimum, and with the exception of the sphere and roller mechanism of Prof. Hele-Shaw,* this has prevented the adoption in applied mechanics of these types of mechanism for the transmission of any but minute forces.

In the endeavour to overcome this difficulty the author found that the ex-axially mounted cone afforded the means of providing a large area of contact between itself and the periphery of a conical roller or disc, without departing from a purely rolling contact, while for many purposes the differential velocity along the line of contact between the periphery of a short roller or of a disc would not have a materially detrimental effect either in accuracy of result or wear of the surface exposed to rolling and differential rubbing friction.



Variable velocity in recording instruments or in heavy machinery may be imparted by using the cone as a speed-controlling element and not directly for transmission, and of this some illustrations may be given.

In Fig. 4, for instance, any intermediate velocity between the maximum and minimum may be given to the wheel A. The primary shaft is seen at S. Upon this are mounted the cone K, capable of longitudinal movement on the shaft, the externally geared wheel B, the pinion C, and the internally geared wheel A, the last being also provided with teeth at J for conveying motion at the varied velocities, or being in the form of a drum, M, for carrying paper. Gearing with the teeth of the wheel B is the pinion E, which is fixed upon the spindle H of the wheel F, which runs in frictional contact with the cone K. Running upon a stud spindle, G, fixed in the wheel B, is a pinion, D, which gears with the internal teeth of the wheel A and with the pinion C. The wheel F is held by a brake, which is put into or out of gear by the movement of the handle, which changes the position of the cone. As shown in the diagram, the wheel F is not touching the cone. It is fixed when the cone is in the position shown, and therefore the wheel B is held stationary by the pinion E, which is on the same spindle. The action of this gearing will be as follows:—Rotative motion being given to the spindle S and pinion C in the direction of the arrow, Fig. 5, the pinion D will revolve in the opposite direction, and the wheel A will be driven in the same direction as D, the velocity of A being proportional to the relation between the diameters of the pinion C and wheel A. The wheel B, and thereby the spindle of the pinion D,

* Paper read before the British Association at Birmingham.

* *Phil. Trans.*, 1885. Brit. Ass. Reports, 1885.

Digitized by Google

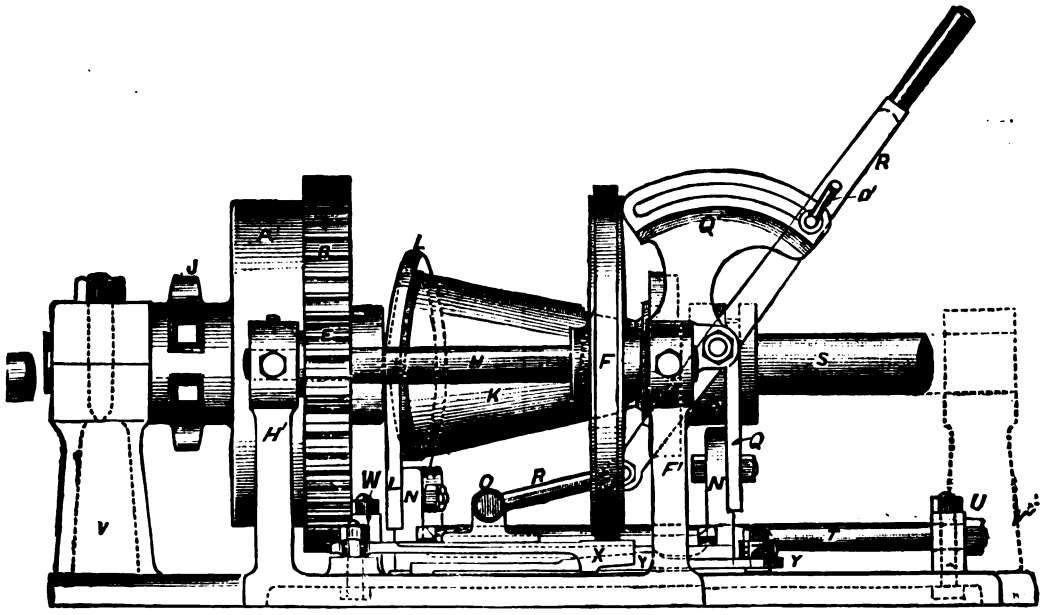
being held fast, the speed of A will be a maximum. Now, if the brake which fixes F be withdrawn and the cone be brought into contact with its periphery, the wheel B will be permitted to rotate in the same direction as C, and at a velocity depending upon the ratio of the diameters of the cones and wheel F, and of the pinion E and wheel B. When the wheel B rotates, the velocity of its rotation is taken from that of A, and the velocity of A will therefore vary in proportion to the larger and smaller diameters of the cone.

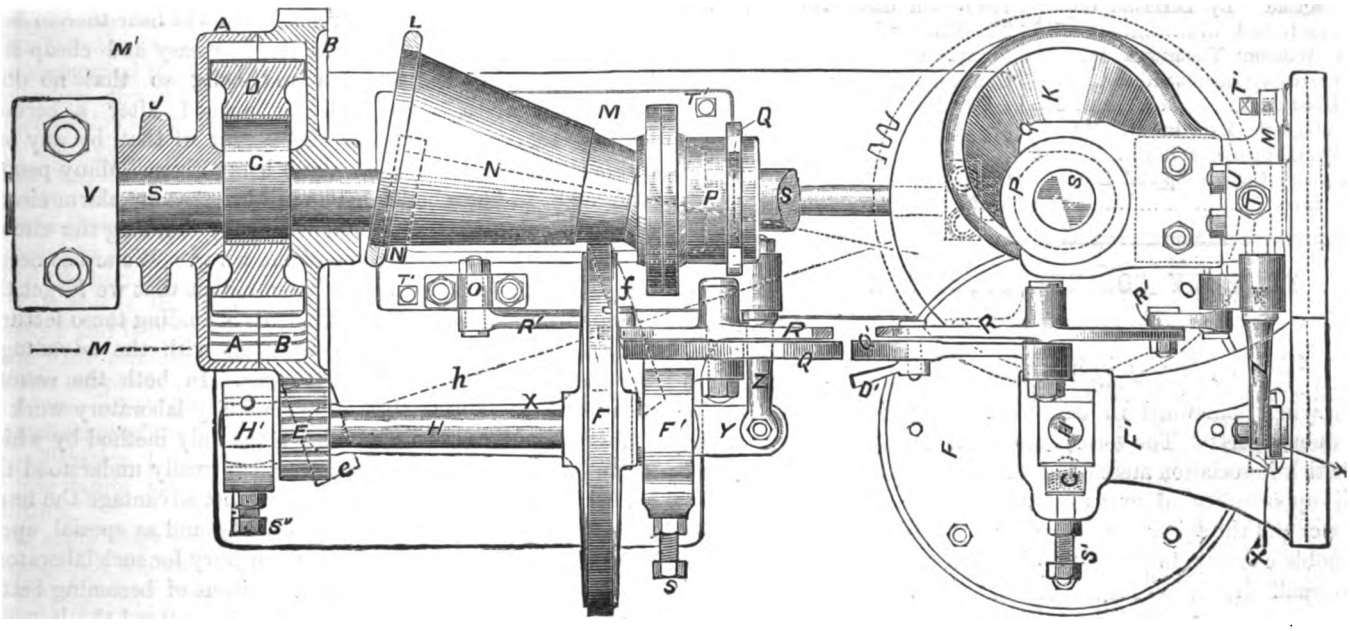
The cone would be moved in the direction of the axis of the spindle upon which it revolves by means of a clutch lever attached to P, and it will be seen that if a pencil be so attached that it moves coincidently with the cone and in contact with paper on M, a curve will be drawn which will vary with the velocity, or lines will be drawn which will show relative velocity.

Instead of using a brake to fix the wheel F, the relative diameters of the wheels and cone may be such that the maximum required velocity of wheel A may be obtained with wheel F in contact with the smallest part of the cone. Inasmuch as the work done on E by the permissive rotation of the wheel B is given up to the cone K by the wheel F there is no loss of work, as there would be if B were permissively rotative by allowing it to slip in a brake.

It will be seen that within the width of the edge of the periphery of the cylindrical disc F there will differential velocity, due to the different diameters of as much of the cone as is included in that width, and the velocity of F will probably be a mean between the maximum and minimum within that width. To avoid the wear and inaccuracy that this would cause in heavy machinery a conical disc, as shown at N, Fig. 4, would be employed.

The possible modifications of this, which may be termed an epicyconoidal mechanism, are almost as numerous as the multifarious applications which are obvious; but it is not necessary here to mention more than the epicycloidal mechanism shown at Figs. 6 and 7, and the bevel or mitre compensating gear used for many purposes.





THE FROST INDICATOR.—In California large numbers of vineyards are fitted with electric bell circuits so arranged as to be closed by a mercury thermometer contact when the temperature falls to zero. By this means the proprietors are warned when their vines are in danger from frost, and many thousands of tons of grapes are annually saved from destruction.

FINSBURY COLLEGE SPECIAL LECTURES.

The great scientific gathering of the year draws attention to the fact that the season has so far advanced that holidays will soon give place to renewed labour. Professors and scholars are hurrying homeward to take their respective shares in the arduous work. The former have met in large numbers at the British Association meeting at Birmingham, and thus have had an opportunity of exchanging opinions, discussing the successes and the failures of the year. Birmingham has long set a noble example in the cause of education, and may point with no small degree of pride to such institutions as the Midland Institute and the Mason's Science College. The latter is the more recent foundation, and is almost entirely due to the munificence of the late Sir Josiah Mason. The primary object of the College is the promulgation of scientific knowledge with a special tendency to the applications of science in practice. Foundations with a somewhat similar object are to be found at Newcastle, Leeds, Nottingham, Manchester, Liverpool, Bristol, and in the City and Guilds Institute in London. All these institutions may be properly viewed as the germs of future universities in which the study of languages takes the second and not the first place. No doubt we must trace the development of broader educational views partly to the various Exhibitions held since 1851, partly to the increased facilities for travel, and hence for wider observation, and last, though not least, to the action taken by the scientific press. It has become plain that teaching which does not forget the future occupation of the taught is as valuable educationally as the curiculum devised by the most ardent supporter of the dead languages. We are of the opinion that the system pursued in these modern universities is indeed better, in that the teaching is more or less applicable to the immediate surroundings of the scholars, increasing, as it does, their knowledge of Nature and Nature's laws, and leading them to investigate phenomena which under the older conditions would remain without interest. We have classed the City and Guilds Institute with the other institutions named, but it is scarcely a fair classification; its work, as originally framed, was a development of that of the Science Department at South Kensington.

The special object of this article is to call attention to a branch of work at the Finsbury College which has, so to speak, brought a new class within the range of its teaching power, and so far has proved eminently successful. The new departure is to be found in the courses of "Special Lectures." The majority of students attending these special lectures were found last year to differ entirely from those attending the other lectures. They were men actually engaged in the work about which the special lectures were intended to give information. Two of the special courses to be given this year are "Electrical," and are given by the principal of the College, Prof. S. P. Thompson. That on "Electric Bells" consists of six lectures, commencing October 7; that on "Electro-Deposition of Metals" commences on November 18. Both these courses are intended to appeal to practical men, and so far as we can judge from the syllabus they will do so. The former course is suited to a much wider audience than the latter, and it would be well if the London householder could be brought to the lecture room. He will hear therein how simple it is to protect his house, how easy and cheap it is to arrange electrical circuits and bells, so that no door or window of a house can be opened after a certain hour by an outsider, or, for the matter of that, by any one inside the house, without an alarm being given. Many people who ought to know better have the idea that an alarm circuit of this kind could be rendered useless by breaking the circuit—for example, by cutting one of the wires. We are so accustomed in England to use the open circuit that we forget the value of a closed circuit, and students attending these lectures will no doubt be made fully conversant with the advantages and the disadvantages of both systems. In both the courses mentioned we notice that supplementary laboratory work is connected with the course. This is the only method by which it can be ascertained if his audience has really understood the lecturer. In order to obtain the greatest advantage the hand as well as the ear must be educated; and as special apparatus is we understand provided at Finsbury for such laboratory practice, we can recommend those desirous of becoming better acquainted with the subjects mentioned to attend the lectures. The proprietors of large, well-organised electro-depositing works may probably fail to see the value of such a course of lectures as the one referred to; but when we consider there are hundreds, if not thousands, of places, where attempts at plating or other form of electro-deposition are made on a very small scale, and in which failure is more often the result than success, we shall be better able to value the information given during such a course. A few hints as to the necessity of cleanliness, and how to obtain it, the strength of current, the time required for a particular class of work, the strength of various solutions, all well known in large works, are little appreciated by the class of workers for whose benefit these lectures are intended, till pointed out and impressed upon them by a

Digitized by Google

long series of failures. Forewarned is forearmed, and hundreds of these humble workers will be glad to receive instruction that will enable them to guard against failure.

CORRESPONDENCE.

THE ELECTRIC LIGHT IN SPAIN.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of 27th August, under the heading of "Notes," I notice the following paragraph:—"Where are the Electric Light Companies?" Your correspondent states that the only alternative offered to the Spaniards with regard to illumination is gas. This is certainly an error, as there are at least four different electric light companies in this country. The people, however, know but little of incandescent lighting, and seem afraid to embark in the speculation. The following proposition was made to the writer some short time back by one of the principal municipalities in Spain, viz., to pay the whole amount of contract four years after date of starting the lighting, and if a breakdown were to occur in said time of four years, the whole claim to be forfeited. You will see from this that it is not so easy to push electric lighting in Spain as your correspondent imagines.—Yours, &c.,

JAMES A. SELBY.

Anglo-American Brush Company, Bilbao, Sept. 4.

THE TELEPHONE SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If there has been an invention within the last twenty years that has shown itself especially capable of large development and application to great usefulness and convenience that invention is undoubtedly the telephone.

When an accurate and quick working system has been offered to the business man in any of our towns, he has long ago recognised it as a means of saving both time and money; but when through some fault in either the subscriber's instrument or the exchange apparatus, or else inattention on the part of any of the operators, any one of these conditions of success (accuracy and speed) disappear, the service then becomes to the subscriber "more nuisance than it is worth;" and hence we have loud complaints against the company, and also find a serious falling off in the number of subscribers.

That this is the case we have, unfortunately, too many proofs; and it is through seeing a "Note" in your last week's issue with reference to the unsatisfactory condition of the Lisbon telephone system that I address these few lines to you.

As one who has had considerable experience in both the manufacture of the instruments and the working of the telephone system, I venture to assert, Sir, that fully 60 per cent. of the faults and irregularities which now occur are preventible.

In some cases a system of false economy on the part of the managers is the main cause. So-called inspectors are engaged at a low rate of wages, many of whom have acquired but the most elementary ideas of the laws of electricity and of the working of the various instruments which they may be called upon to inspect. It may seem to be an exaggerated statement, but I can vouch for the truth of it, that the bell of an instrument has been reported "out of order" by an inspector when the real fault has been "dead earth on line." In many cases he has not sufficient knowledge of the instrument to find the fault, and feels that he must report something, and the consequence is many instruments are sent in to be repaired described as having some fault which upon examination is found not to exist at all. I am afraid that I may seem harsh upon our friends the inspectors, but such is not my idea. The fault is really in those being engaged who are incompetent to do the work. The manager cannot expect for the low money which he offers to obtain the services of a thoroughly competent man.

Then, again, there is not always such a rig'd system of careful inspection as is absolutely necessary that there should be. By this I mean an inspection to prevent faults in batteries, contacts, and connections.

The exchanges also require, I am afraid, in many cases more systematic management to enforce instant attention on the part of the operators.

It may not be a panacea for every evil, but in the great majority of cases good management will be found to be the remedy.

I could name a district in England where, to within a short time since, the cause of the telephone was rapidly declining; but since an energetic, qualified manager has taken charge there things are improving in every way, and we hear from time to time of the rapid and wide extension of the system in the towns of that district.

Apologising for trespassing so largely on your valuable space. Yours, &c., TELEPHONE.

THE REGENT BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As a practical user of electric light by primary batteries, I have read with much interest an account of Macquay's battery—now called the Regent battery. I do not know if this battery has been tested further than the exhibition of *twenty-four* small cells, which are said to have run a 40-volt lamp with a light of *about* 12 candles for six hours!

I observe that many battery makers employ small cells with somewhat intricate fittings and connections, which mean trouble to the attendant after the run is over.

Batteries, of course, are made small to suit certain purchasers, but my experience tells me that the larger the cells are *in reason*, the better work they perform, and the more light they give.

For the past three years I have lighted my principal rooms and part of the parish church by primary batteries of my own making, although in possession of both steam and water-power. My experience with these batteries is such that I can confidently recommend them. They certainly yield a beautiful, luxurious, and perfectly steady light.

I have not found the cost excessive or the management irksome.

The wear and tear of the zincs appear to be in proportion to the light given. The use of an alloy is no novelty, but I think if it is used more cells are necessary. My last "run" with *one charge* of Sullivan's chromic acid mixture, which the firm are good enough to prepare me, has lasted for 54 hours, and the battery is still possessed of sufficient power to run sundry reading lamps without being enough to light the rooms.

The battery consists of 12 cells, and supplies currents for six 8 candle-power 16-volt lamps (one under water in an ornamental aquarium on the dining table) for the dining room, two 20-volt 12 candle power lamps in the hall, thirteen 5 candle-power 10-volt lamps in the drawing room, and four 8 candle power 16-volt lamps in the orangery.

The lamps are turned on where required. Naturally towards the end of the run the battery gets somewhat weaker, and will not light so many lamps at one time, but its constancy is remarkable. The cells are as simple as they can be, and any man or boy can attend to them. As I hope to show some of these cells in town later on in the season, I will not trouble you with a description.

As far as my knowledge goes, I think it is cheaper to use primary batteries alone rather than in connection with secondary, though much may be done by a judicious combination of the two.

Secondary batteries are apt to go wrong when not in constant use. With apologies for troubling you with this.—Yours, &c., CHARLES PENRUDDOCKE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In Dr. Fleming's report on the Regent battery it is stated that "40 watt hours can be obtained at the cost of 1d.," but no particulars are given as to how this cost is arrived at.

Digitized by Google

Perhaps Dr. Fleming will kindly inform us if it includes the waste of zinc and charge left after the E.M.F. and current have been too much reduced to render the remaining latent energy of any practical value, or if it is based simply on the rate of consumption during the time the cells were working to their best advantage.

There is always a difficulty in arriving at the true merits of a primary cell, and I think a few simple questions properly answered would be of more value than the series of isolated facts generally given.

If, for instance, the following questions were duly replied to, we should be in a position to judge the comparative excellence of any primary cell.

1st. What is the working cost in watt hours per 1d. ? The price to include total charge, and the cell to work till either its E.M.F. or current has been reduced by a certain percentage of its original value (the percentage to be taken at, say, 10 per cent., or any other convenient figure to be agreed upon).

2nd. What has been the output in watt hours whilst the cell has been working under the conditions stated above ?

3rd. What are the total number of hours the cell has been working ? and what has been the mean current during that time ?

4th. Has the cell been working continuously ? and if not, what were the successive periods of rest and work ?

5th. What is the ratio between weight of cell and output as above ?

6th. Are any fumes emitted ? and if so, what are they ?

7th. What is the cost of cell, including charge ?—Yours, &c.,

N. G. THOMPSON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : My attention has been called to a statement in the prospectus of the Regent Portable Electric Light Company to the effect that "numerous batteries have been introduced to the public, and none of them are of any practical commercial use."

Will you be so good as to allow me to state that "The Standard Electric Light and Power Company" has been maintaining numerous installations in London and elsewhere of from 10 to 35 lamps each at a fixed price per lamp per annum for nearly a year past. In one instance, where there are 25 lamps, the light has been running continuously for over ten months, and during the last five months the gas has been completely cut off, which is the best evidence of its excellence and reliability. The recharging of the batteries, which is required at intervals of from ten days to two months, according to the amount of light used, is entirely undertaken by this company and carried out on a thoroughly organised system, so that the consumer has merely to turn the light on and off as he has been accustomed to do with gas. The results which we have achieved are so satisfactory both to ourselves and to our customers that we are now making arrangements for extending the business in London on a very large scale.—Yours, &c.

C. A. REEVE, Secretary.

8, Great Queen-street, Westminster, S.W., Sept. 8, 1886.

THE BRITISH ASSOCIATION MEETING.

PRESIDENTIAL ADDRESS.

(Continued from page 350.)

Keeping in view these general conclusions, let us now turn to their bearing on the origin and history of the North Atlantic.

Though the Atlantic is a deep ocean, its basin does not constitute so much a depression of the crust of the earth as a flattening of it, and this, as recent soundings have shown, with a slight ridge or elevation along its middle, and banks or terraces fringing the edges, so that its form is not so much that of a basin as that of the shallow plate with its middle a little raised. Its true permanent margins are composed of portions of the over-crust folded, ridged up and crushed, as if it be lateral pressure emanating from the sea itself. We cannot, for example, look at a geological map of America without perceiving that the Appalachian ridges, which intervene between the Atlantic and the St. Lawrence valley, have been driven bodily back by a force acting from the east, and that they have resisted this pressure only where, as in the Gulf of St. Lawrence and the Catskill region of New York, they have been protected by outlying masses of very old rocks, as, for example, by that of the island of Newfoundland and that of the Adirondack Mountains. The admirable work begun by my friend and fellow-student Professor James Nicol, followed up by Hicks, Lapworth, and others, and now, after long controversy, fully confirmed by the recent observations of the geological survey of Scotland, has shown the most intense action of the same kind on the east side of the ocean in the Scottish highlands ; and the more widely distributed Eozoic rocks of Scandinavia may be appealed to in further evidence of this.*

If we now inquire as to the case of the Atlantic depression, we must go back to a time when the areas occupied by the Atlantic and its bounding coasts were parts of a shoreless sea in which the earliest gneisses or stratified granites of the Laurentian age were being laid down in vastly extended beds. These ancient crystalline rocks have been the subject of much discussion and controversy, and as they constitute the lowest and probably the firmest part of the Atlantic sea-bed, it is necessary to inquire as to their origin and history. Dr. Bonney, the late President of the Geological Society, in his anniversary address, and Dr. Sterry Hunt, in an elaborate paper communicated to the Royal Society of Canada, have ably summed up the hypotheses as to the origin of the oldest Laurentian beds. At the basis of these hypotheses lies the admission that the immensely thick beds of orthoclase gneiss, which are the oldest stratified rocks known to us, are substantially the same in composition with the upper or siliceous magma or layer of the under-crust. They are, in short, its materials either in their primitive condition or merely rearranged. One theory considers them as original products of cooling, owing their lamination merely to the successive stages of the process. Another view refers them to the waste and rearrangement of the materials of a previously massive granite. Still another holds that all our granites really arise from the fusion of old gneisses of originally aqueous origin, while a fourth refers the gneisses themselves to molecular changes effected in granite by pressure. These several views, in so far as they relate to the oldest or fundamental Laurentian gneiss, may be arranged under the following heads :—(1) *Endoplutonic*, or that which regards all the old gneisses as molten rocks cooled from without inward in successive layers.† (2) *Exoplutonic*, or that which considers them as made up of matter ejected from below the upper-crust in the manner of volcanic action.‡ (3) *Metamorphic*, which supposes the old gneisses to arise from the crystallisation of detrital matter spread over the sea bottom, and either igneous or derived from the decay of igneous rocks.§ (4) *Chaotic* or *Thermo-Chaotic*, or the theory of deposit from the turbid waters of a primeval ocean either with or without the aid of heat. In one form this was the old theory of Werner.‖ (5) *Crenitic* or Hydro-thermic, which supposes the action of heated waters penetrating below the crust to be constantly bringing up to the surface mineral matters in solution and depositing these so as to form felspathic and other rocks.¶

It will be observed, in regard to these theories, that none of them supposes that the old gneiss is an ordinary sediment, but that all regard it as formed in exceptional circumstances, these circumstances being the absence of land and of sub-aerial decay of rock, and the presence wholly or principally of the material of the upper surface of the recently hardened crust. This being granted, the question arises, Ought we not to combine these several theories and to believe that the cooling crust has hardened in successive layers from without inward ; that at the same time fissures were locally discharging igneous matter to the surface ; that matter held in suspension in the ocean and matter held in solution by heated waters rising from beneath the outer crust were mingling their materials in the deposits of the primitive ocean ? It would seem that the combination of all these agencies may safely be invoked as causes of the pre-Atlantic deposits. This is the eclectic position which I endeavoured to maintain in my address before the Minneapolis Meeting of the American Association in 1883, and which I still hold to be in every way probable.

A word here as to the metamorphism, a theory which, like many others, has been first run to death and then discredited, but which to the moderate

---

* Address to the Geological Section, by Prof. Judd, Aberdeen Meeting, 1885. According to Rogers, the Crumpling of the Appalachians has reduced a breadth of 158 miles to about 60.

† Naumann, Phillips, Durocher, M'Farlane, &c.

‡ Clarence King, Tornebohm, Marr, &c.

§ Lyell, Kopp, Reusch, Judd, &c.

‖ Scrope, Delabeche, Daubrée.

¶ Hunt, *loc. sit.* The following is Dr. Hunt's summary statement of this theory :—"The globe consolidating at the centre left, it is conceived, a superficial layer of basic silicates, which has yielded all the fixed elements of the earth's crust. This layer formed the first land and the floor of the primeval sea, the acid waters of which, permeating and partially decomposing it, became thereby chemically neutralised. This last cooled layer, mechanically disintegrated, saturated with water, and heated by the central mass, was the source of mineral springs, holding in solution the silicates which built up the ancient gneisses and similar rocks. Granitic veins and zeolites are due to survivals of the process which generated the gneissic rocks. The hypothesis of their formation from materials brought to the surface by mineral springs from the primitive basic layer affords, it is claimed, the elements of a complete and intelligible explanation of the origin of the Eozoic rocks. This upward lixiviation of the primitive mass, and the deposition over it of an acidic granite like rock, would leave below a highly basic material, and the division of the mass thus established would correspond to that of the trachytic and doleritic magmas, which have been conjectured to be the sources of two great types of eruptive rocks. Inasmuch, however, as according to the present hypothesis these two layers of basic and acidic matters are the results of aqueous action, and not of an original separation in a plutonic mass, as imagined by Phillips and Durocher, their composition would be subject to many local variations."

Digitized by Google

degree in which it was originally held by Lyell is still valid. Nothing can be more certain than that the composition of the Laurentian gneisses forbids us to suppose that they can be ordinary sediments metamorphosed. They are rocks peculiar in their origin, and not paralleled unless exceptionally in later times. On the other hand, they have undoubtedly experienced very important changes, more especially as to crystallisation, the state of combination of their ingredients, and the development of disseminated minerals,* and while this may in part be attributed to the mechanical pressure to which they have been subjected, it requires also the action of hydrothermic agencies. Any theory which fails to invoke both of these kinds of force must necessarily be partial and imperfect.

But all metamorphic rocks are not of the same character with the gneisses of the Lower Laurentian. Even in the Middle and Upper Laurentian we have metamorphic rocks, *e g.*, quartzite and limestone, which must originally have been ordinary aqueous deposits. Still more in the succeeding Huronian and its associated series of beds, and in the Lower Palæozoic, local metamorphic change has been undergone by rocks quite similar to those which in their unaltered state constitute regular sedimentary deposits. In the case of these later rocks it is to be borne in mind that, while some may have been of volcanic origin, others may have been sediments rich in undecomposed fragments of silicates. It is a mistake to suppose that the ordinary decay of stratified siliceous rocks is a process of kaolinisation so perfect as to eliminate all alkaline matters. On the contrary, the fact, which Judd has recently well illustrated in the case of the mud of the Nile, applies to a great number of similar deposits in all parts of the world, and shows that the finest sediments have not always been so completely lixiviated as to be destitute of the basic matters necessary for their conversion into gneiss, mica-schist, and similar rocks when the necessary agencies of metamorphism are applied to them, and this quite independently of any extraneous matters introduced into them by water or otherwise. Still it must be steadily kept in view that many of the old pre-Cambrian crystalline rocks must have been different originally from those succeeding them, and that consequently these last, even when metamorphosed, present different characters.

I may remark here that, though a palæontologist rather than a lithologist, it gives me great pleasure to find so much attention now given in this country to the old crystalline rocks, and to their study microscopically and chemically as well as in the field, a work in which Sorby and Allport were pioneers. As a pupil of the late Professor Jameson, of Edinburgh, my own attention was early attracted to the study of minerals and rocks as the stable foundations of geological science ; and as far back as 1841 I had learnt of the late Mr. Sanderson, of Edinburgh, who worked at Nicol's sections,† how to slice rocks and fossils ; and since that time I have been in the habit of examining everything with the microscope. The modern developments in this direction are therefore very gratifying to me, even though, as is natural, they may sometimes appear to be pushed too far or their value over-estimated.

That these old gneisses were deposited not only in what is now the bed of the Atlantic, but also on the great continental areas of America and Europe, anyone who considers the wide extent of these rocks represented on the map recently published by Professor Hull can readily understand.‡ It is true that Hull supposes that the basin of the Atlantic itself may have been land at this time, but there is no evidence of this, more especially as the material of the gneiss could not have been detritus derived from sub-ærial decay of rock.

Let us suppose, then, the floor of old ocean covered with a flat pavement of gneiss, or of that material which is now gneiss, the next question is how and when did this original bed become converted into sea and land. Here we have some things certain, others most debatable. That the cooling mass, especially if it was sending out volumes of softened rocky material, either in the exoplutonic or in the crenitic way, and piling this on the surface, must soon become too small for its shell, is apparent ; but when and where would the collapse, crushing, and wrinkling inevitable from this cause begin ? Where they did begin is indicated by the lines of mountain chains which traverse the Laurentian districts ; but the reason why is less apparent. The more or less unequal cooling, hardening and conductive power of the outer crust we may readily assume. The driftage unequally of water-borne detritus to the south-west by the bottom currents of the sea is another cause, and, as we shall soon see, most effective. Still another is the greater cooling and hardening of the crust in the polar regions, and the tendency to collapse of the equatorial protuberance from the slackening of the earth's rotation. Besides these the internal tides of the earth's substance at the times of solstice would exert an oblique pulling force on the crust, which might tend to crack it along diagonal lines. From whichever of these causes, or the combination of the whole, we know that within the Laurentian time folded portions of the earth's crust began to rise above the general surface in broad belts running from N.E. to S.W., and from N.W. to S.E., where the older mountains of Eastern America and Western Europe now stand, and that the subsidence of the oceanic areas allowed by this crumpling of the crust permitted other areas on both sides of what is now the Atlantic to form limited table-lands.§ This was the beginning of a process repeated again and again in subsequent times, and which began in the Middle Laurentian, when for the first time we find beds of quartzite, limestone, and iron ore, and graphitic beds, indicating that there was already land and water, and that the sea, and perhaps the land, swarmed with animal and plant life of forms unknown to us, for the most part, now. Independently of the questions as to the animal nature of Eozoon, I hold that we know, as certainly as we can know anything inferentially, the existence of these primitive forms of life. If I were to conjecture what were the early forms of plant and animal life, I would suppose that just as in the Palæozoic the acrogens culminated in gigantic and complex forest trees, so in the Laurentian the algæ, the lichens, and the mosses grew to dimensions and assumed complexity of structure unexampled in later times, and that in the sea the humbler forms of Protozoa and Hydrozoa were the dominant types, but in gigantic and complex forms. The land of this period was probably limited, for the most part, to high latitudes, and its aspect, though more rugged and abrupt, and of greater elevation, must have been of that character which we still see in the Laurentian hills. The distribution of this ancient land is indicated by the long lines of old Laurentian rock extending from the Labrador coast and the north shore of the St. Lawrence, and along the eastern slopes of the Appalachians in America, and the like rocks of the Hebrides, the Western Highlands, and the Scandinavian Mountains. A small but interesting remnant is that in the Malvern Hills, so well described by Holl. It will be well to note here and to fix on our minds that these ancient ridges of Eastern America and Western Europe have been greatly denuded and wasted since Laurentian times, and that it is along their eastern sides that the greatest sedimentary accumulations have been deposited.

From this time dates the introduction of that dominance of existing causes which forms the basis of uniformitarianism in geology, and which had to go on with various and great modifications of detail, through the successive stages of the geological history, till the land and water of the northern hemisphere attained to their present complex structure.

So soon as we have a circumpolar belt or patches of Eozoic* land and ridges running southward from it, we enter on new and more complicated methods of growth of the continents and seas. Here we are indebted to Le Conte for clearly pointing out that our original Eozoic tracts of continent were in the earliest times areas of deposition, and that the first elevations of land out of the primeval ocean must have differed in important points from all that have succeeded them ; but they were equally amenable to the ordinary laws of denudation. Portions of these oldest crystalline rocks, raised out of the protecting water, were now eroded by atmospheric agents, and especially by the carbonic acid then existing in the atmosphere perhaps more abundantly than at present, under whose influence the hardest of the gneissic rocks gradually decay. The Arctic lands were subjected in addition to the powerful mechanical force of frost and thaw. Thus every shower of rain and every swollen stream would carry into the sea the products of the waste of land, sorting them into fine clays and coarser sands ; and the cold currents which cling to the ocean bottom, now determined in their courses, not merely by the earth's rotation, but also by the lines of folding on both sides of the Atlantic, would carry south-westward, and pile up in marginal banks of great thickness, the *débris* produced from the rapid waste of the land already existing in the Arctic regions. The Atlantic, opening widely to the north, and having large rivers pouring into it, was especially the ocean characterised, as time advanced, by the prevalence of these phenomena. Thus throughout the geological history it has happened that, while the middle of the Atlantic has received merely organic deposits of shells of Foraminifera and similar organisms, and this probably only to a small amount, its margins have had piled upon them beds of detritus of immense thickness. Prof. Hall, of Albany, was the first geologist who pointed out the vast cosmic importance of these deposits, and that the mountains of both sides of the Atlantic owe their origin to these great lines of deposition, along with the fact, afterwards more fully insisted on by Rogers, that the portions of the crust which received these masses of *débris* became thereby weighted down and softened, and were more liable than other parts to lateral crushing †

Thus in the later Eozoic and early Palæozoic times, which succeeded the first foldings of the oldest Laurentian, great ridges were thrown up, along the edges of which were beds of limestone, and on their summits and sides thick masses of ejected igneous rocks. In the bed of the central Atlantic there are no such accumulations. It must have been a flat, or slightly ridged, plate of the ancient gneiss, hard and resisting, though perhaps with a few cracks, through which igneous matter welled up, as in Iceland and the Azores in more modern times. In this condition of things we have causes tending to perpetuate and extend the distinctions of ocean and continent, mountain and plain, already begun ; and of these we may more especially note the continued subsidence of the areas of greatest marine deposition. This has long attracted attention, and affords very convincing evidence of the connection of sedimentary deposit as a cause with the subsidence of the crust.

We are indebted to a French physicist, M. Faye,‡ for an important suggestion on this subject. It is that the sediment accumulated along

* The first of these is what Bonney has called *Metastasis*. The second and third come under the name *Metacrasis*. *Methylosis*, or change of substance, is altogether exceptional, and not to be credited except on the best evidence, or in cases where volatile matters have been expelled, as in the change of Hematite into Magnetite, or of bituminous coal into anthracite.

† And I believe at Witham's also. ‡ *Trans.* Royal Irish Academy.

§ Daubrée's curious experiments on the contraction of caoutchouc balloons, partially hardened by coating with varnish, show how small inequalities of the crust, from whatever cause arising, might affect the formation of wrinkles, and also that transverse as well as longitudinal wrinkling might occur.

* Or Archæan, or pre-Cambrian, if these terms are preferred.

† The connection of accumulation with subsidence was always a familiar consideration with geologists ; but Hall seems to have been the first to state its true significance as a geological factor, and to see that those portions of the crust which are weighted down by great detrital accumulations are necessarily those which, in succeeding movements, were elevated into mountains. Other American geologists, as Dana, Rogers, Hunt, Le Conte, Crosby, &c., have followed up Hall's primary suggestion, and in England, Hicks, Fisher, Starkie Gardiner, Hull, and others, have brought it under notice, and it enters into the great generalisations of Lyel on these subjects.

‡ *Revue Scientifique*, 1886.

Digitized by Google

the shores of the ocean presented an obstacle to radiation, and consequently to cooling of the crust, while the ocean floor, unprotected and unweighted, and constantly bathed with currents of cold water, having great power of convection of heat, would be more rapidly cooled, and so would become thicker and stronger. This suggestion is complimentary to the theory of Prof. Hall, that the areas of greatest deposit on the margins of the ocean are necessarily those of greatest folding and consequent elevation. We have thus a hard, thick, resisting ocean-bottom which, as it settles down toward the interior, under the influence of gravity, squeezes upward and folds and plicates all the soft sediments deposited on its edges. The Atlantic area is almost an unbroken cake of this kind. The Pacific area has cracked in many places, allowing the interior fluid matter to ooze out in volcanic ejections.

It may be said that all this supposes a permanent continuance of the ocean-basins, whereas many geologists postulate a mid-Atlantic continent* to give the thick masses of detritus found in the older formations both in Eastern America and Western Europe, and which thin off in proceeding into the interior of both continents. I prefer, with Hall, to consider these belts of sediment as in the main the deposits of northern currents, and derived from Arctic land, and that, like the great banks of the American coast at the present day, which are being built up by the present Arctic current, they had little to do with any direct drainage from the adjacent shore. We need not deny, however, that such ridges of land as existed along the Atlantic margins were contributing their quota of river-borne material, just as on a still greater scale the Amazon and Mississippi are doing now, and this especially on the sides towards the present continental plateaus, though the greater part must have been derived from the wide tracts of Laurentian land within the Arctic Circle or near to it. It is further obvious that the ordinary reasoning respecting the necessity of continental areas in the present ocean basins would actually oblige us to suppose that the whole of the oceans and continents had repeatedly changed places.

(To be continued.)

THE BLACKPOOL ELECTRIC TRAMWAY.†

BY M. HOLROYD SMITH.

Without treating generally of electricity as a locomotive power, the object of the present paper is to deal with the special difficulties and conditions arising when it is used for propelling street tramcars. If the cars were running upon a track reserved exclusively for their use, the work would be simple; but in a street other vehicular traffic has to be considered, and not only have numerous Board of Trade conditions to be complied with, but local authorities and householders have also to be consulted and satisfied.

General Conditions.—The general conditions are three: firstly, safety to the public; secondly, efficiency; and thirdly, economy. With some reservations, the first condition may be accomplished by the employment of secondary batteries, which are destined to play an important part in the progressive development of electricity for tractive purposes; but it must be admitted they occupy only a

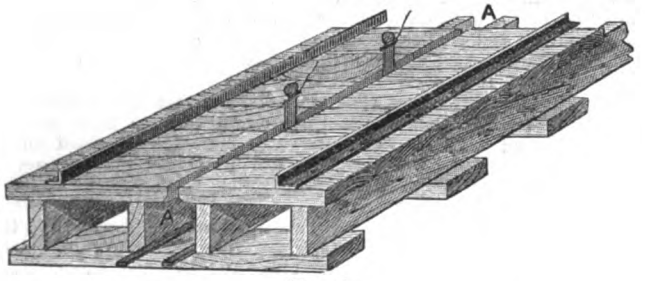

FIG. 1.

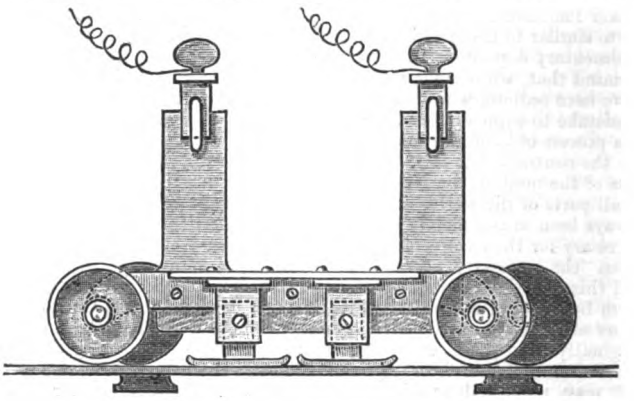
secondary place, when it is shown that electricity can be used direct, and can then fulfil not only the first condition, but the other two also. The employment of the rails as lead and return conductors is out of the question; for in large installations it must fail in regard to all three conditions. Side fence-rails or overhead conductors, though fulfilling the conditions of efficiency and economy, are inadmissible for street purposes. There seems, therefore, but one course, and that is to place the electric conductors underground. This position involves many difficulties, some on first consideration apparently insurmountable.

Before the construction of the Blackpool electric tramway, many progressive experiments were made; they have already been described and published elsewhere, and therefore it will not be necessary to give a detailed account of them here; a brief reference to two will probably be sufficient. The first track laid was only 18in. gauge, and was for convenience made of wood. It is shown in Fig. 1. The channel A contained two copper strips, one of them being the lead and the other the return conductor. The collector trolly which ran upon them is now exhibited, and is shown in Fig. 2. The employment of separate conductors within the channel A, though possessing some advantages, is open to many objections. The chief of these is the cost, because each strip must be of large enough section to carry the whole current. The next objection is risky insulation; and the third is difficulty of dealing with points and crossings. Separate conductors were therefore



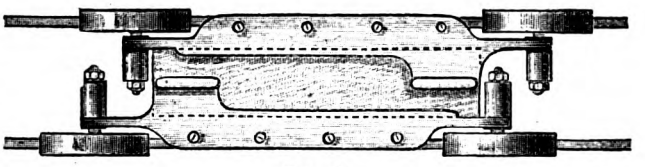


FIG. 2.

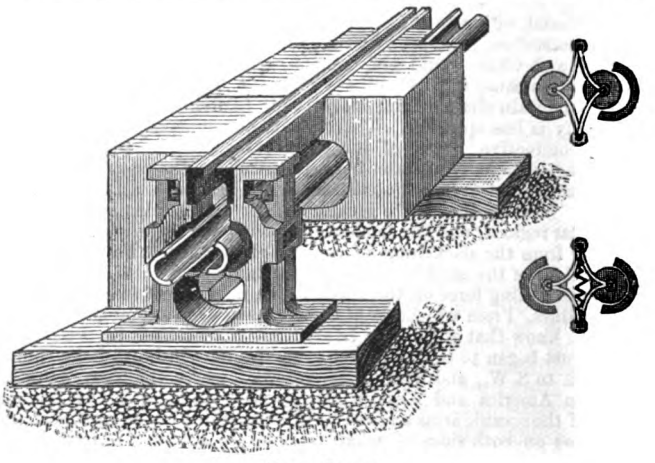
abandoned, and many modifications were designed, including a tubular conductor with an expanding shuttle travelling within it, an arrangement admirably suited for single lines, but inapplicable for one with branches, loops, and crossings.

The first full-gauge line was laid in a field near Manchester, and was 110 yards long. A section of the channel is shown in Fig. 3, and models are exhibited. Here the conductor consisted of two half tubes, held in insulating supports; and the collector, shown in Fig. 4, was composed of two spirally fluted rollers, so held that they



FIGS. 3 & 4.

expanded and constantly pressed against the inside of the two half tubes, and maintained good contact with them, and by revolving cleared away any accidental obstruction that might be within the hollow open tubes. This action was all that could be desired; but the objection to the method was that, in attempting to clear the channel, mud and dirt were liable to be piled against the iron chair and conductor, thereby spoiling the insulation; and when once so piled, cleansing was a difficult and expensive process.

Requirements.—The conditions presenting themselves for solution are numerous, and may be classed as follows, according as they pertain to the conductors, to the motor, or to other general matters:—

* Among American geologists, Dana and Le Conte, though from somewhat different premises, maintain continental permanence. Crosby has argued on the other side. In Britain, Hull has elaborated the idea of interchange of oceanic and continental areas in his memoir in *Trans.* Dublin Society, and in his work entitled "The Physical History of the British Islands." Godwin-Austin argues powerfully for the permanence of the Atlantic basin, "Q. J. Geol. Society," Vol. XII., p. 42. Mellard Reade ably advocates the theory of mutation. The two views require, in my judgment, to be combined.

† Paper read before the British Association at Birmingham. This paper was originally prepared for the Institute of Mechanical Engineers, to which body Mr. Smith expressed his thanks for their aid in its preparation.

Digitized by Google

Class A.—Conditions pertaining to the Conductors.

1. Protected electric conductors, so arranged that constant contact can be made and maintained, and yet not liable to damage.
2. Good and reliable insulation, free from fouling, and renewable in case of failure.
3. Facility for inspecting the whole length of the channel, if necessary.
4. Ready means of regularly cleansing the channel, removing the ordinary street dirt, or any unusual accumulation.
5. Provision for working points and crossings for pass-byes and branches, without short-circuiting or failing to make contact.

Class B.—Conditions pertaining to the Collector.

6. Provision for making and maintaining contact between the motor on the car and the conductors within the channel.
7. Avoidance of damage, either electrical or mechanical, should the collector become blocked.
8. A construction of collector that will preserve its insulation and take the points of the turn-outs without fouling them.

Class C.—Conditions pertaining to the Motor.

9. A design and construction of electric motor, capable of withstanding the sudden and severe strains to which it will be subjected in working.
10. Gearing between the motor and the car-axles that shall work as smoothly and silently as possible, and with little loss in transmission.

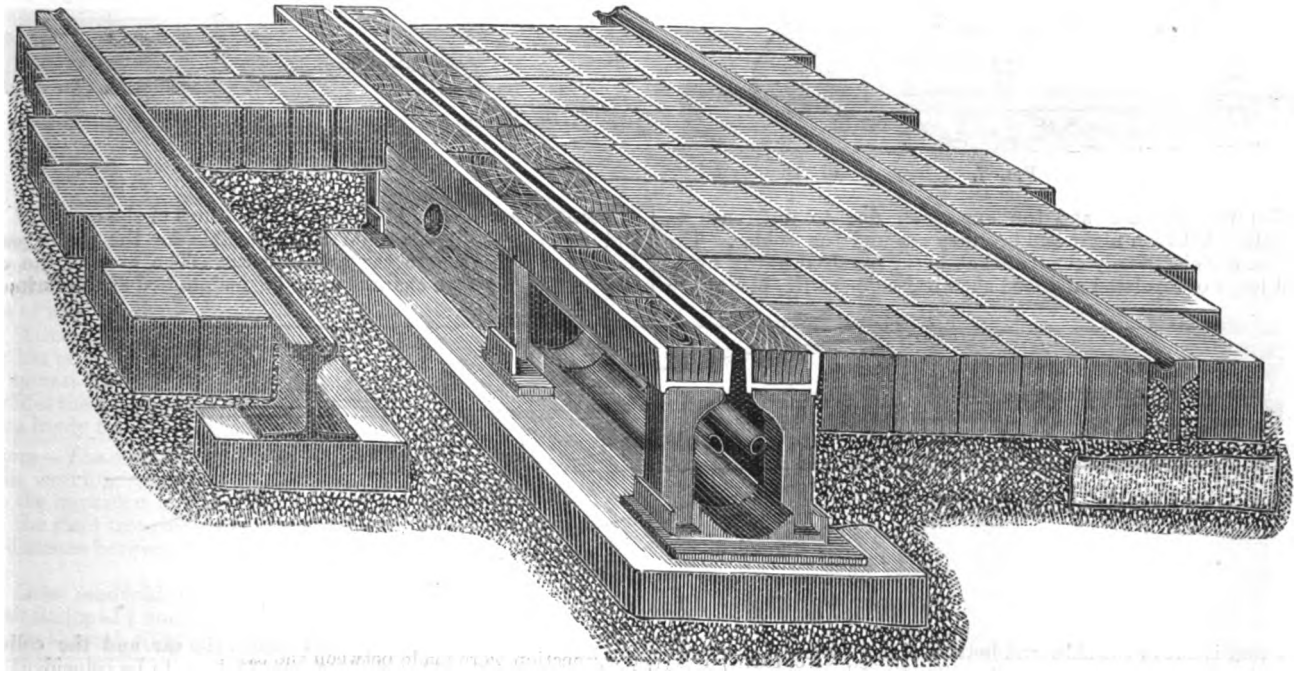


FIG. 6.

11. Electrical and mechanical fittings so arranged that the car can be driven in either direction from either end.
12. Freedom from complication, so that the whole of the machinery can be understood and managed by an ordinary workman.
13. Provision against serious damage in the case of any mistake being made by the driver.

Class D.—General Conditions.

14. Generation and control of the electricity; provision for a variable production; prevention of damage through short-circuiting; and avoidance of lengthy stoppage in case of accident.

Description of Line.—The Blackpool line is nearly two miles in length, and the general plan of it is shown in Fig. 5.* It is a single track, with ten pass-byes and one length of double line. The engine-house and car-sheds are placed near the centre; this position was selected as being the most convenient, and as offering considerable advantages from an electrical point of view, compared with a generating station at one end. The roadway runs along the sea coast, facing directly west and exposed to the full force of the wind and tide from the Irish Sea. So strong are the periodical storms that, though the road-level is well above ordinary high-water mark, the waves dash over in such volumes that the road is flooded, and the doors and windows of the houses are occasionally beaten in; during the winter months it is the custom to board up the doorways of many houses on the south shore. The difficulties in applying electricity underground in such a situation are therefore unusually great. When the tide is over the line, the current of course makes earth. At one time it was intended to employ accumulators for haulage during the flooding, and horses were occasionally used; but owing to the amount of shingle brought over, the grooves in the rails were filled, and the cars kept running off. Working during the floodings has therefore been abandoned.

These circumstances and others afterwards to be mentioned pointed to the necessity of allowing any dirt or shingle that might enter the slit in the surface of the centre channel to fall through freely to the bottom, and also of providing for its easy removal. The sump holes and traps for this purpose are placed at the points marked SS on the plan, and have direct drains connecting them with the sea, advantage being taken of the town drains used for running off the surface water. In Fig. 6 is shown a part section of the roadway in perspective; and in Fig. 7 is shown a transverse section of the channel A; including the cast-iron chair B; the channel steel C forming the cover, which is called "steel troughing" in order to avoid confusion of terms; the side woods D holding the insulators E; and the copper conductors F. The chairs are of cast iron, 11in. high with a 12½in. base and an internal width of 5½in.; the bottom is rounded, and the ends have pockets for holding the side boards. These chairs are placed every yard, and support the steel troughing, which is bolted to their surface; the nuts are covered and locked by a cast-iron cap. The rest of the troughing is filled with wooden blocks, and forms so good a paving that the horses prefer it to the rest of the road. The sides of the troughs are inclined, so that when fixed the space between them is ½in. at the top and 1in. at the bottom, the object being that any stone having once passed the surface may easily fall through, instead of getting hopelessly jammed.

Creosoted wood is used for the sides, with a view to adding to the insulation. The wood sides have a 2½in. hole bored midway between the chairs, for the reception of the porcelain insulator; and ¾in. holes are bored at right angles for the insertion of a wooden peg, which, passing through the groove in the insulator, locks it fast. This method has added greatly to the facility of construction. The roadway under the side pieces is packed; and the centre is concreted, and tooled to form the same curvature as the bottom of the chair.

In Fig. 8 is shown an enlarged view of the insulator or stud; and also the manner of supporting the copper conductors and securing them by the insertion of the wooden pins P. The conductors are made of hard drawn copper, having a conductivity of 96 per cent. of pure copper; they are in lengths of 36ft., and weigh almost exactly 1lb. per foot. They are placed at the angle shown, firstly for convenience in fixing, secondly in order that the collector may partially rest upon them as well as press against them, and thirdly in order that any dirt coming between them and the side boards or chairs may easily fall through.

Tubes.—The tubes are connected one with the other by wedges made of drawn brass, exactly fitting the inside of the tube. Space

* This figure is not given, as it is not necessary for the due understanding of the paper.

Digitized by Google

is left between the ends to allow for expansion and contraction ; and the wedges are secured from shifting by a wrapping of wire. In the first few hundred yards laid the wedges were soldered ; but the operation was difficult, and the expansion due to difference in temperature between night and noonday cracked the solder. The two tubes are electrically conducted at every hundred yards by U shaped loops of insulated and lead sheathed copper wire, placed in a groove that is cut in the sides and bottom of the channel. Over each of these loops, as marked on the plan, is a hand hole, which is made by cutting both of the steel troughs and filling the place with two pieces of a yard length, which are protected by suitable side plates. These hand holes are needful for many purposes, specially for the insertion of the scrapers used in cleaning the channel, and for the removal of collectors, should they become damaged or require adjustment. Only the positive electricity passes along the copper conductors. The return circuit is made by means of the rails ; and to ensure its being electrically good, each rail is connected by a strip of copper passing from rail to rail and plugged into holes punched in the ends.

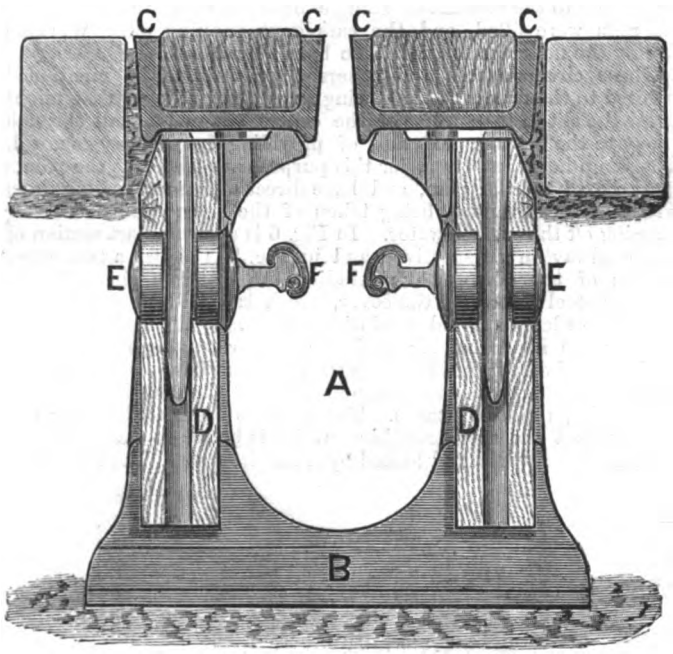

FIG. 7.

Points.—Dealing with the points necessitated by the numerous pass-byes was a matter of no small difficulty ; for in tramways it is desirable that the rail points forming the turn-outs should be as fine as possible, so as to avoid strains and joltings of the cars. If well and properly laid, it should be impossible for the passengers to detect the places where the points occur. The area of the cross section of the centre channel must be maintained at the fork ; and if a rigid connection were made between the car and the collector underground, the channel points would have to be coincident with the rail points, and the surface slit in the channel to remain central between the two rails, which would involve such a long overhanging tongue as to be impracticable. The employment of a flexible connection between the car and the collector renders possible the arrangement shown in Fig. 9, where it will be seen that, while the rail points are fine, the channel point is wide, and is placed some distance back, and that the rail and channels cross each other at a nearer approach to a right angle than would otherwise be possible, thus minimising what would be a structural weakness.

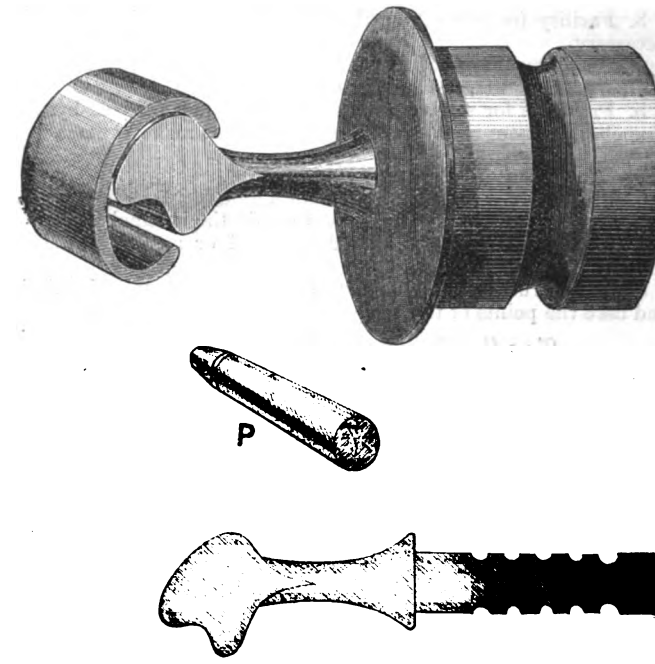

FIG. 8.

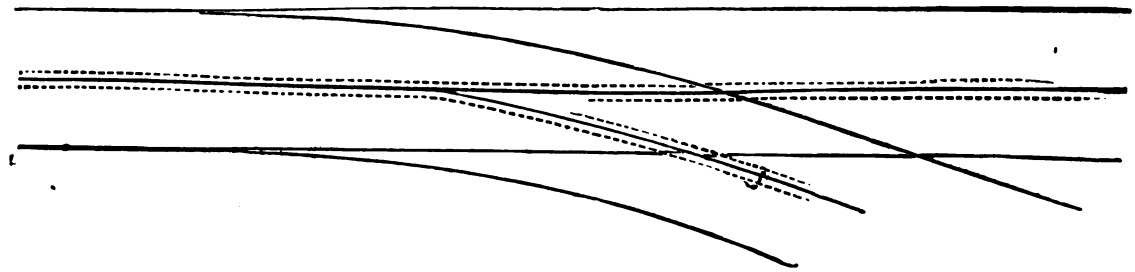

FIG. 9.

FIG. 10.

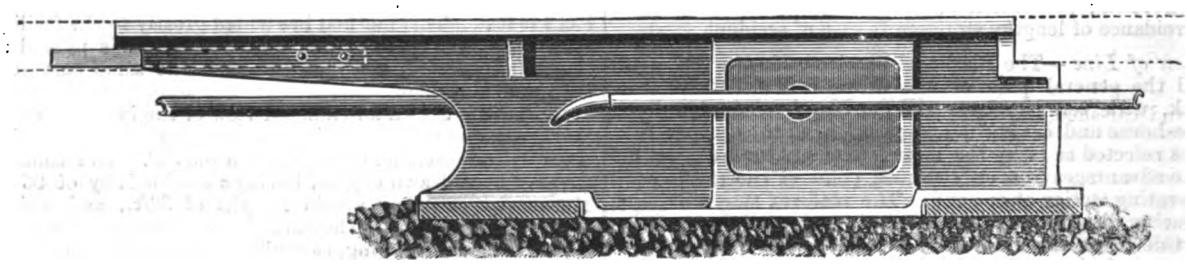

FIG. 11.

In Fig. 10 is shown a side elevation of the point ; and in Fig. 11

a plan illustrating the arrangement of the conductors. The two copper tubes, which have been running parallel with each other in the single channel, here part company, taking the outer position in the channel of the loop line; and they are there joined by subsidiary

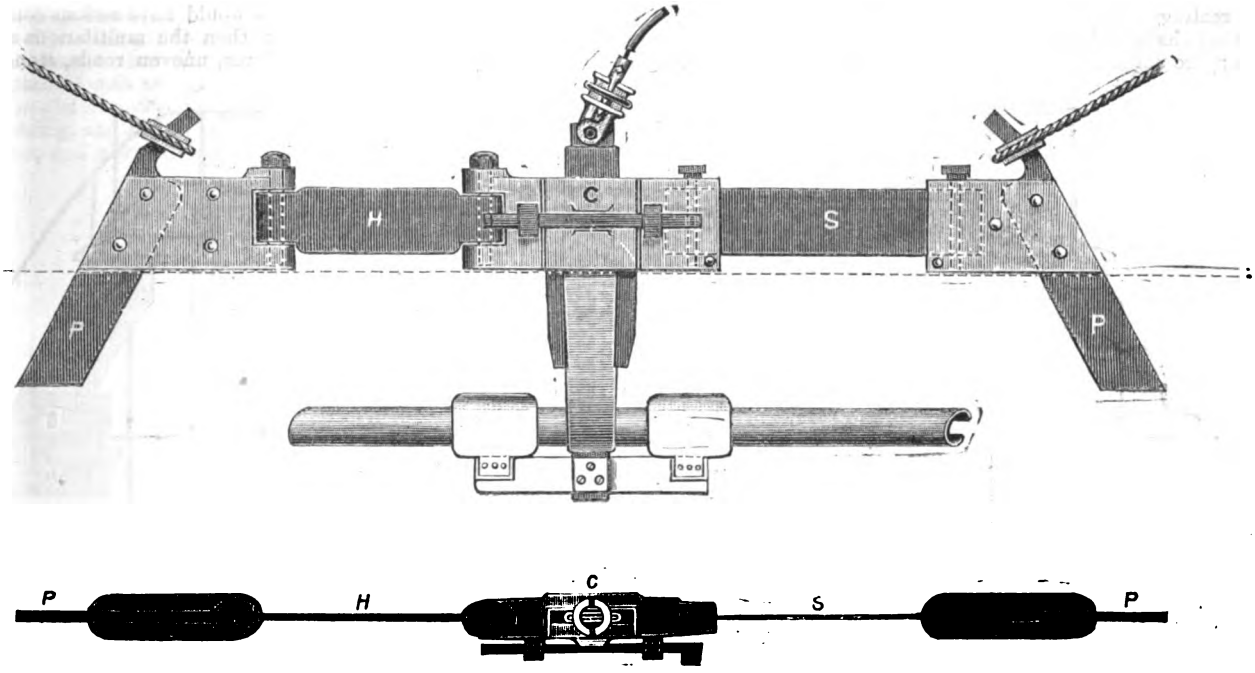

FIG. 12.

tubes, which are electrically connected with the outer or main tubes by one or more of the insulated loops previously described. In order to prevent the collector from fouling when taking the points, the ends of these secondary tubes are fitted with brass horns, as shown. Although the lay of the channel points is such that the collector has no tendency to take the wrong way, yet for further security against such a mishap a steel spring, S, is placed at the toe, which guides the collector to the proper side in taking the points, and opens freely for allowing it to pass when leaving.

Collectors.—The collectors have been perhaps the chief source of trouble in working, partly from inherent faults, but principally owing to the imperfect laying of the line; the ½in. slit or opening between the steel troughing was not even approximately accurate, and the distance between the two conductors was most distressingly variable.

These facts rendered it impossible to use a collector of the form first designed; and it would be wearisome to describe the many stages through which this instrument passed before the form now in use was developed. Samples are exhibited, and are illustrated in Figs. 12 and 13. The collector consists of three main parts, namely, one centre-piece, C; and two clearing ploughs, PP, for enabling it to run in either direction. As already stated, one of the elements of success in working electric tramways with conductors underground is the employment of a flexible collector, flexibly connected. For this purpose the two ploughs are joined to the centre-piece either by a tempered steel strip, S, or by a hinged wrought-iron plate, H, Figs. 12 and 13. The tempered steel plates forming the ploughs are held by cast-iron cheeks, and are placed at the angle shown, and extend downwards a little past the bottom of the steel troughs; their upper ends terminate in a prong or finger, curved slightly backwards. The fingers receive the loop or ring of the hauling ropes which are attached to the front and rear of the car. The ropes are strong enough to stand considerable strain, and their ends are fitted either with a releasing clip, or with a short loop of weaker cord, which is strong enough to bear the stress due to any ordinary obstruction; but should an absolute block occur, then the small loop breaks, or the clip lets go, and the collector is left behind, while the car travels forward. At the same time the ring of the trailing rope slips off the finger of the rear plough; if this were not so, the force required to break the loop of the trailing rope would make the collector kick up, and would cause the contact-making part of the centre-piece to short-circuit with the underside of the steel troughing. The centre piece consists of a cast-iron cheek, holding a plate of strong brass, which is thoroughly insulated and protected by hardened steel guards where it passes through the troughing. The bottom of the insulated plate is bared of insulating material, and has attached to it either a short plate of brass, or two brass wires, forming a T, and holding at each end hard metal wings specially prepared; the forward wing is bent so as to press against the left-hand conductor tube, and the rear one is bent so as to press against the right-hand tube. To the upper end of the insulated plate is fixed a clip, surrounded by an india rubber ring; the clip is bored to receive a heart-shaped terminal, which can be easily pushed into

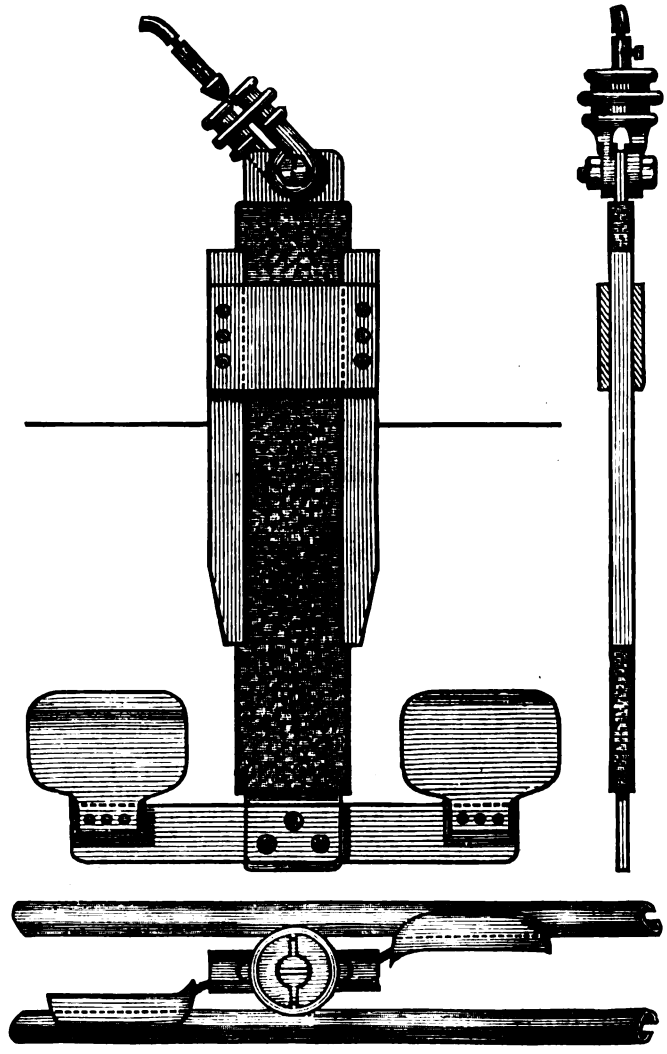

FIG. 13.

it, but requires a fair natch to withdraw it. A similar clip is fixed to the receiving wire under the car; and a short length of curled

insulated wire with a heart-shaped terminal at each end makes a ready connection between the collector and the car.

Cars.—The cars are ten in number, and of various designs. The smallest are light open summer cars, seating thirty passengers. The largest are provided with transverse seats on the roofs, and carry fifty-six passengers. In Figs. 14 and 15 is illustrated a medium size, seating forty-eight. As shown in the plan, the levers of the ordinary chain-brake are placed outside the wheels, so as to leave a clear space under the centre of the car for the motor and the gearing. The mechanical construction of the motor M was specially designed for allowing it to be fixed in the position shown. The bearings are held in a circular frame, large enough for allowing the armature to be passed through it.

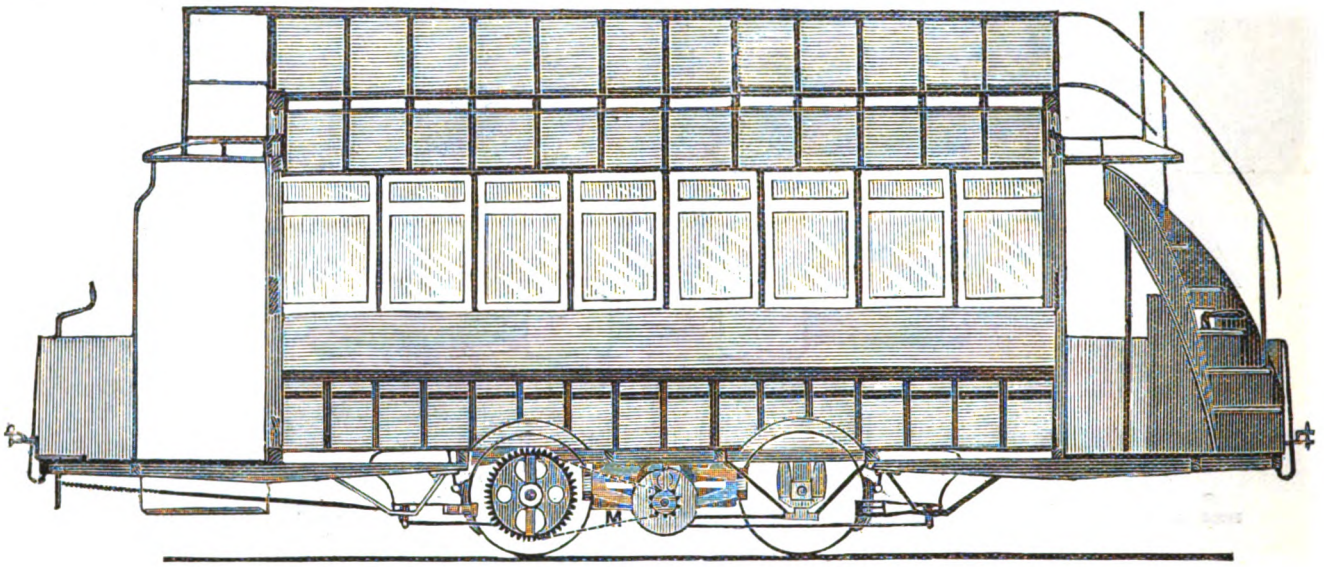

FIG. 14.

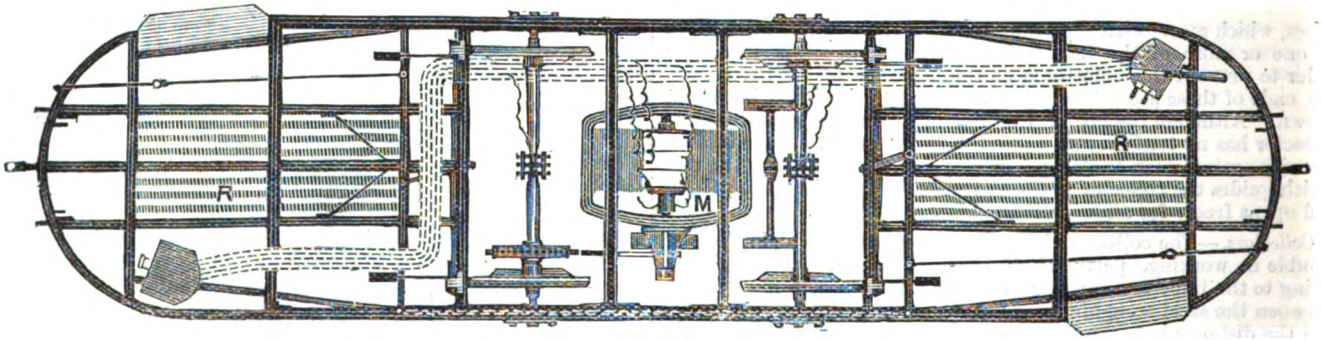

FIG. 15.

Motors.—The motors are series-wound, and of such proportions that they yield a high efficiency, running in either direction without giving any lead to the brushes. Reversal is effected by changing the internal coupling; that is to say, whilst the current through the field is always in one direction, the current through the armature can be reversed, thus changing the relative polarity and consequent direction of motion. Ordinary brushes were found to give constant trouble, due not only to this reversal, but also to the jolting of the car, &c. Many other forms were tried without success before the simple device illustrated in Fig. 16 was adopted, which is found to act remarkably well. Each brush consists of a thin steel plate, SS, insulated from the studs DD, and free to work on them. The steel plates are divided into fingers, which carry little blocks made of a special metal and capable of being easily renewed. The blocks are made to press against the commutator by small bands of india rubber stretching from tip to tip of the fingers. The pressure of the brushes is thereby regulated and equalised, and the vibration and jolting are compensated.

Gearing.—To the circular frame of the motor is bolted the base of an elbow bracket, which carries the invert wheel gearing into a gunmetal pinion on the end of the armature spindle. The box holding the invert wheel has upon its back a chain pinion, from which the power is taken to the large wheel keyed upon the axle of the car. The elbow bracket can be turned upon its base, so as either to slacken or tighten the chain at pleasure, without moving the motor or disarranging the centres of the armature pinion and invert wheel. But for the inevitable stretching of the chain, and the noise when new, this gear would be all that could be desired.

The electric driving of a tramcar involves more than the mere question of the reduction from high to low velocity. The wheels have to drive the car, not the car to take the wheels; but as the car is heavier than the wheels, it is therefore better that the driving power should come from the car. If the motor were attached to the axles in order to obtain a fixed relation between the driving and the driven wheel, then the vibration would have serious consequences. If the motor be fixed to the car, then the multifarious movements due to varying load, springs, curves, uneven roads, stones, &c., all of which disturb the relation between the driving and the driven wheel, have to be compensated for. It has been argued that worm

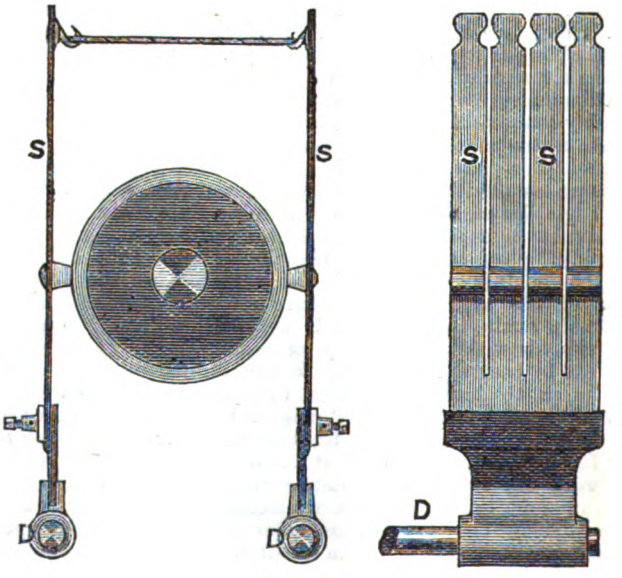

FIG. 16.

gearing is the most convenient for reducing a high velocity to a low one; and also, on the other hand, that the loss in friction is fatal to

Digitized by Google

the economical use of worm gear. The employment of worm gearing is a problem for which the writer believes that no reliable data exist or can be formulated; it is a question of compromise, and the difficulty is to strike the happy medium. Experiments which he has made have given such satisfactory results that his intention is to adopt in future work the modification of worm gear which he has devised for the purpose.

Wiring.—The wiring of the cars is shown in strong dotted lines. In order to control the quantity of current and the consequent speed, resistance coils are placed at R, and are coupled with the switch boxes placed under the car steps. A removable handle is used for driving, and a plug switch for reversal; these are in charge of the driver, and when the car has completed its run in one direction he carries them to the other end of the car; this plan prevents any accidental derangement, as it is impossible for the switches to be worked without them. The coils are arranged in series, and their resistance is about 4 ohms; and most of the switches are of an ordinary type, cutting out 1 ohm at a time. This method is open to the objection that the changes are not sufficiently gradual; and if a heavy current is allowed to pass through the final coil for a considerable time, it may become dangerously hot. It seemed desirable, therefore, that the switch should be so arranged that the coils could be used first in series and then in parallel, in order to obtain a more gradual change, and secure a larger surface for radiation when little resistance was in. A switch accomplishing this object is exhibited.

Generating Station.—In Fig. 17 is shown a plan of the generating station. As the cars have to work all day, the engines and dynamos are in duplicate, each set being capable of doing the full ordinary work, while in case of need both can be used at once. The engines are 25 nominal horse-power, compound non-condensing, of the semi-portable type, with locomotive boilers. A second-motion shaft is employed, in order that either or both of the engines may drive either or both of the machines. The dynamos are placed on a higher level than the engines, which enables the wheels controlling the friction couplings FF to be placed in a position where they can be worked conveniently by the engine man.

Generators.—The generators are four-pole shunt-wound dynamos; but instead of allowing any current from their own armatures to pass round the field magnets, these are separately excited by the little machines MM. As the electromotive force of the external circuit varies directly with the intensity of the field, it can be regulated to a nicety by varying the resistance in the circuit of the exciter. This resistance is by preference placed in the armature circuit of the exciter, namely, between the terminals B and C in Fig. 18. If the resistance were placed in the field of the exciter, the regulation of the electromotive force in the external circuit would probably be more complete; but the magnets of the generators would then discharge through the armature of the exciter, and there would be an extra current due to breaking the circuit of the magnets of the exciter. These extra currents would have tendency to destroy the insulation, and would be otherwise injurious.

The controlling switch has ten points, and the corresponding resistances are as follows:—

Points.	Resistances.	Points.	Resistances.
1	21 ohms.	6	9 ohms.
2	18·5 ,,	7	6·8 ,,
3	16·1 ,,	8	4·8 ,,
4	14 ,,	9	2·4 ,,
5	11·5 ,,	10	0 ,,

The maximum electromotive force of the generators is 300 volts; and each will yield 180 amperes. They can when required be run in parallel. It is unnecessary to give the electrical details of these machines; but it may be mentioned that the total length of No. 17 wire (0·06in. thick) on the magnets of each generator is about fourteen miles.

In Fig. 19 the black curve shows the variation in the electromotive power of the exciter due to varying resistances when exciting one generator, and the red curve when exciting both.

In Fig. 20 is shown the varying electromotive force in the external circuit by the line when No. 1 generator is used, by the black line when No. 2 is used, and by the dotted line when both are excited in parallel.

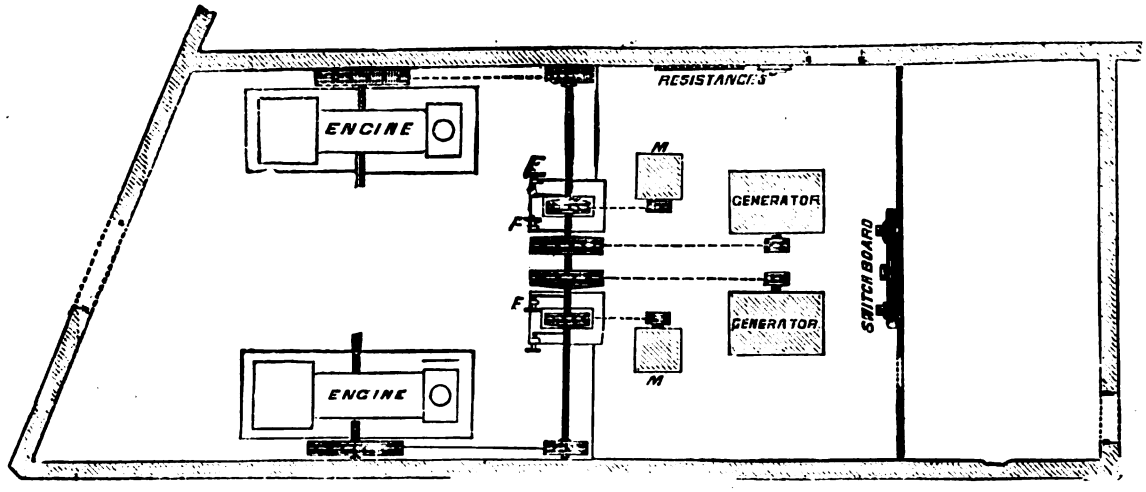

FIG. 17.—Generating Station.

Fig. 18 is a diagram of the instrument board, showing the arrangement of switches, voltmeter, ammeter, and cut-out. Fuses

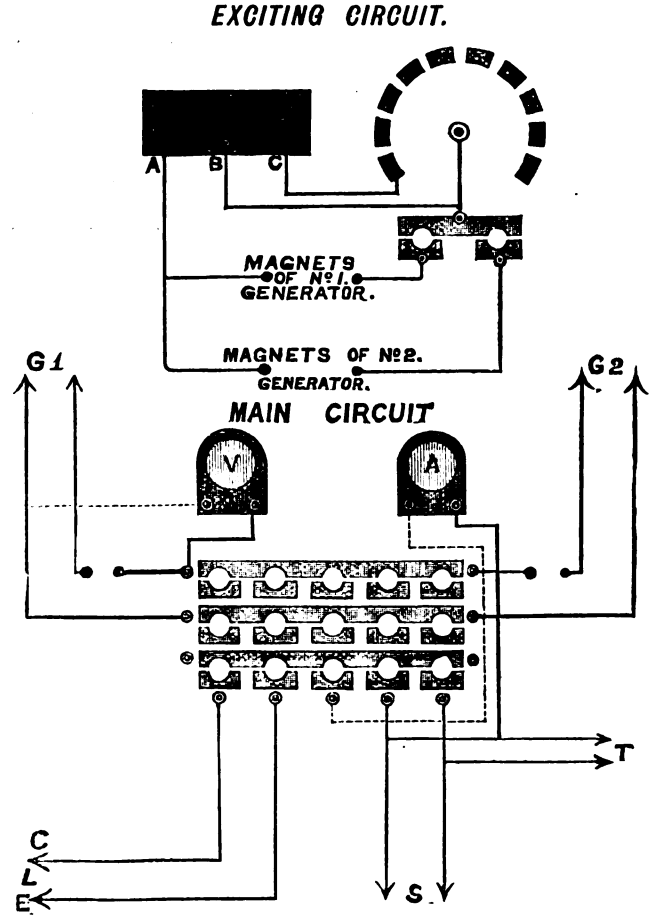

FIG. 18.

have been tried, instead of the cut-out; but their action was not rapid enough to avoid severe strains upon the generators, and flashing at the commutator when an absolute short-circuit occurred. A further advantage of a magnetic cut-out is that it can be easily

Digitized by Google

regulated according to working requirements. Though a multiple-plug switch is somewhat too complicated for ordinary workmen, it forms in the hands of an experienced electrician a perfect means of regulating the direction of the currents from the two generators through the various instruments and to and from the line. A little watchfulness is necessary, especially before running both machines at the same time, as they have occasionally changed their polarity.

Conductivity.—The sectional area of each copper tube represents a solid conductor of 0·575in. diameter, giving a resistance of 0·165 ohm per mile. As there are two tubes running the whole length, and as the line runs right and left from the generating station, the total resistance may be taken as the joint resistance of two miles,

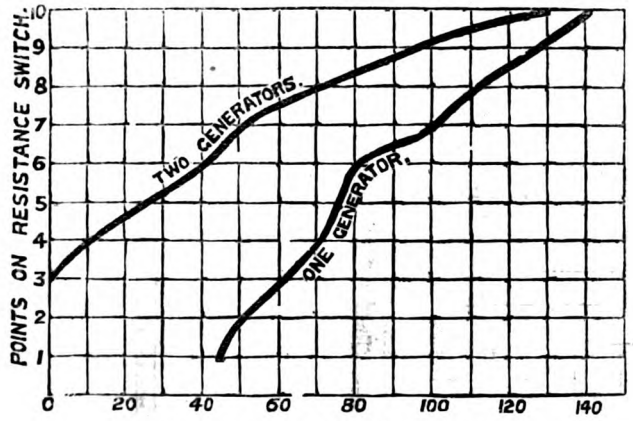

FIG. 19.

which brings the calculated resistance down to 0·041 ohm. The actual resistance is much more than this, as is evident from the fall of potential over the line, which is shown in Fig. 21. The readings are also marked upon the general plan in red figures at the places where they were taken, and are as follows :—

Tram Shed, the electromotive force usually employed of 220 volts.
Foxhall, the junction with the main line..... 210 ,,

Going North.		*Going South.*	
South Pier	207 Volts.	Manchester Hotel	204 Volts.
Royal Hotel	204 ,,	Wellington-road ...	198 ,,
Lane Ends Hotel...	198 ,,	Alexandra-road ...	189 ,,
Bailey's Hotel	189 ,,	Waterloo-road	174 ,,
North End	185 ,,	South End	168 ,,

This fall is probably due to poor joints, faulty connections, etc.

Insulation.—Measurements were taken of the insulation of the line during construction, and 150 yards' length was found to give 4,490 ohms. But it has been practically impossible to measure the insulation of the finished line ; for when the current is off, the condensation and moisture upon the insulators make the resistance very small. This, after a night of heavy rain or sea flood, causes a serious loss. When commencing work in the morning sometimes as much as 100 amperes is absorbed ; but after running the engines for, say, half an hour, the leakage will fall to 30 amperes. The average working loss through leakage may be taken at 25 amperes, which at an electromotive force of 220 volts is equal to 7·2 horse-power. The principal difficulty arises from the shingle brought over by the tides, and the large quantity of fine sand blown into the channel by the high winds. At the commencement much trouble and annoyance resulted from the faulty construction previously referred to ; but now by watchfulness and adjustment any hindrance to working can be avoided.

Efficiency.—No reliable measurements have been taken to ascertain the total percentage of loss in transmission, starting with the indicated horse-power of the engines and the mechanical power developed in propelling the cars. To arrive at this percentage it would be necessary to take a given number of cars of known weight, filled with passengers of known weight also, and to run them at the same time upon a given length of line of known gradient. When planning the works the writer assumed that the efficiency would be only 30 per cent. ; but from the observations taken and the calculations of the different quantities, the actual efficiency is believed to be nearer 45 per cent. As the efficiency of the generators is about 90 per cent. and of the motors about 80 per cent., much further economy must not be looked for in them ; though it should be possible for the loss in the generator to be not more than 5 per cent. and in the motor 10 per cent. The second-motion shaft in the present arrangement fulfils too important an office to be dispensed with ; though by special engines and gearing the same object could be attained with less friction. It is exceedingly doubtful whether any form of gearing can be devised to absorb less power in transmission than that already described ; indeed, a larger percentage of loss might be allowed for the sake of simplicity and silence. The chief part, therefore, in which to look for further economy is the line itself ; and in this the first point is more perfect insulation, and, consequently, less loss in leakage ; and the next is more

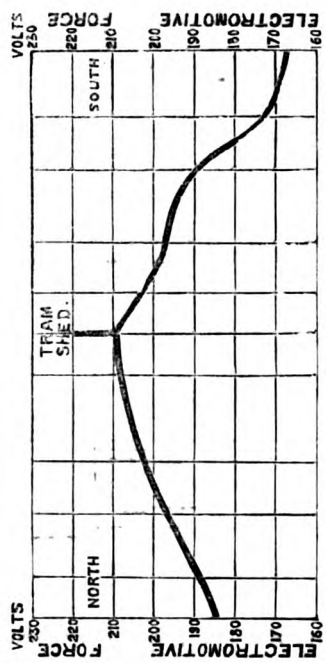

FIG. 21.

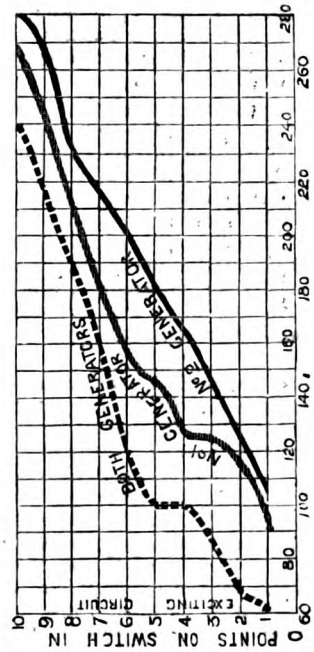

FIG 20.

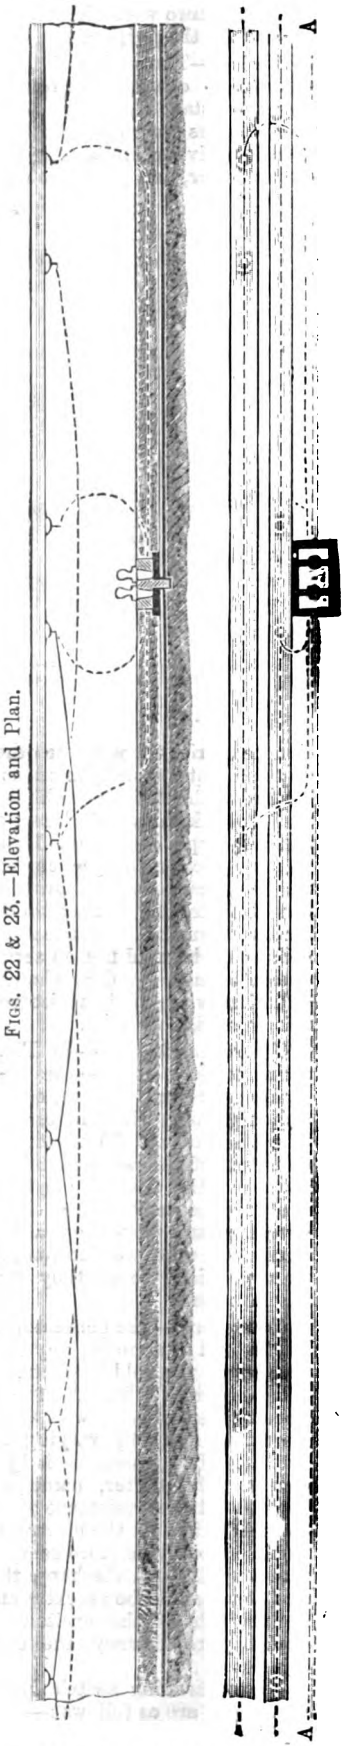

FIGS. 22 & 23.—Elevation and Plan.

perfect continuity in the conductors, and therefore less loss through resistance.

When larger installations are undertaken, considerations other than those already mentioned have to be faced. How it is proposed

Digitized by Google

to deal with these in the future may be suggested by reference to Figs. 22 and 23. Here AA is an insulated cable running the whole length of the line, tapped at regular distances to supply different sections of exposed conductors; each tapping should be covered by a switch controlling two lengths. The conductors should consist of wires or ropes, swung from the surface of the channel, instead of being supported at the sides, thus dispensing with at least 75 per cent. of the insulators, and also placing the insulators where they would be more accessible in case of failure. By alternating the points of support of the wires, and allowing the collector to run under instead of over or against them, better contact may be maintained. By making the sectional area of the channel wider, the risk of filling will be lessened and cleansing will be rendered easier; and by increasing the width of the surface slit even ¼in., the life of the collector would be materially prolonged, and its insulation better secured.

Discussion.

Mr. Horsefall (Chairman of the Blackpool Electric Tramway) said he was not aware until a few minutes before he came into the room that Mr. Smith was going to read a paper. He thought it his duty, as Chairman of the line in question, to endorse what Mr. Smith had said in respect to the difficulties that had been overcome, and which had resulted from the bad way in which the channels and other work had been executed by the engineers. As to the question of the economy of working the line, he had been at the trouble to take out some figures which might be interesting. For the week ending June 4th, their receipts were £67. 1s. 1d., and the working expenses had been £30. 18s. 4d., which included coal, tallow, waste, fireman's wages, as well as those of conductors, collectors, and inspectors of the line. For the last four weeks their receipts had averaged £330 per week, and the cost of material, wages, and everything else, had been about £45 in round figures. Their total receipts since the opening of the line to August 27th, were £4,038. 16s. 1d. That was including the winter months, when, he was sorry to say the receipts did not pay the cost of working. He was in hopes, however, that during the coming winter, now that they had got over many of their difficulties, they would be able to pay the cost of working and make a profit for the shareholders. Personally, although he was not an electrician, as Chairman of the Company, he had had a good deal to do with it, and he must certainly endorse the views set forth by Mr. Smith that morning. He believed that there was a great future for electric tramways in this country if they were properly managed. They had gained experience at Blackpool, unfortunately, at a considerable cost to the Company, which had spent in round figures about £30,000, in laying down the line; but he was quite sure that if another tramway were to be constructed, it could be done at a considerably less sum. He concluded by moving a vote of thanks to Mr. Smith for his valuable paper.

Mr. Douglas Galton said he had listened with great interest to what Mr. Holroyd Smith had had to say in his valuable paper. He would have liked, however, to hear a rather more detailed explanation of the cost of working such tramways; but as the lines had been put down so very recently he imagined it would be rather difficult to get what would be a fair and reliable estimate of the working expenses. The system employed at Blackpool was not the only form of electric traction on tramways in operation. At Antwerp last year—and he understood that there were several carriages of the same kind put on to the tramways at Brussels now in active operation—the tramcars were worked by means of accumulators. He confessed that at first sight he thought that such a system, if it could be proved to be economical, would be preferable, because it did not seem to involve so large an outlay in the first instance, and he supposed there must be a certain expense in keeping the conductors clean. Perhaps Mr. Smith would say what that expense amounted to. He did not know that the experiments at Brussels had gone so far as to determine whether the system was a satisfactory means of traction. Certainly, at Antwerp the results were very satisfactory, but as the lines there were on perfectly level ground, and no hills had to be gone up, he did not think that those results could be taken as a fair guide of what the expenses might ordinarily be expected to be. In Brussels, on the other hand, the ground was hilly, which was a serious difficulty, but if it were found that the tramways there could be worked at a reasonable expense, notwithstanding the inclines, he thought that, as the result, very great additions might be expected to be made to electrical traction on tramways. They were of course just now in the experimental stage of the question, but there was one point which he thought was quite certain, and that was that most people would prefer to have electrical traction, which was most agreeable on tramways, rather than steam or horse-power, if it could be obtained at anything like a reasonable cost.

Another Speaker said he wished to allude for one moment to a remark Mr. Smith had made with regard to the sand on the line. He happened to have lived by the seaside a great number of years, and he knew that there was hardly anything more calculated to fill up all kinds of space than sand when the weather was dry and the wind happened to be blowing from the sea. After a gale of wind, when the sand was in a dry condition, it seemed to find its way into every cavity. Under such circumstances, he had found the rain pipes on his house filled from top to bottom, so that when rain fell it could not run through them at all, and it appeared to him that with a strong wind blowing the working of the line might be seriously interfered with on that account. In the course of his reply perhaps Mr. Smith might say whether the tramway had suffered from that or not.

Sir Frederick Bramwell asked what was the number of amperes required for the work.

Mr. Tait said he was acting as county surveyor of Antrim at the time when the Giant's Causeway line was constructed and when the electric tramway was being made there, and he could not help thinking that £30,000 for a couple of miles of line at Blackpool was a very great outlay for so small an undertaking. The question of providing electricity for tramcars, if it was not to be carried by the cars themselves, was one of very great importance for the future of that kind of locomotion. He did not think that the costs of the experiments both at the Giant's Causeway and on the line now under consideration could be fairly considered safe data to go upon, as they were merely tentative. There was one point in connection with the underground supply system which he would like to get more information about, and that was with reference to the clearing of the space in which the conductors were placed. What were the frequency and the means adopted for clearing it?

Prof. Perry desired to offer his congratulations to Mr. Smith on the success which his system seemed to have attained. No outsider knew the difficulties that an inventor met with in carrying out electro-mechanical inventions in the present state of electrical engineering. Mr. Smith was therefore to be congratulated—quite irrespectively of any cost of his electrical tramway—on being able to work it at all, because he had had to face very great obstacles. He (the speaker) confessed that the track was rather an expensive one. That method of making a track seemed to be very good where there would be no accumulation of sand likely to take place, but it was certainly a most expensive one. Along with Prof. Ayrton he (the speaker) had patented certain contrivances which, in their opinion, would enable electric tramways to be worked efficiently. They had, however, got off just now on a side issue in a slightly different direction in the development of some of those patents which came under the name of telpherage; and when one took up any particular line of investigation one had absolutely no time to turn one's attention into other channels of discovery. One of the important contrivances that he referred to was one in which there was no opening whatever into the space where actual contact was made, the contact being effected from the tramcar outside. The internal contact of the actual conductor was made in the space to which nothing had access from the outside. Both in London and in Paris tramcars had been run by means of accumulators, and at the time Prof. Ayrton and he ran them the weight—he would not say the cost—but certainly the weight of the accumulators was prohibitive. Perhaps some of the gentlemen present might be able to say to what extent the weight of accumulators and their cost had been reduced, so as to make that plan of driving the tramcars encourage the hope of its meeting with any decent chance of success. He felt that the most important thing that any electrical engineer—he thought he might say any mechanical engineer—could devise for the benefit of humanity would be a motor which should have, he would not say any defects electrically, but which should have no defects mechanically. The way in which a man who might know electricity perfectly from a theoretical point of view, but who was ignorant of the mechanical knowledge necessary to give it practical effect, sometimes carried out his work was simply absurd. It could therefore be easily seen what mismanagement sometimes arose when an electrician had charge of an invention. Some of the telegraph engineers present might have noticed that Mr. Holroyd Smith said that the insulation resistance of the line was between 4,000 and 5,000 ohms. He (the speaker) considered that that figure was a very good one for a tramway system. If a telegraph engineer would only figure out to himself how small an amount of power was being wasted in comparison with the tremendous power that was used, he would see that such a resistance was very satisfactory indeed. If that amount of power were wasted on a telegraph line, no message would be sent, but on a tramway its loss was not to be considered as of any moment.

Mr. Leech believed from what he had seen of electric tramcars that they were perfectly under the control of those conducting them, and that they could not only travel with safety at a much quicker speed than steam cars, but they could be stopped almost instantaneously, while they were superior in this, that they were self-contained—not as in the case of the steam locomotive having an engine in front and the car behind, but having their accumulators stowed away under the seats. The accumulators, moreover, had been so much reduced in weight, that the objection had practically disappeared. As far as he had been able to ascertain, tramcars driven by accumulators were a decided success, and he thought it was highly desirable now to try and discover its merits as compared with the plan now set before them by the paper they had listened to on that occasion.

Mr. Gisbert Kapp drew attention to the fact that by the diagrams exhibited the loss of power was as great as 40 volts out of 200, which he characterised as being exceptionally heavy. He wished to know whether that would be the case under what would be considered to be satisfactory working conditions. Prof. Perry had referred to the fact that a great desideratum was a perfect mechanical motor. He (the speaker) had been of that opinion for a very long time, and had done his best to make one, but had failed. He wanted to know whether the gearing on the Blackpool service, which was evidently adapted for reducing speed considerably, was found to be in all respects satisfactory for working the tramway. What it was now chiefly desirable to get in connection with electric tramways was a high speed motor with noiseless and efficient gearing.

Mr. Holroyd Smith, in reply, said that he was afraid if he replied fully to the numerous questions which had been addressed to him, his replies would occupy as much time as his paper. One of the first that occurred to him was that asked by Sir Frederick Bramwell. If Sir Frederick would kindly look through one of the papers he would find the information he desired respecting the number of amperes employed. The E.M.F. of the generating machines could be regulated to a nicety. Their

Digitized by Google

maximum power was 300 volts and 100 amperes each, so that when they were running parallel they got plenty of current for the work. He found that the cars would take 15 to 40 amperes—that was to say, 40 when they were working up hill, and 15 to 20 when they were working on the ordinary roads. Mr. Kapp was perfectly correct in what he had stated in regard to the loss of power. The diagrams were not complimentary to himself as regarded the loss of E.M.F. He attributed the circumstance to the submersion of part of the line at certain periods in salt water. He quite agreed with Prof. Perry, to whom he was indebted for alluding to the fact, that they must not expect that high insulation in tramways—it was not necessary—that was required for telegraphs. In fact, the line in question would be, as far as insulation was concerned, practically good if the total insulation were only 100 ohms—quite good enough for practical purposes. The leakage when large currents had to be dealt with, such as in this case, of 250 to 300 volts—the resistance of 100 ohms was not of much moment. With regard to the system that Prof. Perry mentioned, namely, that of having a covered conductor and occasional contact made with it from the car, he (Mr. Smith) was not quite sure that he was acquainted with its details, but he knew the general idea of the plan, and he was afraid that Prof. Perry would find it almost impracticable if he put it into use. There were many practical considerations that were apt to be lost sight of when one was dealing with matters of this kind in the laboratory. He (Mr. Smith) was afraid that as soon as contact was made they would make earth, and so the current would be lost. Respecting the subject of having good motors, he must confess that he had no small difficulty with that matter. He was unfortunately only a mechanical engineer, and the electricians would not place any trust in him, the result being that he had to leave electrical matters to others much more than he ought to have done; but he had found that ultimately the designs first laid down by himself and rejected by the maker had to be accepted and worked upon before the motors were made with any practical success. If they desired to get a high electrical efficiency a great many mechanical questions which it appeared not at all desirable to sacrifice had to be done away with. They were now getting 80 per cent efficiency, and he held that to a great extent that was due to the simple contrivance he now held in his hand. Electricians had told him that it was out of the question to use such a thing as that. Now, however, there was little or no trouble with the brushes, and the commutators lasted for months, whereas they would not last for a week before. With respect to the gearing alluded to by Mr. Kapp and Prof. Perry, he must say that the gearing now working, but for the statement he had already made with respect to the noise and the stretching of the chain, would be perfectly satisfactory. The arrangements pretty well excluded the dirt, and he had been very careful about the teeth and the method of holding the wheel within its shell. There had been no broken teeth up to the present time. The chains had been the principal drawback, but when any difficulty had arisen from that it had been owing to an undue sense of economy on the part of the management. He had devised a worm gearing, and although he knew it sounded almost unorthodox amongst engineers to say so, one of the paragraphs in his paper showed that in his opinion the worm gearing was a subject upon which no reliable data existed, or could be stated. It was a question of compromise throughout, but if they could strike a happy mean, he thought with worm gearing they would have a great success. He really believed that properly designed worm gearing was going to be the most satisfactory for tramway work. That would give them what Mr. Kapp required, namely, a high speed motor and an absolutely quiet gearing. Mr. Horsefall, the chairman of the company, stated, and perfectly accurately, that the total cost of the Blackpool line was £30,000. Now, what he (Mr. Smith) had to deal with was not the cost of the line, but with the cost of the electrical part of the work. The whole cost of the channel, the engines and engine house, the generators, the wires, electric motors, the switches, instruments, &c., was under £12,000. As to the question of accumulators, he wished to state most emphatically that it was a delusion in the public mind that electricity was going to be put into a bucket the size of a hat, or only weighing about one cwt., and that then it was to do a great deal of work. A tramcar could not be worked with light accumulators. Supposing they had accumulators to work a line they would want three tons of them in each car, and they would have to be renewed three times a day. The total cost of fitting a line with accumulators would be 15 or 20 per cent. more than fitting it with a channel. The total cost of carrying 42,000 people in one week was under £45. He asked whether they could show in this or any other country a tramway worked at such a low rate. He was certain that it could not be done.

COMPANIES' MEETINGS.

The Manchester and District Edison Electric Light Company (Limited).

The annual meeting of this Company was held on Monday, the 6th inst., at the Memorial Hall, Albert-square, Manchester, Mr. V. K. Armitage (the chairman) presiding.

The fourth annual report stated that the results of the year's work compared favourably with those of any previous similar period in the history of the Company, there being a small profit instead of, as previously, a loss upon the twelve months' business. The long-pending actions against infringers of the incandescent lamp patents held in the Manchester district by the Company had since the last report been heard and determined in favour of the Edison and Swan United Company. Though notice of appeal had been given by the defendants in the actions, it was confidently believed that the judgment lately given would be sustained. Should that anticipation prove well founded there could be no doubt that the value of the Company's property would be considerably enhanced. Notice to refrain had been given to all known users of infringing lamps, and every effort to sustain the patent rights was being made by the parent Company. Inquiries as to the cost of installing the electric light were more numerous than at any previous time, and the prospect of work to be done in the immediate future was decidedly favourable. Since the close of the financial year the Directors had had to deplore the loss by death of their esteemed colleague, Mr. W. A. Turner.

The CHAIRMAN moved and Major FLOOD PAGE (London) seconded the adoption of the report and balance-sheet.

The motion was passed after some questions had been asked and answered.

On the motion of Mr. J. F. CHEETHAM, seconded by Mr. CHARLES MOSLEY, Mr. Armitage was re-elected Chairman.

Mr. J. J. ARMITAGE then proposed and Prof. HOPKINSON seconded the re-appointment of Messrs. Jones, Crewdson, and Youatt, accountants, Norfolk-street, Manchester, as auditors, which was passed.

Major TURNER moved and Mr. SYKES seconded a vote of thanks to the Chairman, which was carried unanimously.

The proceedings then terminated.

NOTES.

THE WEST AFRICAN LINES.—Telegraphic communication has now been established with Lagos, Brass, and Bonny (West Africa).

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 10th inst. amounted to £3,116.

LUMINOUS RAIN.—*L'Astronomie* records a fall of luminous rain during a thunderstorm at Sotteville. That is to say the drops on touching the ground produced flashes of red and violet light. Similar phenomena have been previously recorded.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 10th inst. were £2,432, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

CHORLEY, LANCASHIRE.—Messrs. Sharples, of Preston, have received an order from the Chorley Board of Guardians to connect the workhouse hospital and the master's room by telephone, and the different wards and attendants' bed rooms by electric bells.

THE SCHARNWEBER LAMP.—The Scharnweber arc lamp, which was recently described and illustrated in our columns, is now made by the Woodhouse and Rawson Electric Manufacturing Company, who have acquired the sole rights for England and France.

ELECTRIC LIGHT AT CARDIFF.—A new arcade, containing forty-one shops, which has recently been opened in Queen-street, Cardiff, is lit by twelve Brush arc lamps, each of 2,000 candle-power. The installation has been carried out by the Anglo-American Brush Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 31st Aug. are £1,964, as compared with £2,358 in the corresponding period of 1885. The May receipts, estimated at £5,762, realised £5,764.

THE LIGHTING OF THE GENERAL POST OFFICE.—The Post Office has recently ordered two Elwell-Parker dynamos and two Willans engines, with which plant the lighting of certain portions of the premises of the General Post Office will now be carried out in a permanent manner.

GOSPORT AND THE ELECTRIC LIGHT.—An application having recently been made to the Alverstoke Local Board as to the lighting of Gosport by electricity, that authority has come to the conclusion that "the utilisation of the electric light for this purpose is not practicable in the parish."

THE LIVERPOOL ART GALLERY.—One of the rooms at the Walker Art Gallery, at Liverpool, is being fitted with electric light by the Liverpool Electric Supply Company, in view of the forthcoming Autumn Exhibition. If the arrangement gives satisfaction, the lighting will be extended to the whole of the galleries.

THE BLACKPOOL TRAMWAY.—During last week the number of passengers carried on the electric tramway at Blackpool was 44,306. The cost of fuel (coal and coke) was £4 16s. 3d., the total working expenses being £45. 16s. 2d., while the total receipts were £347. 15s. 3d., and the total distance run 2,760 miles.

BIRKDALE PALACE HOTEL, SOUTHPORT. — The Maxim-Weston Company has just completed an installation of the electric light in this hotel. The installation consists of 200 incandescent lamps of 20 candle-power, and 5 arc lights of 1,600 candle-power. The latter are placed in the ball room and grounds.

A NEW THEORY OF THUNDERSTORMS.—Herr L. Solenche having shown experimentally that the friction of ice and water results in the positive electrification of ice, and consequent negative electrification of water, considers it probable that the friction of cumulus and cirrus clouds, may be sufficient to account for thunderstorms.

ELECTRIC LIGHTING IN MADRID.—We learn from the *Imparcial* that the electric light continues to make progress in Madrid. The experiments recently made by the Sociedad Matriteuse de Electricidad for lighting the Mercantile Club by incandescent lamps having proved satisfactory, that institution is now lighted permanently by 100 Swan lamps.

THE PARIS-CREIL EXPERIMENTS.—M. A. Gravier, writing on this subject to the French scientific press, shows that the quantity of material used in the construction of the generator at Creil, would have been sufficient to furnish with the same current four times the number of volts which were actually obtained, if employed in building Gramme machines of the ordinary "A" type.

ELECTROMOTOR WORKING IN THE STATES.—It is understood that some of the American Companies have decided to supply electric power on the rental system, after the example of the owners of the Bell Telephone patents, and will discourage the sale of their motors out-right. In view of the large number of motors in the market, it is difficult to see what is to be gained by such a policy.

"TECHNICAL" JOURNALISM IN THE STATES.—One of our esteemed transatlantic contemporaries, evidently wishing to be complimentary, thus refers to a certain successful electrician:—"He is a fat and jolly scalper, who can yell like a Comanche, but who is believed to be good for $200,000, and weighs about two hundred and fifty pounds." We take it that this is about perfect of its own kind.

ELECTRICITY IN THE GRAVE-YARD.—At Brooklyn a society is being formed to insure its members against the horror of being buried alive. For the first six months after apparent death the bodies are to lie in unclosed coffins, placed in a large chamber, which will be provided with electric signals for communicating with the world without. It has been suggested that a connection should be made with the Telephone Exchange.

RECENT PROGRESS IN ARBORICULTURE. — "Plainfield, N.Y., is noted for its picturesqueness, which is not in the least detracted from by the telegraph poles in the streets." We quote from a Transatlantic contemporary. It appears that this highly satisfactory result has been attained by causing the poles to be "finely finished and painted to represent trees." And so successfully has the illusion been carried out that we are assured that from a little distance a stranger would not recognise the true character of the vegetation.

AN UNSETTLED CLAIM.—The United States Military Telegraph Corps, a body which performed immense service to the Northern Army during the Civil War, has held an annual *réunion* ever since the war came to a close, although as a body it then ceased to exist. Its services have never yet been recognised by Congress, nor have the members received any honorary distinction. At the *réunion* which has just been held at Cleveland it was, however, stated that a Bill is now to be introduced which will render justice to the claims of the survivors.

ELECTRIC LIGHTING AND THE EYE. — When the electric light first became an accomplished fact, some fears were

Digitized by Google

aroused as to the probable effect of the arc light upon eyesight. However, according to Dr. J. A. Andrews, who recently read a paper on the subject before the American Opthalmological Society, these fears are entirely groundless. As to the incandescent lamp, a very curious fact has been ascertained by Dr. Andrews—namely, that workers by this light who suffered from errors of refraction have found their sight to be materially improved by it.

Exhibition of Telephony.—In January next there will be opened at Brussels an International Exhibition of Telephony. The Exhibition will be held under the auspices of the Société Belge des Ingénieurs et Industries, and it is intended to arrange for a series of historical exhibits showing the progress of the art from its earliest infancy. There will also be a number of "conferences" on the various branches of the subject. On this occasion no charge will be made for space, and all expenses attendant upon the installation of exhibits will be defrayed by the committee.

The American Bell Telephone Company.—From some statistics recently published by this company we learn that the gross output of their instruments during the last six months was 27,961; but no less than 13,407 instruments were returned to the company, leaving a net increase in use of 14,554. During the same period last year 22,204 instruments were sent out, and 17,350 returned, showing an increase of only 4,854. The large number of instruments returned is attributed to the operation of the "Indiana Law" forbidding the maintenance of overhead wires.

The Amount of Light Produced from One Pound of Coal.—Recent tests at the Franklin Institute indicate that the amount of light produced by different methods from 1lb. of coal may now be taken upon an average as follows:—With naked arc lights, 150 candles (with shaded arc lights not more than 60 per cent. of the full light is usually obtained); with incandescent lights 20 candles, and with gas 14 to 17 candles. In this estimate steam coal is supposed to be burned under a good boiler for the electric lights, and the gas is supposed to be obtained from a bituminous coal.

The Henry Electric Railway.—At Kansas City what is claimed as a new system of electric railway has been devised by Mr. J. C. Henry. From the details to hand as to the method of gearing the motor shaft to the axles, and of regulating the speed of the motor, we are scarcely able to anticipate any very great success for this system. The arrangements are said to be "designed to be more or less automatic;" at any rate they succeed in being more or less wasteful of power, and considerably *more* rather than less complicated in comparison with any other system with which we are acquainted.

Wire Gauges.—The question of wire gauges has been under discussion in the United States for a long while past. At one time it seemed probable that the British standard gauge would be uniformly adopted by the American manufacturers. The *Electrical World* is, however, of opinion that quotations will ultimately be made only in thousandths of an inch. In that case we shall be enabled to retain our standard gauge all to ourselves, as there is little chance of its coming into use in France or Germany, where hundredths of a millimetre are almost invariably employed for the purpose.

A Heat-indicating Paint.—We have received from Mr. W. Crookes a sample of a heat-indicating paint. This paint is of a bright red colour when cold, but turns brown when subjected to a certain temperature, regaining its original colour on cooling. It is suggested that the paint will be of value for covering the bearings and other parts of machinery which are liable to injurious heating, so that an attendant may be able to see at a glance, without having to feel, whether any part is becoming hot and requires attention. It is stated that 1lb. of this paint is sufficient to cover 100 square feet.

"Lightning Holes."—On many of the summits of the High Alps, at elevations of 11,000ft. and upwards, certain curious cavities which occur in the rocks have received the name of "lightning holes." Sometimes detached masses of rock are found, having holes bored right through from side to side. Prof. Brun, who has been making a study of these phenomena, writes in the *Archives de Genève* confirming the opinion that they are due to lightning. He finds that the lining of the cavity has been completely vitrified by the passage of the lightning, and sometimes it has been scattered around the margin of the hole in the form of small pearly globules.

The Ohmart Lamp.—An arc lamp which has been devised by Dr. Ohmart is said to burn only 1in. of carbon per 100 hours. Some of these lamps are now in use at Boston; the size of the carbon or the candle-power of the lamp is not stated. The result is attained by enclosing the carbon, together with the mechanism of the lamp, in a sealed glass globe, and at the same time certain chemicals, which absorb carbon dioxide, are introduced—potassic hydrate, for instance. It follows that soon after the arc has been formed it is really burning in an atmosphere containing little else than pure nitrogen. The mechanism is designed to give a continuous feed, and it is said that the lamps may be left entirely without attention for weeks together.

The Carbon Industry.—The rapid and enormous extension of electric lighting in America has created a huge demand for arc light carbons. This industry is, on the other side of the Atlantic, almost entirely confined to the Cleveland district, where there are several very large factories belonging to the Wallace Carbon Company, the Boulton Carbon Company, the Brush Company, and the National Carbon Company. A few weeks ago the last-named company made a single sale of one million carbons. At Forest City a new company has recently started, which makes a speciality of cored carbons. Novel and ingenious machinery has been erected by which the manufacture proceeds with great rapidity. The company has already found it necessary to increase its plant.

The Lighting of Theatres.—Dr. Breslauer, of Berlin, has published an account of some observations which he has recently made upon the atmospheric condition of the same theatre when lit in the first place by gas and afterwards by electricity. The increase of temperature from the beginning to the end of the performance was in each case as follows:—In the pit 2·5°C. for electricty, 25°C. for gas; in the boxes 8·1°C. for electricity, 26°C. for gas. The heat is therefore more uniformly distributed with gas, though this is probably merely a local peculiarity depending upon the ventilating arrangements. The volume of carbonic acid per 1,000 parts was as follows:—In the pit 0·555 for electricity, 3·926 for gas; in the boxes 1·178 for electricity, 4·537 for gas.

Central Station Lighting at Berlin.—The number of lamps supplied by the Staedtische Electricitæt's Werke on the Edison system at Berlin is now about 8,000. The charge per lamp-hour of 16 candles is a fraction under ½d., but in addition to this the consumers pay a rental of 5s. 6d. to 7s. 6d. per lamp per annum, and a further charge of 31s. 6d. for the meter. The cost of installing the lamps and of making connection with the mains is also charged against the consumer. In the neighbourhood of the Frederichstrasse a central lighting station has quite recently been established by Messrs.

Digitized by Google

Siemens and Halske. It is supplied by three *shunt-wound* machines, each for 500 lamps at 65 volts, and driven by separate engines. No further details have yet been made known.

A NEW SPECIES OF GRAPHITE.—M. G. A. Nussbaum is said to have produced a species of graphite whose specific resistance may be made upwards of a thousand times as great as that of the ordinary forms of hard carbon. At present the inventor modestly confines himself to the proposal to employ this material for regulating the amount of light given by glow lamps. This is not a direction in which any great distinction can be achieved. We would rather suggest that M. Nussbaum should turn his attention to obtaining the material in the form of "filaments." If the substance be sufficiently homogeneous it ought to be possible to make a 20 candle-power 100-volt lamp with a good stout ribbon-shaped "filament," which should work at a more economical rate and last longer than any lamp at present in the market.

THE CONDUCTIVITY OF WOOD.—Some experiments which have been tried recently as to the electric conductibility of various woods are of interest. The selected woods were of well-seasoned sound pieces, 3in. by $\frac{3}{4}$in. by $\frac{3}{4}$in. size, into which terminals 2in. apart were inserted, and the resistance of the samples taken between these points. The pieces of wood were kept for some time in a dry warm place to prevent surface conduction by moisture. The resistances obtained were mahogany 40 megohms, pine 214 megohms, rosewood 291, lignum vitæ 397, walnut 478, and teak 734 megohms. These results were obtained with the measuring current flowing with the grain, when taken across the grain the results were 50 to 100 per cent. greater. We believe that these experiments were undertaken on behalf of the United Telephone Company.

THE SUN LAMP AT ROME.—The principal railway station at Rome has been lit by sun lamps for some time past. It has, however, been decided to replace these by ordinary arcs. Difficulties arise with the sun lamp on account of the high temperature to which the whole body of the lamp is exposed. For this reason the cost of maintenance, together with the frequent renewals of the marble blocks, render the system much more expensive than that of open arcs. In addition to this, it is well known that the expenditure of energy per candle-power is very high in this type of lamp. If, however, the constructive difficulties could have been overcome the sun lamp ought certainly to have occupied a field of usefulness midway between the incandescent and the arc lights. But as matters stand, we fear that this, the most beautiful of the semi-incandescent type, is doomed to extinction.

THE THOMSON LIGHTNING ARRESTER.—When any of the numerous types of lightning protectors which are found (more or less) serviceable upon telegraph lines are adapted to arc light circuits, certain serious difficulties arise, for after a discharge has taken place through the protector the line will either be practically short circuited, or else the circuit is broken. To overcome this difficulty Prof. Thomson has introduced a pattern consisting of a V-shaped piece of metal, the two arms of the V being insulated from one another, but approaching within one-sixteenth of an inch. An electro-magnet connected in the line circuit is placed immediately below the fork, and the two arms are joined, one to earth and the other to line. Consequently, if an arc should be momentarily formed after the passage of a lightning discharge, it is repelled by the magnet, and sliding up the V is speedily extinguished.

ELECTRICAL SURGERY.—Upon the 8th August M. Albert Coindeau, while entertaining a select circle of admiring friends by inserting knives, forks, and sword-blades into his œsophagus, unhappily found himself unable to recover a valuable silver-plated fork. This implement measured 8$\frac{1}{2}$in. in length, and weighed over 2oz. Feeling annoyed at the loss, he applied to Dr. Polailler to assist in its recovery. With the aid of an electrical apparatus, designed for the purpose by M. Trouvé, the exact position of the fork was determined, and an incision being made, it was successfully extracted. Unhappily M. Coindeau did not himself survive. M. Trouvé's apparatus consisted of a slender probe, bearing two insulated points at its extremity. These were joined in circuit with a battery, and a not very sensitive galvanometer, so that the current passing was not sufficiently strong to give a deflection until the points touched the metal.

THE SUNDERLAND TELEPHONE EXCHANGE.—This exchange has recently been fitted with the American "multiple" switch-board, which enables a single operator to make connection between any two subscribers, however numerous may be the total number on the exchange. Besides Sunderland, the only towns in this country whose telephone exchanges are at present worked upon this principle are Liverpool and Glasgow. The practical advantages of such a system are very obvious. The system in general use requires the co-operation of two or more operators to make any connections beyond the limits of a single board which supplies some two or three hundred subscribers. The multiple switch-board, while sufficiently simple in working, is, however, a sowewhat complicated apparatus to fit up. At the Sunderland Exchange, where there are at present less than 300 subscribers, over seven miles of wire were used, and about 3,700 connections had to be made.

EARTH CURRENTS.—M. Lauderer has presented to the Academie des Sciénces a further note upon the subject of earth currents. M. Lauderer has a theory that the origin of earth currents may be traced to the action of winds upon the surface of sea and land. In this way he is able to some extent to account for the variable character of these currents, and hence for the rather puzzling fact of their independence of terrestrial magnetism. Monsoons and trade winds, and other more or less constantly directed wind currents, should upon this theory serve to determine constant earth currents in the localities where they blow. This verification of the theory has, however, yet to be obtained. On the other hand, M. Lauderer considers that the coincidence of sun spot maxima and minima with the extreme variations of earth currents tends to confirm his views, because the force of the trade winds is directly dependent upon the heat of the sun.

A MAMMOTH "BRUSH" DYNAMO.—The Cowles Electric Lighting Company are erecting very extensive works at Lockport, N.Y. They will be able to avail themselves of water-power at this place to the extent of at least 2,000 horse-power. The Brush Company are now building for them several dynamos of great size, which are to generate the current for the electric furnaces. The following figures give some of the details of one of these machines which has just been completed. This dynamo weighs altogether very nearly 10 tons; the weight of the armature is 1·92 ton. The total weight of copper used is 6,250lbs. The outside dimensions are 14ft. in length, 5ft. 2in. in height, and 4ft. 2in. in width. The machine is designed to absorb 355 horse-power, to run at 410 revolutions, and to give 3,000 amperes with 83 volts. The field-magnets are shunt-wound, and take a current of 80 amperes. The diameter of the pulley is 40in., and its face 45in. It will be driven by two 30in. Victor turbines.

PHOTOGRAPHY BY LIGHTNING.—Some good landscape photos have recently been taken in the United States by Mr. A. S. Barker by means of lightning flashes during a stormy night.

Digitized by Google

A high wind was blowing at the time, and in one of the positives there are distinct traces of the leaves of the trees having moved during the exposure. The *American Meteorological Journal* is inclined to think that this may be accepted as good evidence that the duration of a flash of lightning is not in reality so short as is usually assumed. But, on the other hand, the *Electrical World* very properly points out that it is sufficient to suppose that more than one flash occurred during the exposure. If the flashes had succeeded each other at intervals of, say, one-tenth of a second, there would have been time for the leaves to move, but to the naked eye the flash would have appeared continuous. In any case the evidence is not sufficient to throw much doubt upon the conclusions drawn from Wheatstone's classical experiments, at least as to the order of magnitude to which the duration of the discharge is to be assigned.

THE NEWCASTLE EXHIBITION.—Our readers are already aware that an International and Colonial Exhibition on a large scale is to be held in Newcastle-upon-Tyne next summer. The site selected is a portion of the Town Moor, including the Bull Park. The annual show of the Royal Agricultural Society will be held on the Town Moor immediately adjoining the Exhibition. The building as at present planned will cover about 250,000 square feet. It will be built in the form of a rectangle, enclosing a garden of about three acres. One of the features of the Exhibition will be a model coal mine, illustrating the different methods of working which have been adopted. The whole Exhibition, including the mine and the garden, is to be lighted with the electric light A special committee has been made responsible for carrying this out, and circulars are being sent to the principal electric lighting companies and firms enclosing plan and sections of the building, and inviting them to state the terms on which they would be willing to light any portion of the building or grounds. We understand that the committee will be glad to send these invitations to any electricians who have not received them, and it is important that all proposals should be in the hands of the committee by the 28th inst. Applications should be addressed to "The Secretary, Exhibition, Newcastle-on-Tyne."

TELEPHONE RESTRICTIONS.—In the House of Commons on Tuesday last Sir H. Havelock-Allan asked the Secretary to the Treasury whether he was aware that the Post Office authorities had recently refused the Northern District Telephone Company permission to run wires for the purpose of telephonic communication over parts of the North-Eastern Railway Company's system, although the railway company was willing to allow the necessary posts and wires to be erected; whether he was aware that, in consequence of that refusal, the telephone company was unable to connect several of the principal firms in Hartlepool with the Telephone Exchange system, thus depriving those firms of the advantage which other traders in the district possessed of telephone communication with the Tyne and Tees districts, and with Sunderland; and whether, in view of the answer, he would state what course the Government proposed to take in the matter? Mr. Raikes replied that the Post Office has, subject to the concurrence of the railway company, granted permission, in some cases, to the Northern District Telephone Company to erect telegraphs on the North-Eastern Railway, and in some cases has refused it. He was not aware that several firms in Hartlepool had been deprived of telephonic communication.

THE PARIS EXHIBITION OF 1889.—The French Government has published a decree containing the regulations for the International Exhibition to be held in Paris in 1889. The following clauses will be of interest to our readers:—The Exhibition will be opened on May 5th, 1889, and will close on 31st October following. In the section devoted to each nation, the exhibits will be divided into nine principal groups, which will be subdivided amongst themselves into classes. The 6th group is devoted to "Apparatus and Processes of the Mechanical and Electrical Industries." Class 62 of this group contains the following subdivisions:—Production of electricity; electrostatic apparatus, batteries and accessories, dynamos and magneto-electric machines, accumulators; transmission of electricity; cables, wires, and accessories, lightning conductors, measurement of electricity, and apparatus connected therewith. Applications of electricity; telegraphy, signalling, telephones, microphones, photophones, electric light, electromotors, electric railways, transport and distribution of force, transformers, medical electricity; electro-chemistry; electro and permanent magnets; mariners' compasses; and electric clocks; various apparatus. No rent will be charged for space at this Exhibition, and motive power will be supplied gratuitously, provided that due notice of requirements be given.

THE LUGO LONG-DISTANCE TELEPHONE.—Mr. O. Lugo has devised an instrument, which is a combination of an ordinary magneto telephone, with a speaking condenser, similar to that originally constructed by Prof. Dolbear. Dolbear's telephone it will, however, be remembered consisted merely of two parallel and opposed plates, connected respectively to line and earth. The present instrument contains from 40 to 50 annular condenser plates, which are placed outside and surrounding the coil of the magnets. One pole of the condenser is connected with one end of the coil and to line, and the other pole to earth, the coil itself occupying the usual position in the circuit. Although we do not quite follow Mr. Lugo's explanation of the action of the condenser as given in the columns of the *Electrical World*, yet from the theoretical investigations which have been made in this country upon the effect of condensers connected with circuits traversed by harmonic currents, and containing self-induction, there can be no doubt that such a combination will have a tendency to assist in the preservation of tones which belong to the neighbourhood of some one particular rate of vibration or its octaves, but whether this action will be of much practical value is extremely doubtful. The volume of sound will also be somewhat reinforced by the articulations of the condenser itself, but this action has not very much to do with the length of line which can be spoken over, a loud-speaking telephone and a long distance telephone being by no means necessarily synonymous terms.

DYNAMO MACHINES AT THE ROYAL GUN FACTORY, ENFIELD. Captain Cardew, when testing three large dynamos recently supplied by Messrs. R. E. Crompton and Co., for the lighting of the new Nordenfelt Gun Department, adopted a novel but excellent plan of testing the efficiency. He took one dynamo and drove it as a generator, with the current from this machine he drove another as a motor, and from the mechanical power generated he drove a third machine as a generator. The electrical output of the third machine was measured by the same instruments as the electrical energy supplied to the motor, and was found to be 86 per cent. of it. If, therefore, the efficiency of these two machines was the same, as it is reasonable to suppose it would be, being identical in pattern, the motor yielded 92·5 per cent. of the electrical energy supplied to it as mechanical work, and the dynamo driven from it returned 92·5 per cent. of this again as electrical energy. This system of testing is absolutely beyond suspicion of error, as all the measurements taken are electrical, and the two tests of readings being taken by the same instru-

Digitized by Google

ments, any errors of calibration or otherwise will cancel themselves, and in no way affect the result. All the machines were quite new, and were hardly worked under the best conditions; so that it is quite possible that their best efficiency approaches 94 per cent. It seems that this plan of testing, where three dynamos are at hand, is the most accurate one that can be adopted, and we think, with Capt. Cardew, that this system will be extensively used wherever the requisite number of machines are available.

SOME REMARKABLE EXPERIMENTS. — M. Henri Möhlenbruck, writing to *l'Electricien*, describes some very remarkable experiments which he has recently performed, and which seem to show that in the mesmeric condition an electric current may have a powerful inductive action upon the human nerves. The experiments were made with an apparatus consisting of a ring of iron wires, wound with silk-covered copper, the latter being placed in circuit with a microphone and a battery cell. The ring was about 9in. in diameter. In the first experiment a watch was placed near the microphone, and the ring was put upon the head of the mesmerised subject. He immediately began to beat time with the ticking of the watch. When the microphone contact was touched with a quill feather he placed his fingers in his ears. The microphone was then removed to a distant apartment, and the connection of the circuit being completed as before, a violin was played in the distant room; the patient showed the most distinct indications that he heard the music. The next experiment was obviously to speak to the microphone. "To my great surprise," says M. Möhlenbruck, "the patient repeated the words." The last experiment described is that of sending a continuous current through the circuit. This had the effect of causing the patient to throw his arms around in a circle in the vertical plane. The direction of motion was reversed with the reversal of the current. When the patient was asked what he felt like, he said he was turning. M. Möhlenbruck concludes his letter by stating that he has made a great many more experiments not less interesting than these, and has constructed many different kinds of apparatus to aid in these researches. He promises to give further details if they appear to be of scientific value. We await these revelations with breathless interest. It is clear, however, that the interests of the Bell Telephone Companies are greatly prejudiced by these researches. In future we shall be able to conduct telephonic communication with only a transmitter and a mesmerised boy.

THE PROJECTED CANADA-AUSTRALIA CABLE. — In the House of Commons this week, Mr. Stanhope, in answer to Sir S. Wilson, said the subject of telegraphic communication between this country and Australia had been brought under the notice of Her Majesty's Government by the Government of the Dominion of Canada, and it would receive careful consideration. The expense appeared to be great, and, until the opinion of the Australian colonies had been taken, the Government would not be able to form any judgment on the question. On the same subject we may give the following extract from a Wall-street journal merely for what it may be worth. Our own opinion is that so long as the scheme is put forward as a commercial enterprise, it has not the smallest chance of being carried out. A rough calculation of the probable outlay involved and a very liberal estimate of the probable traffic suffices to show the impossibility of a remunerative investment being found in this direction. The *Post* has a Montreal special devoted to Canada telegraph plans giving attention particularly to cable plans. Mr. John W. Mackay is represented to be interested in the proposition, and the Canadian Pacific engineer has prepared the following table of routes for the cables:—(1.) Brisbane or Sydney to North Cape, connecting at the former with the Australian Telegraph system, at the latter with the Telegraph system of New Zealand, 1,300 knots; (2.) North Cape to one of the Fiji Islands, 1,240; (3.) Fiji to Fanning Island, 2,270; (4.) Fanning Island to one of the Sandwich Islands, 1,200; (5.) Sandwich Island to Barclay Sound or Port San Juan, Vancouver Island, 2,730; (6.) Barclay Sound, across Vancouver Island and the Strait of Georgia to Vancouver City, the terminus of the Canadian Pacific Railway 100. Geographical miles 8,900. As soon as Mr. Fleming arrives from England a syndicate will be formed probably composed of J. M. Mackay, Hon. D. A. Smith, Sir George Stephen, and some New York and London capitalists, when the company will be launched forthwith. The Canadian Pacific Telegraph system will be opened to the public by the end of the month.

THE CHARGES FOR FOREIGN TELEGRAMS.—On Wednesday last in the House of Commons Sir G. Campbell asked the Postmaster-General why Great Britain charged for telegrams to be sent abroad a rate (1d. per word) much exceeding that charged by France and other countries, and double that charged in the United Kingdom; where the papers were to be found showing how and on what terms the Submarine Telegraph Company obtained a monopoly of the communications between this country and France; and on what terms that company was entrusted with the working of the Government lines to Holland and Germany.—Mr. Raikes, in reply, said that "not a few telegrams contain only three or four words, and the hon. member had not observed that, while a telegram of three words can be sent from England to France for 7½d., a telegram of the same length in this country costs 6d., and in France half a franc. Where there is a word rate pure and simple it is not unreasonable that the charge should be higher than where the word-rate is qualified by a minimum. At the same time I may say that the matters to which the hon. member draws attention are of considerable importance, and that they will form the subject of careful consideration when the relations between the Post Office and the Submarine Telegraph Company are reviewed prior to the termination of the subsisting agreement. The monopoly to which the hon. member refers was granted many years ago by the French Government, and I can only suggest that the papers may have been published in the official journal of that Government. The terms on which the Submarine Telegraph Company is entrusted with the working of the cables to Holland and Germany are stated in the agreement scheduled to the Telegraph Act of 1868. This agreement will be found in the appendix to the report of the Select Committee on the Bill. Fifteen firms connected with the Stock Exchange sent in a petition in February calling attention to delay and irregularity in the transmission of messages from the Continent, and expressing a hope that, when the monopoly of the Submarine Company terminated in 1888, the Post Office would make arrangements to improve the service. The complaint was general, and an answer was sent to the effect that the company did not admit that there was undue delay when the wires were in working order, but that if particulars of specific cases were furnished inquiry would be made. I would point out that the monopoly was not granted by this country, but by the French Government." The Postmaster-General was asked a similar question on Saturday last, and replied that no alteration could be made in the foreign telegrams tariff except at the International Telegraph Conference, which meets every five years.

ON THE TREATMENT OF SECONDARY BATTERIES.*

BY BERNARD DRAKE AND J. MARSHALL GORHAM.

The possession of a reliable means of storing electrical power is now universally recognised. For electric lighting, whether temporary or permanent, whether domestic or public, it is almost an essential—for the commercial application of electricity to motive power it is a necessity. The theory of secondary batteries or accumulators, by means of which this storage is obtained, has already been so ably dealt with, and is, probably, so well known to all present, that it is unnecessary to enter into it in this short paper, the object of which is to bring to your notice some practical points of treatment which are essential in order to render secondary batteries commercially reliable.

These points have been arrived at by experiments carried on by Mr. Gorham and myself, in the course of the manufacture of the batteries of the Electrical Power Storage Company.

The three main difficulties which we had to encounter were—

1. The destruction of the lead grid or conductor.
2. The buckling or warping of the plates.
3. The falling out of the active material.

These three failings, principally affecting the peroxide plates, militated seriously against the commercial success of accumulators, of which durability forms so important a factor. We therefore carried out a large number of experiments, with a view to ascertain their various causes, and, by removing them, to render the secondary battery with which which we had to do as reliable for durability as it already was in other respects.

Here I may mention that these failings, although common, were by no means universal. For instance, the E.P.S. accumulators in the Bank of England have been in use for more than 2½ years, and continue to give excellent results. That they do so confirms the conclusions to which experiment has led us. We will take first :—

(1) The destruction of the lead grid or conductor. This was the most serious difficulty to face, as on it depended the life of the battery.

The prevalent idea was that it was due to overcharging; that after the peroxide plate was fully charged any further charge caused an evolution of oxygen which rapidly destroyed the grid. We therefore proceeded to charge some cells without cessation in order to ascertain the exact amount of current which would entirely destroy the lead conductor or grid. It was soon evident that the process was, at any rate, a slow one; but the experiment was continued, until the full prescribed current had been passed through, for more than two months. At the end of that time it was found that the lead conductor was practically as sound as before charging. The coating of fine peroxide formed on the surface was very thin; there was no sign whatever of buckling, and, further, the specific gravity of the solution, when the cells were left in their then fully charged condition, remained absolutely unaltered. The conclusion thence drawn was that the oxidisation of the grid caused by charging only penetrated to a very limited depth, and then ceased entirely, and that the coating of fine peroxide formed actually protected the grid not only from deterioration by overcharging, but also from local action, hitherto supposed to be unavoidable. It was then established that the life of the grids was not proportional to the amount of charging, *i.e.*, to the number of ampere hours *put into* a cell. Was it due to the number taken out? To ascertain this was the object of the next experiment.

For this purpose a battery was divided into two halves, one of which (A) was repeatedly run out, and the other (B) was never discharged beyond the point at which the E.M.F. commenced to drop. This experiment also extended over a considerable time, but gave the instructive result that when exactly the same number of ampere hours had been taken out of each half, the plates in the first half (A) showed signs of expansion or growing, whereas in those of the second half (B) no change could be detected. The life of the grid then was also not dependent on the *amount* of ampere hours taken out, or on the work done, but on the treatment of the plates, first as to charging up, and afterwards as to total or partial exhaustion. Further, it was satisfactorily proved that there was no necessity to employ a conductor of unoxidisable material, providing the simple precautions were taken—

1st. To fully charge the cells.

2nd. To avoid discharging them entirely.

The second point to be considered is :—

(2) The buckling of the plates.

This had hitherto been attributed to two or three causes—charging too rapidly; discharging too rapidly; impurities in the acid or oxides employed. Experiment soon showed that the real cause must be sought for elsewhere. We found that the buckling was almost invariably accompanied by a hard white enamel (sulphate of lead) on the face of the plates, and further, that where the extra cells in a battery had received more charging than the remainder, the plates in these cells were frequently quite free from sulphate, and the consequent tendency to buckle, while the rest of the battery had failed. This proved that the enamelling could be prevented by charging, and was not due to impurities in the oxides or acid used; further, that when the plates were free from sulphate there was no tendency to buckle. Experiment also showed that in the case of the first use of cells, when the acid was first put in, the specific gravity dropped in spite of the charging, indicating the formation of sulphate; by persevering in charging the sulphate disappeared, and with it the tendency to buckle. The conclusion was then that in order to avoid buckling of the peroxide plates, cells on their first use (whether new or after long disuse) should be charged incessantly until they are considerably over-charged. Hence the radical change in the instructions issued to users of the E.P.S. Batteries. Whereas hitherto they had been specially cautioned against overcharging, they are now urgently required to overcharge new cells and to charge incessantly.

(3) The separation of the active material. In almost every case where this occurred the plugs of active material fell out of the plates in complete halves and in a very hard condition; and analysis showed that they contained an excess of sulphate, due, as before explained, to insufficient charging. On the other hand, in a few instances the active material was found to have become disintegrated and fallen off in a fine powder, and this was specially observable when on account of a leak in the receiving vessel and consequent frequent addition of water, the solution had become extremely weak. In this case practically no sulphate was present, and the mass lost cohesiveness.

The conclusion is, then, that a certain proportion of sulphate in the material is necessary to bind together, but that excess must be avoided. This due proportion once ascertained the third difficulty is overcome for all the ordinary work of secondary batteries.

It should be mentioned, however, that there is a constant demand for an accumulator which can be discharged without injury at an abnormal rate for special purposes. Such rapid discharge results at present in the scaling off of the oxides and destruction of the plates, but as it causes the formation of sulphate, which is the binding not the disintegrating agent, the cause of the scaling, and, therefore, its remedy, must be sought elsewhere, and on this point discussion is invited.

I venture briefly to recapitulate the conclusions to which our experiments have led us.

1st. That the life of the leaden grids or conductors, and their freedom from buckling, are in no way dependent either on the amount of charging or discharging of the cells.

2nd. That cells on the occasion of their first use, and also after long intervals of idleness, should be very fully charged, and in the first case incessantly.

3rd. That they should never, under any circumstances, be entirely run out, and, in fact, should not be discharged below the point at which the E.M.F. begins to drop perceptibly.

4th. That the coating of fine peroxide formed during charging is actually a protection to the plate against the injurious effect of over-charging, and against local action.

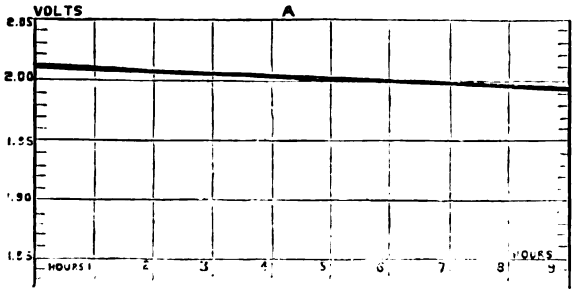
5th. That a certain small proportion of sulphate is necessary to give cohesiveness to the active material, but an excess of it causes the oxide to separate bodily from the conductor.

* Paper read before the British Association at Birmingham.

Digitized by Google

If the precautions here indicated be taken, we believe that the accumulators now made by the company with which we are connected will answer every ordinary commercial requirement during a very considerable time, but an accumulator is not at present known which, without sacrificing capacity and efficiency, will stand the extraordinary rate of discharge sometimes demanded. As we thought it might be of interest to give some reliable figures on the results which may be expected from cells as they are now made, we have, during the last few weeks, made very careful tests with some cells taken at random from stock and worked in accordance with the practical requirements of an electric light installation.

It will be seen from the curve marked A, which is the mean of six consecutive discharges, that the E.M.F. is practically constant during a discharge of such duration as the cells would ordinarily be called upon to give, namely, 9 hours, the fall of

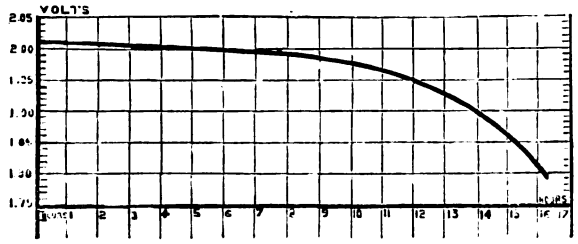


Curve A.

electromotive force during this period amounting to only ·02 of a volt. When the cells were discharged for 4½ hours, left standing for a day, and then discharged for another 4½ hours, the result was exactly the same as when the discharge was continuous, both as regards E.M.F. and efficiency. In fact, we were able to obtain a short time back from a similar cell, left fully charged for a month, an output of 380 ampere-hours.

The charging of the cells under test was always continued for about an hour after the gases commenced to be given off, so as to comply with the requirements of our working instructions, and to keep the plates in good order. This naturally reduced the efficiency or return both in ampere-hours and watt-hours; but in spite of this overcharging the result of six consecutive charges and discharges gave an efficiency of 90 per cent. ampere-hours and 80 per cent. watt-hours.

Curve B shows the capacity of the cells in ampere-hours when discharged at 25 amperes rate, and is the mean of two continuous discharges. It will be noticed that with 10 per

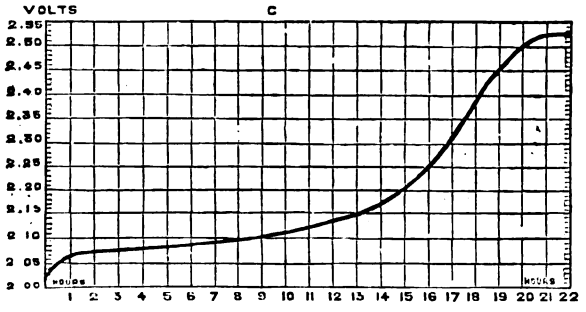


Curve B.

cent drop of E.M.F. the capacity is over 400 ampere-hours, and that the maximum output given in the lists of the company is reached with a drop of under 5 per cent. in E.M.F.

The curve marked C shows the rise of E.M.F. during the charge, the current being throughout kept constant at 22 amperes. It will be seen that at the commencement of the charge the E.M.F. required was only 2·02 volts, that after 220 ampere hours had been put in, representing about half the charge, the E.M.F. had risen to 2·13, and that when the cells were giving off gases freely the E.M.F. was as high as 2·53 volts. This curve will no doubt be of interest to those who manufacture dynamos for use with secondary batteries, as it shows clearly the range of E.M.F. for which provision has to be made if the current is to be kept constant. In most instances, however, we arrange for a maximum E.M.F. of 2·5 volts per cell to be charged, and allow the rate of charging to be diminished as the cells become full.

The cells tested were of the 15 L type, and contained 7 peroxide plates weighing 36lbs. in all, and 8 of spongy lead weighing 33½lbs. These plates are not made to give the maximum output from the minimum of weight, but the chief consideration is durability coupled with efficient working. They give a capacity of about 5 ampere-hours per lb. of plate, which in the S type plates is increased to 6½ ampere-hours per lb. for tramcar work; and where durability is of minor importance there is no difficulty in obtaining considerably higher results. The internal resistance of a single cell was measured during discharge, and found to vary from ·0012 ohm when the cells were fully charged, to ·0026 ohm when discharged, to 10 per cent. drop of E.M.F. This was tested by observation of the volts, first on open circuit and after-



Curve C.

wards discharging at a known rate, but owing to the tendency of the cells to rapidly recover their E.M.F. when left partially discharged, it is somewhat difficult to get reliable results after the E.M.F. has dropped to any extent.

We are convinced that the above figures are absolutely reliable, as the strictest precautions were observed by Mr. Butler, the head of our laboratory, in calibrating the instruments used and checking the results. The current was measured by frequent readings from a Siemens dynamometer, checked by a voltameter, the two being found to agree within 1 per cent. The E.M.F. was measured with a reflecting galvanometer calibrated by means of Clarke's standard cells and freshly made Daniel cell, the total resistance of the galvanometer circuit being 40,000 ohms.

PRIMARY BATTERIES.*

BY A. RÉNÉ UPWARD.

After briefly reviewing the forms of primary battery from the simple elementary cell to those of Daniell, Grove, Bunsen, &c., the author points out that the quantity of current given by the combustion of a given weight of zinc is the same in all batteries, but not the work done by the battery. The E.M.F. is proportional to the net gain of power in the chemical reactions.

The difficulties in the way of obtaining a perfect battery having been recapitulated, the author's battery, the chief characteristics of which are the use of free chlorine gas and the absence of polarisation in consequence of hydrogen not entering into the reactions, was described. The zinc being always in a solution of zinc chloride no local action occurs; there is no fear of mixing of liquids, as only one liquid is used. The further advantages of this form of cell are enumerated as follows:—

No fall in E.M.F., due to the solution becoming weaker, as the outer cells are always full of practically pure chlorine gas; no acids used in the cells (only pure water added); no liquids to remove; absence of smell or fumes; no amalgamation of the zincs; no destruction of the terminals; economy.

The chlorine generator and gasholders were described, as well as the chlorine cell itself, the battery, and the arrangements for the continuous automatic supply of gas to the cells.

Discussion.

Mr. Desmond FitzGerald said he would like to point out in connection with the sentence in Mr. Crawley's paper, reading "a gas instead

* Paper read before the British Association at Birmingham.

Digitized by Google

of a liquid to act upon the zinc," that it was perfectly understood by all electro-chemists that if chlorine were brought into contact with zinc directly, whether or not there was carbon in the same electrolyte out of contact with the chlorine, the zinc was consumed entirely by local action without any possibility of obtaining a current. Therefore, it was altogether a mistaken idea to suppose that in the Upward battery the chlorine acted directly on the zinc. The ultimate result might be the same as if it did, but the principle to be followed in the construction of the battery undoubtedly was to bring the chlorine into contact with the carbon only, and as far as possible avoid any contact between the chlorine and zinc. To another statement made by his friend and old pupil, Mr. Crawley, he must demur, namely, that chloride of zinc solution had no action upon zinc. Chloride of zinc solution, as a matter of fact, had a very powerful action on zinc, a fact which all those who had had occasion to observe the extreme facility with which sub-chloride of zinc and the basic chloride of zinc were formed would be able to appreciate. In regard to Mr. Drake's paper, he could only compliment the E. P. S. Company on the energy and the measure of success with which they had overcome the inherent objection to their negative element, which was that it contained the elements of destruction within itself.

Prof. BLYTH said the storage cell was now so perfect that one felt that the attempt to construct primary batteries for electric lighting to compete with them had but little chance of success. He was very glad, however, to see so good a battery brought forward.

Prof. SILVANUS THOMPSON said he had made an experiment to test the statements current with reference to the chlorine battery. He took an ordinary cell of glass and placed it in two porous pots side by side. In one of these he placed a stick of zinc and in the other a plate of carbon, and the whole thing was filled up to a certain height with water, with a little chloride of zinc dissolved in it. He thus had a strong solution of chlorine and water. This produced absolutely no effect upon the E.M.F. when poured around the zinc, but raised the E.M.F. to the full value when poured around the carbon. He, therefore, concluded that the chlorine was an excellent depolariser, and that this was its function in the Upward battery. He looked upon Mr. Upward's battery as an extremely ingenious and possibly valuable way of making a constant Leclanché cell, by putting the manganese in a separate generator to evolve the chlorine separately, and then transferring the chemical action from the generator and distributing it through tubes to the respective cells. With respect to the formation of sulphate of lead in the battery which Mr. Drake's paper dealt with, it was pretty clear from the therma-chemical data, if anyone took the trouble to work out the thermal values of the connections, that the only chemical explanation that could be given of the battery was that the real electrolyte was sulphate of lead, and yet, in spite of that, if they got too much sulphate of lead in the battery, it became almost unworkable. He had made an inquiry into this, and the result he came to was that the sulphate which was disastrous in our batteries was not the ordinary sulphate of lead, but was the basic sulphate, for he had no difficulty at all in reducing, by protracted charging, the ordinary sulphate Pb SO_4 to spongy lead or to peroxide. But in the case of a battery that had been left partially discharged there was this same sulphate of lead in the presence of a partially deoxidised peroxide, giving rise to a reaction between the lower oxide and the sulphate, and to the formation of the irreducible basic sulphate Pb_2 SO_5. The latter was a hopelessly bad conductor. Mr. Drake said his figures, where the efficiency was expressed in ampere-hours, were 90 per cent., and the efficiency in watt-hours was 80 per cent. There was something curious about this, and he thought the whole thing wanted carefully defining, for he did not think so close an agreement as 80 or 90 per cent. was obtainable, seeing the difference between the E.M.F. and the internal resistance during charge and during discharge.

Mr. PREECE said that in practice the resistance of a secondary cell in discharging was very much less than it was in charging. There was a remarkable fact connected with secondary batteries that had not yet received the attention it deserved, namely, that not only was the resistance of a secondary battery cell when being discharged very much less than when it was being charged, but the resistance varied with the current of discharge. The larger the current of discharge the less the resistance, and the result was that a secondary battery was an automatic governor. In lighting up with the secondary batteries it had been thought that if the number of lamps was added to, some special contrivance would be needed to make the E.M.F. constant, but owing to this remarkable fact of the varying resistance, the E.M.F. remained practically constant. He could speak with experience of the use of the E.P.S. cells, for he had employed them for the purpose of lighting his house during the whole of the present year. The cells had been greatly improved of late, and they now left nothing to be desired. During the time he had used them he had never observed a flicker or had a disturbance or alteration of any kind, and he attributed that principally to the fact that he had implicitly obeyed the instructions given by the company. They did not receive the rough treatment which at one time the E.P.S. Company used themselves to give them. He had seen the company short-circuit a cell and raise a platinum strip a quarter of an inch thick to incandescence. They might anticipate, he thought, that secondary cells would last thoroughly for ten years or more. With regard to primary batteries, the function which the Upward battery was intended to fulfil was rather the function now performed by the gas engine than that of the primary battery. Mr. Upward used a secondary battery to light up a house, but the primary battery kept the secondary battery properly charged. Being in continuous use for 24 hours, the secondary cell was well charged when the time came to light up. He had during 30 years had something like 300,000 primary cells under observation, and, therefore, could speak of them from experience. He did not look upon primary batteries with any favour for electric lighting purposes. But the Upward battery had started quite a new feature, and was a very promising battery. He did not like the smell of chlorine, but when all difficulty with regard to leakage had been got over he thought there were a great many places (in the country particularly, where gas could not be produced) where this battery would come in very usefully for small installations. With regard to Prof. S. P. Thompson's remarks, the efficiency of a secondary cell was certainly 80 per cent. He had kept an accurate record of current that went into the battery, and the mean of current that came out of it, during the last twelve months, and he certainly got an efficiency out of his cells of 80 per cent.

Prof. SILVANUS THOMPSON said his remarks with reference to the internal resistance of the battery were more particularly in relation to what happened if the same current were used in charging and discharging.

Mr. HENRY LEA said he had used, since October or November last, 24 E.P.S. cells for lighting his house, and although the observations had not been taken continuously, as far as he could judge of the action generally of the batteries, Mr. Drake's statements had been borne out. The batteries should be well charged; no harm would be done by overcharging them, and as long as they were frequently overcharged they would preserve their good condition, as far as could be judged from the appearance of the plates.

Mr. R. E. B. CROMPTON said he regarded a good primary battery as a great desideratum, but he must concur with a previous speaker who pointed out that after all it was only proposed that the primary battery should take the place of the gas engine and dynamo, and must compare with that plant in facility of working and in cost. He was sorry to say that there was such competition in the manufacture of engines and machines that the cost of those parts of an installation was now so small that he did not think Mr. Upward could get below it. He could speak with experience on the subject of accumulators. He had employed them in central station lighting, and was carrying out a large experiment in making accumulators take the place of the gasometer in gas works, for he was convinced that that was the only way in which they could be properly employed in central station lighting. He had been working entirely with the view of getting a certain weight of lead and not a greater number of ampere-hours, and greater rapidity of discharge. He had already succeeded in getting a rapidity threefold greater than the company had obtained. Nothing greater than three amperes per square foot of peroxide plates had been mentioned, but he had got to 9 or 10 amperes without in the least damaging the cells. That was to say his cells ran down in one-third the time. He thought the reason of this was that the plates employed were comparatively homogeneous. They consisted of plates of lead cast in a particular manner, becoming porous in the act of casting, and subsequently sawn into thin plates, capable of giving a very heavy discharge indeed without any sign of distortion or any sign of flaking or of the active material being thrown to the bottom of the cell. He attributed the lack of flaking to the homogeneous nature of the plate. When the plate consisted of a grid pasted with a comparatively soft material, under the severe action of a heavy discharge there were distorting actions set up in the plate and a twisting or buckling of portions of the surface. That was perhaps a very crude way of explaining what took place, but he had watched it himself and knew that that was exactly what happened. But when a porous plate was employed consisting of a number of cellular things like a honeycomb, the whole of the interior of the surface being covered with an active material, this throwing down could not take place. The exterior surface was so small in extent that it did not matter. That was one way out of the difficulty of getting rapid discharge from accumulators. He could second what Mr. Preece had said as to the resistance of accumulators. A great portion of the work done in accumulators in the charging was done in the latter part of the charge. What appeared to be resistance mounted up very rapidly; that was probably due to bubbles of gas on the surface of the plate. As everybody wished to charge very fully, they continued to charge until bubbles were formed, and consequently a great deal of work was done on the plate which was never got back as useful work. He would not say that he had got absolutely 80 per cent. from his cells, but he had got very near to it.

Mr. SWAN asked whether, in the Upward battery, chlorine produced from hydrochloride of lime had been utilised. It was exceedingly cheap, costing only about £6 or £7 per ton, and it would seem to offer a means of getting chlorine in a very simple manner. After the nauseating repetition of very small changes in the form of primary batteries claiming to be inventions, even if only a change in the form of the vessel from square to round, it was quite refreshing to see some new departure. This battery of Mr. Upward was a new departure in the use of an excess depolariser almost automatically combined. The great difficulty seemed to him to be—and he admired the bravery with which that difficulty had been encountered—to prevent any escape of chlorine. Unfortunately the smallest escape of chlorine—and it seemed impossible to prevent a small escape—would be a quite fatal objection to its use with any comfort in the house, considering how pernicious chlorine was and how it corroded all kinds of metal.

Mr. G. K. WINTER spoke of the governing power of the battery in connection with its use for the lighting of trains. Although, of course, the secondary battery put on as a shunt on the dynamo was perfectly able to keep the E.M.F. from rising too high, provided the storage batteries had enough, yet in lighting trains it was of very great importance to get the storage batteries as small as possible, and find some other device to prevent the E.M.F. from rising too high for the safety of the lamps.

Mr. CRAWLEY, in reply to Mr. FitzGerald, said they were well aware of the fact that when Bl was in direct contact with Zn, there was a furious reaction, which was entirely local. But, in point of fact, there was *no* free chlorine whatever in the chlorine cell, for a weighed zinc plate hung up in a cell for days suffered no diminution of weight. Mr. FitzGerald also said that $Zn Cl_2$ *should* act on Zn and form sub-chlorides; perhaps

Digitized by Google

it should, but in practice they did not find it do so appreciably. A piece of cleaned raw roof zinc was weighed and found to be 233·2 grains; it was then wrapped round with clean iron wire to promote local action, then placed in $Zn Cl_2$ solution taken from a working cell and left for days, at the end of which period it was unwound, well washed and wiped, and weighed 232·9 grains; loss, 0·3 grain. If this sub-action existed, therefore, it was so small as to be completely negligible. The theory which Mr. Fitzgerald had shown by means of the blackboard was that which they published some months ago in the pages of the *Electrical Review*, but which he (Mr. Crawley) omitted in reading the paper, as he had been particularly asked to be as brief as possible. In reply to Prof. Blyth, first, the battery did not compete with secondary batteries; on the contrary, for lighting purposes it was always worked in conjunction with them. 2nd. They had had a battery at work for nine months continuously. 3rd. The resistance of the porous pot did not vary at all; by using pots of proper porosity the zinc chloride solution was kept somewhere between 1·2 and 1·4 sp. gr.; there was no practical variation of resistance, as the specific resistance of $Zn Cl_2$ solution was between those rather wide limits practically constant. Prof. Thompson had spoken of Cl as the depolariser, which was, perhaps, natural at first sight. But a depolariser implied the existence of H, and as far as he had yet tried, nothing of the action in which H came in could give the E.M.F. which the cell did. On the other hand, the E.M.F. of the cell was practically identical with that due to the direct combination of Zn and Cl. The action took place electrolytically, certainly, and not directly; but if Prof. Thompson would look into the action he would find that, nevertheless, the final effect was that the E.M.F. was that due to the direct combination. Mr. Crompton said that the battery could never compete with the dynamo for cheapness. It would in any but what he would consider very small work never attempt to do so. But for such small work as must be done by batteries—and there was a great deal—it was the one which did its work with no waste of zinc, with the very cheapest possible chemicals, and the minimum of attention. In reply to Mr. Swan, they had worked with chloride of lime, but so far without very satisfactory results.

THE CENTRAL STATION AT ST. ETIENNE.

The Edison installation at St. Etienne, to which we have already briefly referred, presents several points of considerable interest, especially as the work has been carried out in the face of difficulties, in some respects of the same character as those which are likely to present themselves in this country. St. Etienne, as most of our readers are aware, is a large manufacturing town in the south-east of France. The district to be lighted lies in the centre of the town, where ground space is very valuable. It was therefore found necessary to place the machine room entirely outside the district, and at a distance of nearly 100 yards from the nearest lamps. This is, of course, a serious matter when a parallel system of distribution is adopted, and still more when, as in the present case, a simple two-main circuit is laid down. The installation is to be capable of supplying 3,000 lamps, for which 400 horse power will be provided; at present, however, only one half the total plant is required. The whole of the machinery, boilers, engines, dynamos, and subsidiary apparatus had to be placed in a building covering only 200 square metres of ground space, and in addition to this special precaution had to be taken to avoid any annoyance either from smoke, noise, or vibration to the houses on either side. The fact that these difficulties have been successfully grappled with undoubtedly reflects great credit upon the engineers, Messrs. V. Bietrix et Cie., by whom the arrangements were designed and carried out.

It was of course necessary to make the most of the vertical space. The boilers, four in number, were therefore fixed side by side in the basement. The four engines were placed on separate foundations built up between the boilers to a height of 18ft. from the basement. The engines are compound and non-condensing—water is dear at St. Etienne. They make 160 revolutions per minute, and at a pressure of 85lb. develop 70 to 75 horse-power. Under 155lb. of steam in the smaller cylinder the power is increased to 180 or 190 horse-power.

The cylinders, which are placed in tandem, are steam jacketed, and owing to the elevation of the engines above the boilers, the jackets are well drained and the water of condensation is returned to the boilers. The live steam is thus kept very dry. The consumption of fuel is said not to exceed 2·5lb. per horse-power per hour.

Each engine has a fly wheel on either side, and from one of these it drives by belting on to a countershaft, which runs the whole length of the room. This countershaft is placed, however, at a lower level than the floor of the engine room, so that it comes between the engines and the boilers. The dynamos are bolted to a substantial masonry foundation, which is built up from the basement to a height of 17ft. 4in. from the level of the boiler room. This masonry also serves to screen the heat and vibration from the party wall of the adjoining building. The lower part of it is also built into the brickwork of the furnaces, and forms part of the foundation of the chimney shaft, 150ft. in height. The dynamos are thus at a slightly lower level than the engines, but they are in the same apartment, and the belts by which they are driven from the countershaft come up through the vertical space thus exposed.

As all the engines drive on the same countershaft, any one or more of the engines and any one or more of the dynamos can be worked together. The eight pulleys upon the countershaft are provided with friction clutches, so that any required change can be made with great ease. The feed water is heated by means of the exhaust steam, and injectors are provided in case of accident to the feed pumps. The four boilers are all connected to one main steam pipe, so that any one or more can be employed with any one or more of the engines. The boilers are provided with electric apparatus to maintain the water level.

Turning next to the electrical arrangements, there is nothing particulaly noticeable in the Edison dynamos except that they are *not* of the improved Edison-Hopkinson type. They are each intended for 500 lamps of 16 candles and 110 volts. They are all normally connected to the same main collector, which conducts the current to the switch-board. An ammeter and a voltmeter are provided for each machine, and any of the feeders can be thrown in or out of circuit as may be required; the usual and well-known details of the Edison system are, in fact, carried out in their entirety, including the signal lamp connected through an earth circuit to give an idea of the insulation of the line. This remark applies, however, only to the indoor arrangements; out of doors the Edison conductors have been abandoned in favour of ordinary cables.

Considering the great good sense and judgment exhibited throughout this installation we are not surprised at this change. We have never been able to perceive any advantage in Edison's hemispherical conductors which could compensate for the large number and difficult character of the joints which are required. The method adopted for determining the dimensions and distribution of the conductors and feeders is noteworthy, and, though scarcely in accordance with the ideas of English electricians upon the subject, may yet prove serviceable with certain modifications (although we are not much inclined to think that a simple two main parallel distribution is ever likely to be undertaken in this country). In the first place it appears that the mains themselves, as distinguished from the feeders, were carried round the circuit just as required, and are apparently all of the same size throughout. It is then determined to allow a uniform fall of potential of 10 per cent. between the terminals of the machines and the extremity of the feeders. The problem is then considered to be reduced to that of determining the number, position, and dimensions of the feeders which will give this result—presumably under the condition of all the lamps being alight at the same time, as 10 per cent. is to be the *maximum* loss of potential. In order to determine these points a model of the district was prepared, and conductors were put in which represented the actual resistances of the circuit (including the lamps), both in position and in amount. By means of a battery arranged so as to have an E.M.F. of the same proportionate value, and connected to the proper points, the best size and position of the feeders were then determined experimentally. This empirical method is ingenious, and answers its purpose so far that it leads to a solution by means of which the required service can be maintained in the leads, but of course it cannot yield an economic solution. It seems to us that the proper way is to follow Thomson's law as far as possible, and only depart from it when, as is sometimes the case, it involves a variation in potential exceeding the required limits.

THE POST OFFICE TELEGRAPHS.

Pressure on our space has compelled us to omit our usual review of the POSTMASTER GENERAL'S ANNUAL REPORT, which was issued at the commencement of the present month. Its interest and importance, however, demand some notice at our hands, even now. Lord WOLVERTON'S Report includes the first complete half-year of work under the revised tariff for telegrams, and we naturally turn to its pages to learn what has been the outcome of the financial experiment about which so much was predicted, for and against, in the autumn of last year. The scheme has now been in operation nearly a year; and, on the whole, we think its advocates have reasons to be satisfied with the result. They can at least show that the revenue is gradually improving on itself, and may, if it keeps on growing at the present rate, overtake the profit balance under the old tariff within a calculable number of years. On the other hand, its critics and opponents are afforded some grounds for their opposition by the accounts now published, which are brought down to the end of March of the present year. A loss of £40,233 is a sufficiently formidable sum for a Department which, during many years past, has uniformly boasted of being an earning and not a spending branch of the public service. Nevertheless, it may be urged that the penny post was introduced with a loss that was not made good till comparatively recent times; and those who think that the Post Office and the Telegraph are analogous businesses, are entitled to augur favourably from the history of the former.

In one respect the analogy is more close than it was a few years ago. Formerly it had to be pointed out that a telegraph wire is not a letter-bag, and that the cost of every telegram was a fixed sum, whereas, roughly speaking, the cost of despatching a bag of letters was the same whether the bag were full or half full, large or small. But the progress of electrical invention has done something at least to lessen this distinction. With the aid of multiplex telegraphy the capacity of the conductor has been immensely augmented; and the adaptation of the Wheatstone fast-speed system to multiplex lines has increased their powers in even greater proportion. To most of the great centres of industry telegrams are now sent, so to speak, in bundles, and their despatch approximates more and more to the transmission of carriers by pneumatic pressure, and letter-bags by railway. In this respect the electrical branch of the English Telegraph Department is ahead of every other telegraph service in Europe or the United States; and its limits of expansion in this direction have probably been well nigh reached, though the area of extension will of course enlarge with the development of traffic in districts that are at present adequately served with the ordinary appliances. The mistake which is made by the fanatics of cheap telegraphy is in supposing that any increase to the means of transmitting messages quickly and cheaply will everywhere be followed by a proportionate increase in their number. This has not been the case in countries where cheap telegraphy has long been the rule, and is not likely to be so here. A large addition to the number of telegram senders has doubtless resulted from the reduced charges; but the bulk of the increase lies with the regular class of customers who now send more telegrams because their cost is less.

The increase of messages under the reduced tariff has probably realised the highest expectations, the number being 16,787,540 in the last half of the year, against 11,314,423 under the old rate in the first half. Some error appears to have crept into the Report on page 9 in regard to the decrease of revenue, which is so stated that precisely the same difference is shown between the first and second halves of 1885-6, and the last halves of 1884-5 and 1885-6—a coincidence too extraordinary to be true. However, the loss on the year's receipts for the transmission of messages is what we have stated above, though fortunately the net revenue is not affected to nearly this extent. Some note is taken of the growth of business since the end of the financial year, and the figures are very remarkable. In April the number of messages was 40 per cent. over the number in April, 1885, and the receipts only £11,800 less. In May the increase was 51 per cent., while in June the percentage of increase had risen to 61, and the revenue was actually £2,800 in excess of the amount received in the corresponding month last year. Some further explanation would have been acceptable here; for without it we are unable to understand how an increase of 61 per cent. in the number of messages has more than balanced the lowering of their initial cost by 100 per cent. But probably the average payment per message exceeds the minimum charge in a higher ratio under the sixpenny tariff than it did under the shilling tariff.

One item of revenue is somewhat startling. No less than £18,214 was received during the year 1885-6 in fees for registered addresses. A hint is let fall that the abuse of this privilege may lead to its curtailment, and we are not surprised at it. On expensive lines, and lines of very limited capacity, where the saving of a few words is not only a boon to the sender, but is welcome also to the administration, the

Digitized by Google

registration of abbreviated addresses is a perfectly legitimate arrangement. On inland lines with a popular tariff there is absolutely no justification for such a system at all. It is employed, to our own certain knowledge, as a means of advertisement, and is cheap at the price. But it is very dear to the Telegraph Departments, who are put to a vast deal of trouble for a very small payment, and who are deprived of a legitimate part of their revenue by a mere commercial subterfuge. The rule operates very harshly, too, on persons who are well enough known without their full address, but who now, as has recently been pointed out, "cannot be found," because their addresses have not been registered, there being other people of the same name in the vicinity. Thus the Department, while anxious to restrict the practice, virtually encourages the public in patronising it. When it is seen that a good deal of delay must arise from these abbreviated addresses, we may expect that many people will discontinue their fees. What will happen then? We confess we see no escape but by abolition of the system altogether in connection with inland telegrams. For the present the Report merely points out that "it would be much more to the advantage of the public to have their inland messages addressed in such a manner as would secure their immediate delivery without reference to records."

CORRESPONDENCE.

A SMALL ARC LAMP.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The progress of electric lighting some time ago created a field for arc lamps, of simple and compact construction and reasonable cost, which could work with a small current and in the same circuit with incandescent lamps, connected in parallel with each other.

For some time past I have made experiments with different kinds of such lamps, the most satisfactory coming under my notice being the Siemens and the one which I shall attempt to describe in the following lines.

Unfortunately, these lamps do not work without a resistance inserted in series with them. This circumstance not only involves a considerable loss of energy, but increases the first cost of the lamp; besides, as the resistance is considerable, it occupies so much space that it is not an easy matter to hide it away from sight.

The most satisfactory arrangement with respect to steadiness of light is as follows:—To obtain 65 volts as pressure on the mains, 40 volts pressure on lamp and a resistance of 8·3 ohms in series with the lamp, the current being 3 amperes, length of arc 1mm, and candle-power 150. We have thus—

Total energy used per lamp	$65 \times 3 = 195$	volt-amperes.
Energy lost in heating	$25 \times 3 = 75$	,,
Energy utilised in lighting	$40 \times 3 = 120$	,,

the loss being therefore about 38 per cent. I may here mention that the greater the current necessary for the lamp the less the loss in heating the requisite resistance becomes.

Thus, for instance, if the current is 6 amperes the pressure on lamp should be 44 volts, pressure on mains 60 volts, length of arc 2mm., and candle-power 300. Therefore,

Total energy used per lamp	$60 \times 6 = 360$	volt amperes.
Energy lost in heating	$16 \times 6 = 96$	,,
Energy utilised in lighting	$44 \times 6 = 264$	,,

the loss being therefore about 27 per cent.

If the current is 9 amperes, the pressure on lamp should be 48 volts, pressure on mains for a steady and reliable light need only be 58 volts, length of arc 3mm., candle-power 450. Therefore

Total energy used per lamp	$58 \times 9 = 522$	volt-amperes.
Energy lost in heating	$10 \times 9 = 90$	,,
Energy utilised in lighting	$48 \times 9 = 432$	,,

the loss being therefore 17 per cent. Now, in most cases this loss can be conveniently obtained if the branch leads are of iron instead of copper wire.

Thus, although most of the original difficulties encountered by designers and makers of such lamps have now been got over, this great difficulty of doing away with the resistance connected in series with each lamp, when several lamps are working in parallel with each other, has yet, I think, to be overcome.

The lamp I wish to describe is essentially electrical in its regulation. This is perhaps effectually settled by the strong necessities of cheapness and simplicity of construction. The principle of the lamp is that of a Gramme dynamo acting as a motor, and in determining the various proportions the following requirements must be attended to:—

Firstly, the armature should have two separate circuits of two distinct sorts of wire wound on it, the thick wire being in the main circuit, and the thin wire in the shunt circuit (in Fig. 1 the thick wire is represented by the shaded parts).

Secondly, there should be two separate and adjustable brush holders, one for each circuit (they are not represented in either of the figures), but there is room for the one above the armature and for the other below. They can be very conveniently fixed to the two pole pieces; the upper commutator is shown.

Thirdly, the ratios of currents and diameters in the thick and thin wire circuits on the armature must be such that when the arc is of normal length the polarities produced by the ampere turns of the two different circuits on the iron core of the armature should exactly balance, and the armature should remain stationary.

Lastly, the ampere turns of the main and shunt wire circuits wound on the magnet cores, should be more or less identical, and should be so connected up that the different circuits on one side produce one and the same pole, on the other side the opposite pole.

By calculation the following results are obtained for a lamp working with three amperes and 40 volts:—

(α) The shunt wire on the magnet cores. Per core—diameter 0·35mm., layers 47, turns 8,695, resistance 154·5 ohms, ampere turns 1,050.

(β) The main wire on the magnet cores. Per core—diameter 1·2mm, layers 4, turns 240, resistance 0·5 ohm, ampere turns 720.

(γ) The shunt wire on the armature core. Per division—diameter 0·25mm., layers 10, turns 250, resistance 6 ohms, ampere turns 12·5.

(δ) The main wire on the armature core. Per division—diameter 1·5, layers 2, turns 8, ampere turns 12.

And although the requirements are thus carefully attended to, it is advisable when regulating the lamp to the greatest nicety to try the effect of different shunts on the currents in the two different armature circuits. When the most sensitive arrangement is discovered, then the necessary shunt resistance can be introduced into the lamp in the form of a bobbin wound with german silver wire. When the polarity produced by the thick wire on the armature is stronger than the counter polarity produced by the thin wire, this occurs either when the carbons are together, or when the arc is less than of normal length. Then the armature revolves in that direction which raises the upper carbon; when the arc becomes too long, the armature revolves in the opposite direction, and should gently feed the upper carbon downwards.

Fig. 1 represents the upper portion of lamp in plan; the parts shown are armature, commutator, pole pieces, iron cores and bobbins of wire, respectively denoted by letters (a) (c) (p) (c) and (b). Fig. 2 represents the lower portion of lamp, and likewise the upper portion in elevation; the parts shown are the screw (s), which can be regarded as an elongated axis of the armature, the upper carbon holder (h), the lower carbon holder (h'), the lever (l) attached to the lower carbon holder for adjusting the lower carbon accurately opposite the upper carbon. This is effected by moving the lever (l) somewhat to one side, thereby releasing a screw and thus giving the carbon holder freedom for movement in any direction; the lower

carbon holder is insulated from all the other parts of the lamp. The arrangement for lifting the upper carbon holder up and down the brass side tubes; this is effected by lifting the weight (*w*), by which movement the small comb (*x*), gearing into the screw (*s*), is pressed back, and the upper carbon holder can be moved up or down. An insulated copper wire descends the right hand tube, and is attached to the under carbon holder.

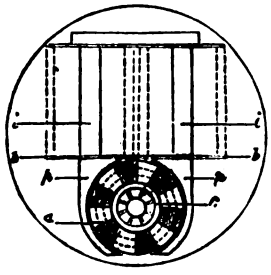

FIG. 1.

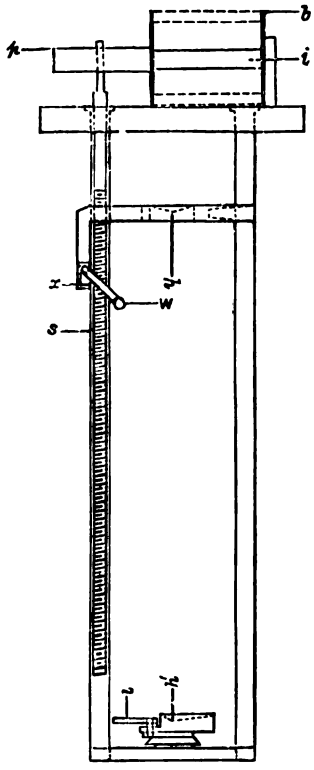

FIG. 2.

The carbons used are, above, a Siemens cored carbon, diameter 11mm., length 200mm.; below, a homogeneous carbon, diameter 6mm., length 200mm. These carbons burn with a current of 3 amperes, and an arc 1mm. in length for ten hours.

For the extra resistance which it is necessary to insert in series with the lamp, german silver wire of 1·2mm. diameter can be conveniently chosen; 10 meters of such wire make a spiral coil 20in. long 1in. diameter, and have a resistance of 1·7 ohm. The drawings are a quarter of natural size.—Yours, &c,

H. E. C.

LITHANODE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Without accepting the terminology mixed up with some parts of Mr. FitzGerald's article under the above dubious title, I cannot help feeling interested in the description of his experimental investigation of the subject. A brief recapitulation of my unwitting manufacture of "lithanode" nineteen years ago will perhaps strengthen rather than hinder Mr. FitzGerald in the pursuit of his experiments. In 1868 or 1869 Mr. Faure came to me with samples of his carbon bottle battery as a great improvement on Bunsen's. I bought some on trial, and found them about half as good as described, but still very good. I showed Mr. Faure the sulphate of lead battery I was using in large quantities, which, since the great practical improvement I had made in it, appeared to me to be perfectly satisfactory. I made a further slight improvement in it, and patented it in 1873, but the battery Mr. Faure saw was as follows:—In a three-pint stone jar, a cylinder of zinc presenting 60 square inches of surface on each side contained within it a porous jar, which again contained five thin sheet-tinned copper cups supported on a central wire. In the outer jar was put sea salt and water, and in the inner jar the cups were filled with sulphate of lead. The exact nature of its action could hardly be demonstrated until it had been in use some months. It then showed that in spite of the great weight of the lead sulphate, the whole of each mass was supported—raised—from the copper cup about a full sixteenth of an inch, resting on a layer of minute bubbles of hydrogen gas. The lead sulphate was in process of electrolytic conversion into peroxide, and in most cases it took about 18 months to convert the whole mass in each cup into a hard black lump. A primary battery could be thus serviceably utilised whilst producing the solid plates of "lithanode" described by Mr. FitzGerald. Instead of the half spherical cups, the lead sulphate should be contained in flat dishes, pressed down by weights of some inoxidisible material. After proving the trustworthiness of the battery above described in such important cases as the Grand Hotel at Scarborough, which, with over 340 bells in use, was in good order after 18 months, nothing but the small size and cleanliness of the Leclanché battery could induce me to give the latter the preference. Indeed, such experiments as Mr. FitzGerald's may cause a return to the lead battery as a primary battery.—Yours, &c.,

WALKER MOSELEY.

WINDING GALVANOMETER COILS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should like to be informed by one of your numerous readers the way coils of astatic reflecting galvanometers are wound. Are they first wound on a skeleton frame, and solidified in paraffin wax, and then slipped into the boxes of the coil frame? A sketch of the tool used would simplify matters. On opening the coil (if hinged on frame) to look at the magnet, one sees no flange on the inner face of the coil, but the layers of wire are visible.—Yours, &c.,

London, Sept. 8, 1886. G. H. HEMECANS.

THE TELEPHONE SYSTEM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am afraid the letter under the above title, signed "Telephone," is not likely to be backed up in the way that is necessary for immediate reform to be effected; but the attempt to rouse attention is natural and praiseworthy. I do not deny the *possibility* of reforming the telephone management in this country, for I have done more unlikely things myself; but there seems to be a peculiar paralysis affecting all telephone enterprise in Britain, and it is so little understood, and no single individual can afford to devote the requisite time to the work, otherwise the most obstinate, the most cunning, or the most imperious of telephone managers would have to succumb if the simple facts connected with British telephone exploitation were fully exposed. After being a year in the service of the United Telephone Company I had to draw up a report of things as I found them, and in self-defence I printed the report for the edification of the directorate. This was three years ago, and still that report would substantially apply to the present time. The criticism of "Telephone" is milk and honey compared to it. There is practically a deadlock in the development of one of the most useful inventions ever known. The remedy most likely to be effective promptly is to get a memorial from telephone subscribers, electricians, and others to the Board of Trade showing the justice and necessity for the present Patent Law to be made retrospective as regards the telephone. In the present law it is provided that if there be any reasonable evidence that an invention is not being supplied to the public in a satisfactory manner, the invention may be made by others, and a reasonable royalty awarded to the inventor or assignees after due investigation by the tribunal provided for in the said Act.

There would be nothing inconsistent or extraordinary in the proceedings I recommend. If the Board of Trade would not directly take the initiative in introducing a short Bill to meet the case, they would hardly refuse to facilitate the matter in other ways.

If the telephone invention is to be looked upon as an unconsidered trifle, then let it be held in the legal vice of private monopoly for four more years, when the patents lapse. The new birth will astonish the present "exchange subscribers."—Yours, &c.,

WALKER MOSELEY.

ABSOLUTE NEGATIVE CHARGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I beg to thank Mr. Williams for troubling to reply to my letter; but at the same time I must say that I cannot agree with all that his letter contains in support of the word electrostatics. No doubt it is convenient at times to make use of words and examples which only apply in part to the subject under consideration; still, it is advisable to dismiss them when they have performed that part, otherwise the part which did not apply might lead to confusion. Thus, electrical action is often explained by reference to hydraulics; if electrical action were to be compared to hydraulics in every case, I am afraid it would soon be found that "electricity into hydraulics won't go."

I apologise for again referring to a subject which perhaps only interests a few and bores a great many; for although a theory is necessary to understand a subject, yet practical application is of a more useful and enduring nature, and of greater interest to the general reader. With the advance of practical science many theories have been formed and many upset, while many more may be awaiting the same fate. I fear that if Mr. Williams's letter were to remain unanswered, I would appear to acquiesce in all it contains, and to abandon the views I expressed in my previous letter.

I agree with everything except that which relates to electrostatics. Unquestionably the word electrostatic was applicable to the double-fluid and single-fluid theories; when it was thought possible to have isolated charges of plus or minus electricities; to have an electric charge bound. But it seems that with the reasoning of the molecular theory the word static is out of place, the present explanation of the static circuit being so nearly akin to that of the dynamic. I fail to grasp the idea that leakage is an accidental action, but rather the natural action of electricity in completing its circuit, by distribution on substances in that circuit, in the inverse ratio of their conductive resistances.

I hope to be excused in giving the following illustrations to make my meaning appear clearer:—

In every text-book on electricity a list of substances is given, beginning with the best dielectric and ending with the best conductor. About half-way down the list we emerge from dielectrics into conductors. So we might expect that on a circuit consisting of dry ice and oil, static action would be manifest on one half of the circuit and dynamic on the other! Again, the action which takes place in a

circuit consisting of a battery, an insulated iron sheathed cable, and a condenser, the further plate of the condenser and one pole of the battery being put to earth, explained with the use of the word static, may prove, if it proves nothing else, that the words static and dynamic used in connection with electricity have a closer relation to each other than the explanation of the two words as given in a dictionary would warrant. Thus, talking of electricity in the form of a current, we would have dynamic electricity along the metal conductor, static on the condenser plate, static on the dielectric separating the two plates, and, I suppose, static and dynamic in turns on the further plate of the condenser. Whether static or dynamic electricity completes the circuit by returning to the negative pole of the battery I will not attempt to explain; perhaps a little of both. Of course, a similar action would be taking place between the conductor and the sheathing of the cable, but in a lesser degree, on account of the greater resistance, or lesser inductive capacity of the insulating material of the cable, compared with the dielectric in the condenser. Is it by accident that the electrical action takes place between the two plates of the condenser? I am afraid the telegraphing public would be rather alarmed if they were informed that their messages were transmitted merely by accident.—Yours, &c., LIONEL E. CAINE.

Villa Real, Algarve, Sept. 9, 1886.

INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will anybody be kind enough to give me the following instructions? Is there a way to stop the induction or suppress it between telegraph and telephone wires, and how?—Yours, &c., AMATEUR.

THE "VOLTA."

The electric launch "Volta," which made the passage from Dover to Calais and back on Monday last, was built at Millwall by Messrs. Stevens and Smith, the electric fittings being designed throughout by Mr. Reckenzaun. The "Volta" is an undecked boat, 37ft. in length, 7ft. beam, and draws about 24in. when fully loaded. Underneath her deck floor she carries 61 accumulator cells, each containing 39 plates and weighing when filled about 72lb.; thus the total weight of the batteries was over two tons. The boat herself, with all other fittings, weighs five tons, and on Monday, with her passengers on board, the total weight could not have fallen far short of eight tons. The cells have a capacity of about 240 ampere-hours; the normal rate of discharge is about 28 amperes, which, at 120 volts, is equivalent to 4½ horse-power. Dividing 240 by 28 we get 8½ hours as the maximum period of discharge. The exact time occupied by the Channel voyage, both ways, was 8 hours 5 minutes, and during this period she covered at least 50 miles on the outward trip, the tide having carried her some considerable distance out of her straight course. The result thus shown cannot fail to be considered satisfactory, but at the same time it is fair to add that upon this occasion the weather was everything that could be desired, the sky cloudless, and "the narrow seas" as quiescent as by any chance they ever are.

Returning to technical details, the motors, two in number, are of the well-known Reckenzaun type, their armature shafts are mechanically coupled, and they drive the screw directly without intermediate gearing, an arrangement, which obviously offers great advantages in the way of simplicity of construction and absence of noise and vibration. All on board remarked the extreme smoothness of working, which, in this respect, is far superior to anything that can be attained by a steam launch. The screw is three-bladed, 20in. in diameter and 11in. pitch. Its normal speed is 600 revolutions per minute, and the type has been specially designed by Messrs. Stevens and Smith, after numerous experiments with various forms of screw-blades for running at a high velocity.

The motors are series-wound, the resistance of the field-magnets being 0·2 ohm and the armature 0·16 ohm, and they weigh about 4cwt. each. By means of a switch, which alters the electrical connections, three different speeds may be attained, of which the details above given refer to the slowest, the motors being then coupled in series. By coupling in parallel, which is effected by a single motion of the switch handle, the current is increased to 90 amperes, and the revolutions to 1,000 per minute, and about 14 horse-power is then developed. Of course, this rate cannot long be maintained, but it is extremely valuable in case of an emergency to be able to drive for a short time at high speed. Under these conditions the boat makes 12 or 14 knots an hour. The third speed is attained by sending the current through one motor alone; this gives 800 revolutions with 60 amperes. It may be noted that when working normally with the two motors connected in series the current through each section of the armature wire will be $\frac{28}{2} = 14$ amperes; when the two are worked in parallel the current will be $\frac{90}{4} = 22{\cdot}5$ amperes; but when a single motor is used the current increases to $\frac{60}{2} = 30$ amperes, more than double the normal armature current. The direction of rotation is reversed by reversing the current in the field-magnets, and without shifting the brushes, the latter having no lead in either direction. Under all circumstances the full number

Digitized by Google

of cells are retained in circuit, so that the battery is always charged and discharged as a whole.

The voyage on Monday was effected almost without incident. We left the Admiralty Pier at 10:40 a.m., reached Calais at 2:32 p.m., started on the return journey at 3:14 p.m., and landed at Dover at 7:27. Although the return voyage occupied the longer time by about 20 minutes, yet the outward trip was actually longer by from two to three miles. The difference in time was mainly due to the slight breeze which in mid-Channel blew from the N.E. Soon after leaving Dover a gannet was seen floating on the water fast asleep. Before he quite realised his position one of the crew had him safely on board. It proved to be a very handsome bird, as large as a goose, and was brought ashore alive and unhurt.

The good people at Dover took much interest in our proceedings, and seemed to be under the impression that the "Volta" was intended to be placed upon the route to compete with the "Calais-Douvres."

As a matter of fact it may be well to add that the owners of the boat do not attach any exaggerated value to their enterprise from a scientific, or even from a technical point of view. At the same time they are undoubtedly entitled to congratulation on having made a highly successful demonstration of what can, under favourable circumstances, be accomplished by an electric launch, and all those who took part in the proceedings will retain pleasant recollections of the first occasion on which the Channel has been traversed by electric power.

WELDING BY ELECTRICITY.

A NEW APPLICATION.

Prof. Elihu Thomson, whose name is so well known in connection with the remarkable "Thomson-Houston" system of arc lighting, has recently given attention to the subject of welding by electric heat, and has attained results which bid fair to become of the highest practical importance. It is a well-known fact that it is a matter of the utmost difficulty to weld two pieces of metal together without leaving a more or less conspicuous bulge at the joint. In the case of wires it is quite impossible by ordinary methods of welding to avoid a considerable thickening.

Prof. Thomson has, however, found that if by suitable arrangements a powerful current be passed through the two ends of the wire while held in position, they unite together with a perfectly welded joint, which is nearly uniform in texture with the rest of the wire. This joint can be bent, twisted, hammered, and drawn without rupture.

Copper, brass, iron, steel, and German silver wires may not only be welded together by this process, but it is also easy to join German silver or brass to steel or iron, and doubtless other combinations will succeed when tried.

The manner in which the idea is put into practical operation is extremely simple, and will be readily understood by reference to the accompanying illustrations, Figs. 1 and 2, which we copy from the *Electrical World*. As will be seen, wires from an alternating source of electricity are led to a coil, P, wound round one side of an iron ring, F. A secondary coil, S, consisting of a few turns of heavy copper cable, is wound upon the same core. A resistance, R, is placed in circuit with the primary, so as to vary the strength of the current, and a switch, Z, permits of breaking the circuit at will. The ends of the secondary coil are attached each to one of a pair of copper blocks, L, L', which carry clamps for holding the wires in position, and for rapid manipulation they are hinged, as shown in Fig. 2. A nut, N, and a compressed spring permit the arms to be drawn together.

The wires being brought into contact by gentle pressure, the current is allowed to pass, the ends of the wires fuse, and, being pressed together, form a perfect welded joint.

Of course it is important that the wires shall be clean to insure good contact, and though usually the joint is well formed without any flux, such as borax, there is no objection to its use in slight amount in certain cases.

The advantages which this method presents over the usual manner of jointing must be evident. It enables the accomplishment in an easy manner of what was before very difficult or impracticable.

This method of welding is not confined to the electrical art alone, but promises to be of great benefit in the mechanic arts in general. By its means, chain links, rings, &c., can be easily welded, and the wires composing endless iron and steel cables can be joined without splicing, leaving the cable of uniform section throughout. Any wire can evidently be made practically of any length and without a perceptible joint. The invention also presents a great advantage in joining the ends of steel band saws, permitting the formation of joints without heating the metal to any considerable distance on each side of the joint, so that temper, elasticity and finish remain uninjured. Other applications will readily suggest themselves, and the invention must be looked upon as one of the most important of the recent applications of electricity.

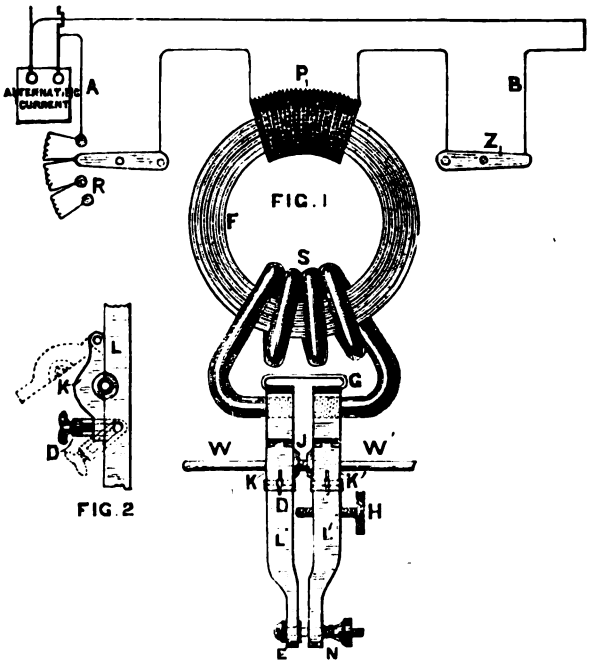

FIG. 1

FIG. 2

From the easy manner in which even heterogeneous metals are joined by this process, it would appear that the passage of the current in the presence of heat puts the metal in a peculiarly favourable condition, so that it welds easily. Hence Mr. Thomson proposes, in the case of large pieces, where the current alone would be insufficient to engender a welding heat, to heat the pieces additionally by external means, the presence of the current acting so as to make the weld more perfect.

A MERCURIAL AIR PUMP.*

BY JAS. T. BOTTOMLEY, M.A., F.R.S.E.

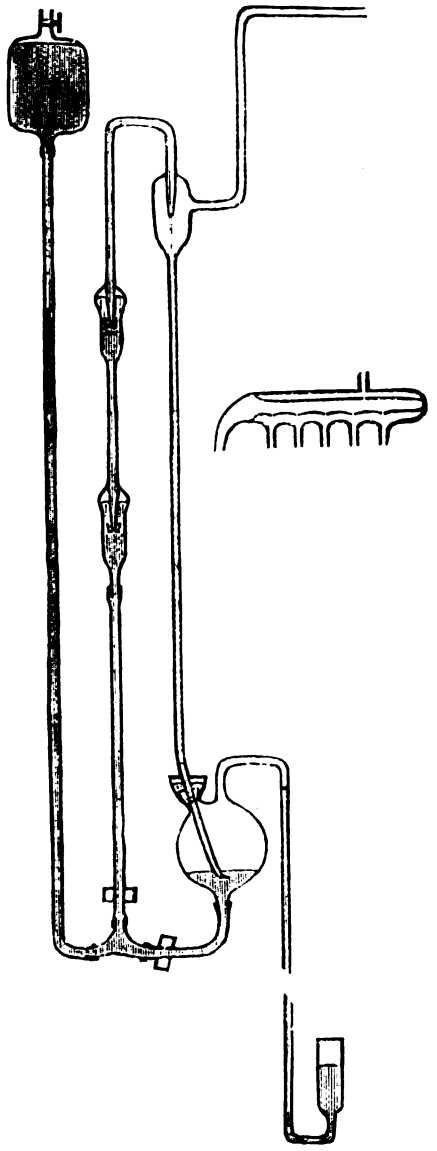
The primary object of the pump described in this paper is the removal of the mercury, which works the pump, from contact with the external atmosphere. When the Sprengel pump is used for producing and maintaining a nearly complete vacuum during a course of experimenting, which lasts over a good many days or weeks, it is found that the mercury running down through the pump and discharging into the open air, takes up minute quantities of air, which it carries with it in a state of very intimate mixture. This air intimately mixed with the mercury is not given up in passing through the air traps, but is deposited upon the walls of the pump head, and collects there into bubbles, which, though at first exceedingly minute, gradually increase to a sensible size. These bubbles ultimately escape from contact with the glass and deteriorate the vacuum.

The pump to be now described, as will be seen from the diagram, consists of a combination of a single-fall Sprengel with a Geisler pump; and, in addition, the moveable reservoir is furnished with an air-tight stopcock by means of which

* Paper read before the British Association at Birmingham.

Digitized by Google

the air is got rid of from that reservoir and prevented from re-entering. In using the pump it is first worked as an ordinary Geisler pump till nearly all the air of the space to be exhausted has been removed. In this way advantage is taken of the comparatively great speed of the Geisler pump. When a good exhaustion has been obtained the stopcocks and the lift of the movable reservoir are so managed that the pump is thereafter used as a Sprengel, the small remaining traces of air being pumped by the Sprengel into the exhausted chamber of the Geisler; and when a sufficient quantity of air has been collected in this chamber, it can be removed by a single Geisler operation.



ON AN ELECTRIC MOTOR PHENOMENON.*

BY W. M. MORDEY.

About fifteen months ago, on the occasion of running and testing a Victoria electric motor in the works of the Anglo-American Brush Electric Light Corporation, an unexpected phenomenon was observed to the writer and his assistant, Mr. Watson. The motor was a 30 horse-power series-wound high-tension machine constructed to work with a current of 20 amperes. When the driving generator (a large Brush machine wound for 20 amperes) was started, the motor connected in the circuit also started, but ran slowly, and developed but little power. As there was apparently some fault in the connections, or elsewhere, it was necessary to examine the machine and circuit. In order to stop the motor, the circuit was broken by taking one of the leads out of the terminal to which it was connected. On doing this the motor, which at the time was running slowly in the usual direction, stopped suddenly, and instantly ran backwards—*i.e.*, in a direction reverse to that which was usual, at a rate of speed rather greater than its former forward rotation, slowly decreasing in speed until it stopped. It appeared at the first glance as if some connection still existed with the generator, but this was not the case, and it became evident that the machine contained within itself the cause of this behaviour. An examination of the circuit revealed the fact that the fields of the motor, instead of being joined in series with the armature, had, by mistake, been placed as a shunt across it. Otherwise, everything was in proper order. When the connections were put right, the motor ran without any unusual feature.

In considering the action to find the cause of the reversal, it will be seen in the first place that the slow speed at which the motor ran when connected with the generator was the result of the smallness of the current in the armature. The winding being intended for a series connection, the resistance of the fields was comparatively low, and when the armature and fields were connected in parallel, almost a normal field was produced, the armature receiving only a small portion of the current. To understand what took place when the circuit of the generator was opened it is only necessary to consider the case of any shunt motor. We know that when a motor is running its E.M.F. is, as it were, always trying to send a current in an opposite direction to that which is being forced through its armature. On cutting off the supply of current, this opposing E.M.F. is able to assert itself, and the motor becomes converted into a generator, the momentum of the armature and of any machinery that is being driven keeping up the motion for a short time, and causing the armature to generate a current, which circulates through the armature and fields. In fact, the shunt motor under such conditions acts like a series generator with its terminals short-circuited, the momentum of the armature and of any connected machinery being quickly exhausted, and the armature coming to rest. The intensity of this breaking action depends to some extent upon the form of the "characteristic" of the machine when working as a generator. Properly constructed shunt motors, having fields wound to a comparatively high resistance, do not show this action to any marked degree, unless a suitable external circuit is provided, because the high resistance of the field circuit prevents the generation of more than a small current; and shunt motors, which are incapable of acting as shunt generators, do not exhibit it at all. But most machines which are provided with shunt fields, the resistance of which is low, show it very clearly, and in a series machine on short circuit—that is to say, working merely through its own low resistance fields, as in this case—the action may be very strong, especially if the generating "characteristic" is not readily made to drop. Thus the armature is quickly brought to rest. But this does not explain why, when it had actually stopped, the armature started again in the opposite direction with a considerable velocity. This will be understood by referring to the figures. Fig. 1 shows the connections and the course of the current when the motor is supplied with the

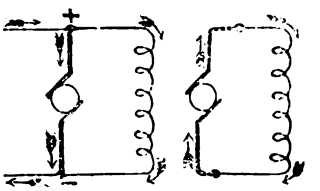


Fig. 1. Fig. 2.

current, and when it may be supposed to be running forward in obedience to the action of the current. Fig. 2 shows the direction of the current under the two conditions which successively occur when the external circuit is broken. In the first place, as already explained, on opening the external circuit, the momentum of the armature causes a current to be generated, which, it will be seen, flows through the armature in a direction opposite to that in Fig. 1,

* Paper read before the British Association at Birmingham.

Digitized by Google

but in the same direction in the fields as before. This at once stops the armature unless the momentum is very great. Secondly, the momentary induced (extra) current follows in the same direction, at the moment when motion has ceased, and causes the armature to start again in the reverse direction.

This extra current is produced in both the armature and field magnet coils, but mainly in the latter, as the self-induction in them is comparatively great.

It may be of interest to add that the motor in question has for several months been working very successfully in New Zealand, where it is used to supply power to the machinery at the Phœnix Gold Mine. The current is generated by Brush dynamos driven by water power at a considerable distance from the mine, and is conducted to the motor by means of a copper wire the size of an ordinary telegraph wire (·165in. in diameter) supported on poles. The total length of the conductor is six miles.

This is a case of the installation, amongst the mountains of a remote colony, of apparatus by which 30 horse-power is being transmitted by a wire, of which five miles weigh less than a ton, with an effective useful return of over 65 cer cent., no skilled labour being supplied or required. There is nothing in this instance of transmission which scientific men can regard as novel, but it is an eminently practical one, and I may, perhaps, therefore, be permitted to draw attention to it in this place, because, although a great deal has been written as to the possibilities of the electrical transmission of power, there is still a scarcely-concealed scepticism on the subject.

It had been proposed to utilise the breaking power of motors by turning their momentum to account for the purpose of stopping them. I do not think this should be done. If power is to be wasted, by all means waste it in the brake block, or somewhere where it can do no harm, and not in a dynamo where excessive and sudden loads are very objectionable. Only in two cases would I recommend the use of motors as generator brakes. First, where a collision or accident of some kind could thereby be prevented, and, second, where the power generated could be utilised, and not simply wasted in heating the machine.

While speaking of electrical motors another point may be mentioned which is of some interest.

In Marcel Deprez's experiments in France failure seems to have been caused by the extra currents, induced on opening the circuit of the motor, breaking through the insulation, and special precautions have been taken to reduce the current very considerably before the circuit is opened. In motors this is less necessary than in generators. It is well known that if the armature circuit of a shunt generator is opened a very considerable arc may be formed by the continued generation of current at the moment of breaking the circuit and by the extra current. In series of generators a similar, but perhaps more severe, effect is produced, although if suitable care in construction is taken no breach of insulation need occur. I may mention that I have frequently opened the circuit of Brush generators, giving from 2,000 to 3,000 volts and 10 amperes by withdrawing one of the wires from its terminal, and I have never broken down a machine by doing so, although the arc which has followed the wire has been fully 12in. in length.

But what I wish to point out is the difference between the behaviour of a shunt generator and a shunt motor if the armature circuit is opened. In the case of the former, a very severe arc may be formed, as everybody knows who has lifted one of the brushes when such a machine was running. But in the latter case—that of a shunt motor—one of the brushes may be removed from the commutator with the formation of only a very small arc. It will readily be seen why this is so. In the motor armature there is an opposing E.M.F. very nearly equal to the supplying E.M.F., and consequently the extra current effect is greatly subdued, any extra current from the line passing through the field-magnet coils.

The problem of how to stop a motor without first stopping the generator seems to me, therefore, to be a very simple one, and undeserving of the very elaborate and ingenious devices which have been considered necessary in connection with the very interesting experiments already alluded to which have been going on for some years in France.

To stop the current at the generator possibly requires more care, and where the machine cannot be readily stopped the excitation of the fluids should perhaps be reduced before opening the armature circuit. The case of a series motor is rather different, but is not the same as a series generator, as it is practically only the extra current from the field-magnets which has to be considered.

DESCRIPTION OF EXPERIMENTS FOR DETERMINING THE ELECTRIC RESISTANCE OF METALS AT HIGH TEMPERATURES.*

BY J. T. BOTTOMLEY.

This paper gives an account of apparatus and experiments for the purpose of determining the electric resistance of certain platinum wires at temperatures varying from 0° C. up to a temperature of dull redness, or even a little higher. The wires experimented upon are wires which have been used and are in use in investigation of heat radiation at different temperatures in vacuums in air and other gases. The necessity for knowing with accuracy the rate of variation of electric resistance with temperature of the wires was explained in previous communications (1884-1885) to Section A of the British Association. The variation of electric resistance of platinum with temperature differs so much in different specimens that it is necessary to determine its value for each particular wire which is used in the investigation just referred to. The principal apparatus described are an air thermometer and a copper heating jacket, but a somewhat detailed account is also given of other heating apparatus employed and the electrical arrangements. The air thermometer used is shown in the diagram. It is formed from a piece of thin glass tube from $\frac{3}{8}$in. to $\frac{1}{4}$in. in internal diameter. This is allowed to fall in before the blow-pipe, and drawn out to a capillary tube at each end, and one of the ends A is conveniently turned up along the side of the bulb. The length of the bulb is from 2in. to 2$\frac{1}{2}$in. The thermometer is filled with perfectly dry pure air with the help of an aspirator, and the capillary tube A is closed by drawing off a small portion by means of a finely pointed blow-pipe flame, care being taken that the blow-pipe flame does not play on the open end, which might contaminate the air within. When a number of those bulbs are made and filled at one time, the end B is also closed after the filling with pure air, and the thermometers are then ready for use. When the thermometer is to be used it is placed in position, and very soon after the heating commences the end B of the capillary tube is opened with a file. When the bulb has taken the temperature which is to be measured a hand blow-pipe is brought and B is closed again. The thermometer having been removed from a hot space it is allowed to cool, is carefully cleaned if need be, and is then weighed. The weighing so obtained (after a small correction for air contained which it is often necessary to apply) gives the weight of the glass. The thermometer is then immersed in mercury or water which has been boiled and cooled (water is preferred by the author for reasons stated), and the extremity of the capillary tube is cut with a glass knife. The water entering fills the space with the exception of the air which was left in the thermometer at the high temperature. A second weighing is then taken. Lastly, the end B is opened and the thermometer is filled with water, and the third weighing is taken. The small portions of glass cut off are of course weighed with the thermometer, and care is taken as to drying the outside of the thermometer from weighings 2 and 3. A barometer is also read at the closing and at the opening of the thermometer, and the temperature of the water used is noted. Also the observed barometric pressure at opening is corrected from vapour pressure when

* Paper read before the British Association at Birmingham.

Digitized by Google

water is used, care being taken to ensure as far as may be done that the air left in the thermometer is saturated with moisture, though the experiment is carried through with tolerable quickness to avoid loss of air by absorption in the water. Weighing number 1 being subtracted from weighing number 3 the whole volume of the thermometer (which must be corrected for expansion of the glass) is obtained. Weighing number 2 being subtracted from weighing number 3 the volume of air at high temperature is obtained. From the ratio of these two volumes the temperature is calculated by well-known formulæ. For temperatures below redness the thermometers are made of German or some hard English glass for higher temperatures of combustion tubing. A few words will suffice to describe the copper jacket. It consists of a considerable number [eight exhibited] of sheet copper cylinders, each having a bottom put one inside the other. These concentric cylinders fit each other very closely, there being only space for the lapping, with a few turns of the thinnest asbestos thread to hold them together and keep an air space of perhaps $\frac{1}{32}$nd of an inch. The internal diameter of the innermost cylinder is about 1in. A stopper of woven asbestos closes the open end of the innermost cylinder, and supports the air thermometer of the electrodes of thick copper, to which the platinum wire to be tested is attached by silver soldering. The platinum wire is in the form of a spiral, with turns well separated and wide enough in diameter to admit the bulb of the air thermometer. A very powerful Fletcher's solid flame burner gives ample heat to raise the whole copper cylinder and its contents to redness. Experiments described have shown that the temperature within the copper cylinder may be kept for any length of time so constant that there is no variation of electric resistance perceptible with exceedingly sensitive electric measuring apparatus. Temperatures lower than 300°C. have generally been detertermined with the aid of the vapour of liquids at high boiling points. A very convenient series of organic liquids was proposed by Doctors Ramsey and Young two years ago. The determination of the electric resistance of a wire was made by the potential method. An electric series is formed, consisting of a high gravity Daniel, the platinum coil to be tested, a known coil of platinoid on the inside of a large tin vessel filled with cold water (which contains a lump of slaked lime to prevent rusting of the vessel), lastly, a rheostat to regulate the series. Electrodes of a high resistance (10,000 ohms) galvanometer are clipped on alternately to the standard coil and the platinum wire under test.

THE BRITISH ASSOCIATION MEETING.

PRESIDENTIAL ADDRESS.

(Continued from page 370.)

This consideration opposes enormous physical difficulties to any theory of alternations of the oceanic and continental areas, except locally at their margins. I would, however, refer you for a more full discussion of these points to the address to be delivered to-morrow by the President of the Geological Section.

But the permanence of the Atlantic depression does not exclude the idea of successive submergences of the continental plateaus and marginal slopes, alternating with periods of elevation, when the ocean retreated from the continents and contracted its limits. In this respect the Atlantic of to-day is much smaller than it was in those times when it spread widely over the continental plains and slopes, and much larger than it has been in times of continental elevation. This leads us to the further consideration that, while the ocean-beds have been sinking, other areas have been better supported, and constitute the continental plateaus; and that it has been at or near the junctions of these sinking and rising areas that the thickest deposits of detritus, the most extensive foldings, and the greatest ejections of volcanic matter have occurred. There has thus been a permanence of the position of the continents and oceans throughout geological time, but with many oscillations of these areas, producing submergences and emergences of the land. In this way we can reconcile the vast vicissitudes of the continental areas in different geological periods with that continuity of development from north to south, and from the interiors to the margins, which is so marked a feature. We have for this reason to formulate another apparent geological paradox, namely, that while in one sense the continental and oceanic areas are permanent, in another they have been in continual movement. Nor does this view exclude extension of the continental borders or of chains of islands beyond their present limits, at certain periods; and indeed the general principle already stated, that subsidence of the ocean-bed has produced elevation of the land, implies in earlier periods a shallower ocean and many possibilities as to volcanic islands, and low continental margins creeping out into the sea; while it is also to be noted that there are, as already stated, bordering shelves, constituting shallows in the ocean, which at certain periods have emerged as land.

We are thus compelled to believe in the contemporaneous existence in all geological periods, except perhaps the earliest of them, of three distinct conditions of areas on the surface of the earth. (1) Oceanic areas of deep sea, which always continued to occupy in whole or in part the bed of the present ocean. (2) Continental plateaus and marginal shelves, existing as low flats or higher table-lands liable to periodical submergence and emergence. (3) Lines of plication and folding, more especially along the borders of the oceans, forming elevated portions of land, rarely altogether submerged and constantly affording the material of sedimentary accumulations, while they were also the seats of powerful volcanic ejections.

In the successive geological periods the continental plateaus when submerged, owing to their vast extent of warm and shallow sea, have been the great theatres of the development of marine life and of the deposition of organic limestones, and when elevated they have furnished the abodes of the noblest land faunas and floras. The mountain belts, especially in the north, have been the refuge and stronghold of land life in periods of submergence, and the deep ocean basins have been the perennial abodes of pelagic and abyssal creatures, and the refuge of multitudes of other marine animals and plants in times of continental elevation. These general facts are full of importance with reference to the question of the succession of formations and of life in the geological history of the earth.

So much time has been occupied with these general views that it would be impossible to trace the history of the Atlantic in detail through the ages of the Palæozoic, Mesozoic, and Tertiary. We may, however, shortly glance at the changes of the three kinds of surface already referred to. The bed of the ocean seems to have remained on the whole abyssal, but there were probably periods when those shallow reaches of the Atlantic which stretch across its most northern portion, and partly separate it from the Arctic basin, presented connecting coasts or continuous chains of islands sufficient to permit animals and plants to pass over.* At certain periods also there were not unlikely groups of volcanic islands, like the Azores, in the temperate or tropical Atlantic. More especially might this be the case in that early time when it was more like the present Pacific; and the line of the great volcanic belt of the Mediterranean, the mid-Atlantic banks, the Azores, and the West India Islands point to the possibility of such partial connections. These were stepping stones, so to speak, over which land organisms might cross, and some of these may be connected with the fabulous or prehistoric Atlantis.†

In the Cambrian and Ordovician periods the distinctions, already referred to, into continental plateaus, mountain ridges, and ocean depths were first developed, and we find already great masses of sediment accumulating on the seaward sides of the old Laurentian ridges and internal deposits thinning away from these ridges over the submerged continental areas, and presenting very dissimilar conditions of sedimentation. It would seem also that, as Hicks has argued for Europe, and Logan and Hall for America, this Cambrian age was one of slow subsidence of the land previously elevated, accompanied with or caused by thick deposits of detritus along the borders of the subsiding land, which was probably covered with the decomposing rock arising from long ages of sub-aerial waste.

In the coal-formation age, its characteristic swampy flats stretched in some places far into the shallower parts of the ocean.‡ In the Jurassic the American continent probably extended further to sea than at present. In the Wealden age there was much land to the west and north of Great Britain, and Prof. Bonney has directed attention to the evidence of the the existence of this land as far back as the Trias, while Mr. Starkie Gardiner has insisted on connecting links to the southward as evidenced by fossil plants. So late as the Post-Glacial, or early human period, large tracts now submerged formed portions of the continents. On the other hand the internal plains of America and Europe were often submerged. Such submergences are indicated by the great limestones of the Palæozoic, by the chalk and its representative beds in the Cretaceous, by the Nummulitic formation in the Eocene, and, lastly, by the great Pleistocene submergence, one of the most remarkable of all, one in which nearly the whole northern hemisphere participated, and which was probably separated from the present time by only a few thousands of years.§ These

* It would seem, from Geikie's description of the Faroe Islands that they may be a remnant of such connecting land, dating from the Cretaceous or Eocene period.

† Dr. Wilson has recently argued that the Atlantis of tradition was really America, and Mr. Hyde Clarke has associated this idea with the early dominance in Western Europe of the Iberian race, which Dawkins connects with the Neolithic and Bronze ages of archæology. Mr own attention has recently been directed, through specimens presented to the McGill College Museum, to the remarkable resemblances in cranial characters, wampum, and other particulars of the Guanches of the Canaries with aborigines of Eastern America—resemblances which cannot be accidental.

‡ I have shown the evidence of this in the remnants of Carboniferous districts once more extensive on the Atlantic coast of Nova Scotia and Cape Breton ("Arcadian Geology).

§ The recent surveys of the Falls of Niagara coincide with a great many evidences to which I have elsewhere referred in proving that the Pleistocene submergence of America and Europe came to an end not more than ten thousand years ago, and was itself not of very great duration. Thus in Pleistocene times the land must have been submerged and re-elevated in a very rapid manner.

Digitized by Google

submergences and elevations were not always alike on the two sides of the Atlantic. The Salina period of the Silurian, for example, and the Jurassic, show continental elevation in America not shared by Europe. The great subsidences of the Cretaceous and the Eocene were proportionally deeper and wider on the eastern continent, and this and the direction of the land being from north to south cause more ancient forms of life to survive in America. These elevations and submergences of the plateaus alternated with the periods of mountain-making plication, which was going on at intervals at the close of the Eozoic, at the beginning of the Cambrian, at the close of the Siluro-Cambrian, in the Permian, and in Europe and Western America in the Tertiary. The series of changes, however, affecting all these areas was of a highly complex character, and embraces the whole physical history of the geological ages.

We may note here that the unconformities caused by these movements and by subsequent denudation constitute what Le Conte has called "lost intervals," one of the most important of which is supposed to have occurred at the end of the Eozoic. It is to be observed, however, that as every such movement is followed by a gradual subsidence, the seeming loss is caused merely by the overlapping of the successive beds deposited.

We may also note a fact which I have long ago insisted on,* the regular pulsations of the continental areas, giving us alternations in each great system of formations of deep sea and shallow water beds, so that the successive groups of formations may be divided into triplets of shallow water, deep water, and shallow water strata, alternating in each period.

But I must here call your attention to still another geological paradox, namely, that the deep sea, which is so great a barrier to the passage of the shallow water animals, seems, under certain conditions, to afford facilities for the transmission of land animals and plants. The connections established by the observations of the "Challenger," and so well expounded by Wallace and Hemsley,† between the floras of oceanic islands and the continents, establish this conclusively. Thus the Bermudas, altogether recent islands, have been stocked by the agency chiefly of the ocean currents and of birds, with nearly 150 species of continental plants, and the facts collected by Hemsley as to the present facilities of transmission, along with the evidence afforded by older oceanic islands which have been receiving animal and vegetable colonists for longer periods, go far to show that, time being given, the sea actually affords facilities for the migrations of the inhabitants of the land, greater than those of continuous continents.

In referring to the ocean basins we should bear in mind that there are three of these in the northern hemisphere—the Arctic, the Pacific, and the Atlantic. De Rance has ably summed up the known facts as to Arctic geology, and more recently Dr. G. M. Dawson has prepared for the Royal Society of Canada a *resumé* and map of what is known of the geology of the Arctic basin,‡ in comparison with Canadian geology. From this it appears that this area presents from without inwards a succession of older and newer formations from the Eozoic to the Tertiary, and that its extent must have been greater in former periods than at present, while it must have enjoyed a comparatively warm climate. The relations of its deposits and fossils are closer with those of the Atlantic than with those of the Pacific, as might be anticipated from its wider opening into the former. Blanford has recently remarked on the correspondence of the marginal deposits around the Pacific and Indian oceans,§ and Dr. Dawson informs me that this is equally marked in comparison with the west coast of America,‖ but these marginal areas have not yet gained much on the ocean. In the North Atlantic, on the other hand, there is a wide belt of comparatively modern rocks on both sides, more especially towards the south, and on the American side; but while there appears to be a perfect correspondence on both sides of the Atlantic, and around the Pacific respectively, there seems to be less parallelism between the deposits and forms of life of the two oceans as compared with each other, and less correspondence in forms of life, especially in modern times. Still in the earlier geological ages, as might have been anticipated from the imperfect development of the continents, the same forms of life characterise the whole ocean from Australia to Arctic America, and indicate a grand unity of Pacific and Atlantic life not equalled in later times,¶ and which speaks of contemporaneity rather than of what has been termed homotaxis.

We may pause here for a moment to notice some of the effects of Atlantic growth on modern geography. It has given us rugged and broken shores composed of old rocks in the north, and newer formations and softer features towards the south. It has given us marginal mountain ridges, and internal plateaus on both sides of the sea. It has produced certain curious and by no means accidental correspondences of the eastern and western sides. Thus the solid basis on which the British Islands stand may be compared with Newfoundland and Labrador, the English Channel with the Gulf of St. Lawrence, the Bay of Biscay with the Bay of Maine, Spain with the projection of the American land at Cape Hatteras, the Mediterranean with the Gulf of Mexico.

Thus far our discussion has been limited almost entirely to physical causes and effects. If we now turn to the life-history of the Atlantic, we are met at the threshold with the question of climate, not as a thing fixed and immutable, but as changing from age to age in harmony with geographical mutations, and producing long cosmic summers and winters of alternate warmth and refrigeration.

We can scarcely doubt that the close connection of the Atlantic and Arctic oceans is one factor in those remarkable vicissitudes of climate experienced by the former, and in which the Pacific area has also shared in connection with the Antarctic Sea. No geological facts are indeed at first sight more strange and inexplicable than the changes of climate in the Atlantic area, even in comparatively modern periods. We know that in the early Tertiary perpetual summer reigned as far north as the middle of Greenland, and that in the Pleistocene the arctic cold advanced, until an almost perennial winter prevailed, half way to the equator.

It will, I hope, meet with the approval of your veteran glaciologist, Dr. Crosskey, if I invite your attention chiefly to the old Lyellian doctrine of the modification of climate by geographical changes. Let us, at least, consider how much these are able to account for.*

The ocean is a greater equaliser of extremes of temperature. It does this by its great capacity for heat, and by its cooling and heating power when passing from the solid into the liquid and gaseous states, and the reverse. It also acts by its mobility, its currents serving to convey heat to great distances, or to cool the air by the movement of cold, icy waters. The land on the other hand cools or warms rapidly, and can transmit its influence to a distance only by the winds, and the influence so transmitted is rather in the nature of a disturbing than of an equalising cause. It follows that any change in the distribution of land and water must affect climate, more especially if it changes the character or course of the ocean currents.†

At the present time the North Atlantic presents some very peculiar, and in some respects exceptional, features, which are most instructive with reference to its past history. The great internal plateau of the American continent is new dry land; the passage across Central America between the Atlantic and Pacific is blocked; the Atlantic opens very widely to the north; the high mass of Greenland towers in its northern part. The effects are that the great equatorial current running across from Africa and embayed in the Gulf of Mexico, is thrown northward and eastward in the Gulf Stream, acting as a hot water apparatus to heat up to an exceptional degree the western coast of Europe. On the other hand, the cold Arctic current from the polar seas is thrown to the westward, and runs down from Greenland past the American shore.‡ The pilot chart for June of this year shows vast fields of drift ice on the western side of the Atlantic as far south as the latitude of 40deg. So far, therefore, the Glacial age in that part of the Atlantic still extends. Let us inquire into some of the details of these phenomena.

(To be continued.)

‡ Meeting of May, 1886. The paper is not yet published.

§ A singular example is the recurrence in New Zealand of Triassic rocks and fossils of types corresponding to those of British Columbia. A curious modern analogy appears in the works of art of the Maoris with those of the Haida Indians of the Queen Charlotte Islands, and both are eminently Pacific in contradistinction to Atlantic.

‖ *Journal* of Geological Society, May, 1886. Blandford's statements respecting the mechanical deposits of the close of the Palæozoic in the Pacific area, whether these are glacial or not, would seem to show a correspondence with the Permean conglomerates and earth-movements of the Atlantic area; but since that time the Atlantic has enjoyed comparative repose. The Pacific also seems to have reproduced the conditions of the Carboniferous in the Cretaceous age, and seems to have been less affected by the great changes of the Pleistocene.

ON ELECTROLYSIS.

BY PROF. OLIVER J. LODGE, D.SC.

(Continued from page 354.)

IV. Discussion of the Law (c) and Questions concerning Polarisation.

The chemical changes which go on in a circuit wholly electrolytic, or in any homogeneous portion of a circuit, are decomposition and identical recomposition, and consume no energy; accordingly no fresh E.M.F. is needed to send a current through a circuit wholly electrolytic or through a homogeneous electrolyte, *when the force is really applied to it* (*i.e.*, not merely applied to electrodes), and Ohm's law is possibly obeyed by electrolytes exactly as by metals. But at junctions of metals with electrolytes, or of electrolytes with one another,§ permanent chemical changes may

* The late Mr. Searles V. Wood, in an able summary of the possible causes of the succession of cold and warm climates in the northern hemisphere, enumerates no fewer than seven theories which have met with more or less acceptance. These are:—

1. The gradual cooling of the earth from a condition of original incandescence.
2. Changes in the obliquity of the ecliptic.
3. Changes in the position of the earth's axis of rotation.
4. The effect of the precession of the equinoxes along with changes of the eccentricity of the earth's orbit.
5. Variations in the amount of heat given off by the sun.
6. Differences in the temperature of portions of space passed through by the earth.
7. Differences in the distribution of land and water in connection with the flow of oceanic currents.

† Von Woeickoff has very strongly put these principles in a Review of Croll's recent book, "Climate and Cosmology; American Journal of Science," March, 1886.

‡ I may refer here to the admirable expositions of these effects by the late Dr. Carpenter, in his papers on the results of the explorations of the "Challenger."

§ Du Bois Raymond proved polarisation to be possible at liquid-liquid junctions. He also asserts the existence of "*innere Polarisation*" in a uniform liquid, which would be contradictory of what is said above; but

Digitized by Google

occur, and at such places a finite E.M.F. must be situated; and the resultant of these may be negative, when it is called polarisation, or positive, when the whole arrangement is called a battery. Total polarisation may be regarded as the sum of two kinds:—

(*a*) Temporary polarisation, existing during continuance of current.

(*b*) Residual polarisation, existing afterwards.

Residual polarisation is caused by a more or less permanent alteration of the service of the electrodes by clinging or combined ions. Under this head comes the whole subject of secondary batteries.

Concerning temporary polarisation less is known.* On Helmholtz's theory it is caused by the deposited but unliberated and still charged ions being unwilling to part with their charges. Whenever the ions are able to combine with the electrode or with the liquid, and thus retain their charges, temporary polarisation is very small. It seems undoubtedly due to the same circumstances as cause the extra energy of the nascent condition of a substance; and it varies very much with the particular state of combination, or uncombination, into which the ions enter when set free from their former union.†

The above expression, in the form $\Sigma(J\epsilon\theta)$ or $\frac{\Sigma\theta''}{46,000}$, or $\frac{\Sigma\theta^{(n)}}{23,000n}$, may be used to calculate the theoretical E.M.F. of a battery cell formed of specified constituents in which known reactions go on.

Now is the law really true? Is E. really the E.M.F. needed to decompose a given substance? Or is it only a partial statement of a truth? It may at once be admitted that whatever *direct* thermal effects the current may produce, being an expenditure of energy in other than chemical directions, must lie outside the range of the above law, inasmuch as they falsify the assumption of (iv.) Irreversible or frictional heat, and likewise reversible or thermoelectric heat, must thus be considered separately. If ever the E.M.F. of a cell or a voltameter is seriously different from the value calculated on chemical ground it is to be examined whether there be not local heatings or coolings in the cell, whereby the E.M.F. may be either diminished or increased, being really the sum of two E.M.F.'s., a chemical one and a physical or thermoelectric one. But all this being understood and allowed for, as was really done by Thomson in his original paper in 1851, is the law sustained by experiment for cases other than the Daniell cell and a few other simple ones? For instance, when two substances combine and produce heat, is any of the heat a direct result of their union, or are electric currents the direct primary result and heat a secondary or derived result? If any of the heat be primarily generated, then it is to be surmised that this portion of the whole combination energy is electrically inactive, having no effect on either the positive E.M.F. of a battery or the negative E.M.F. of a voltameter. Secondary actions, for instance; it has long been a subject of debate whether the solution of zinc oxide in acid, or of zinc sulphate in water, contributed its full quota to the energy of the current and the E.M.F. of a cell, or whether the combination of zinc with oxygen was more intrinsically effective.

Joule showed how to attack the question for substances composing batteries, by immersing the battery in one calorimeter and its outer circuit in another. Whatever heat necessarily and intrinsically appears in the cell itself must be heat primarily and directly generated; but if all the heat of the battery can be made to appear in the outer circuit, by making the resistance of this circuit high enough, it is proof positive that the primary result of the chemical changes is electric current, not heat; and so in Joule's experiments with certain substances it appeared to be. More cells have since been tried, with the result that some directly heat, while others directly cool, themselves; though the bulk of their energy still seems to take primarily an electro-kinetic form. Helmholtz has discussed the whole question from the point of view of reversibility, *i.e.*, has applied the second law of thermodynamics as well as the first. Directly this mode of treatment is suggested it is almost obvious that a cell which heats or cools itself must have an E.M.F. variable with temperature, according to the law

$$Qd\mathrm{E} = -\mathrm{J}\frac{d\mathrm{T}}{\mathrm{T}}\mathrm{H},$$

where H is the reversible heat generated in the cell during the passage of a quantity Q of electricity, and $\frac{d\mathrm{E}}{dt}$ is the rate of change of E.M.F. per degree at the absolute temperature T.

Hence, to investigate the sum of the reversible heat coefficients for a whole cell, it is only necessary to experiment on the variability of its E.M.F. with temperature, and to write

$$\Sigma\Pi = \frac{\mathrm{H}}{\mathrm{Q}} = -\frac{\mathrm{T}}{\mathrm{J}}\frac{d\mathrm{E}}{dt}.$$

The properly calculated E.M.F. is then simply $\Sigma(J\epsilon\theta)$ but

$$\mathrm{E} = \Sigma\mathrm{J}(\epsilon\theta - \Pi).*$$

In a Daniell cell it happens that $d\mathrm{E}/dt$, and therefore $\Sigma\Pi$, is very nearly 0.

It is true that with voltameters a difficulty is often experienced, in reconciling the theoretical conclusion that a certain minimum E.M.F. is essential to the decomposition of a given substance, with the practical observation that any E.M.F., however small, can cause a constant leak through an electrolyte; but it has been pointed out, at sufficient length already, how all this is capable of easy explanation by means of secondary chemical reactions. For, remember that θ is the thermal value of the reaction which actually goes on. Now if the action is such as permits the ions to dissolve in the liquid, or to combine indirectly with each other, less energy is expended, and less E.M.F. therefore required, than if they were really set free. We must not take θ as measured for one kind of reaction and try to fit it to a case where an altogether different reaction is going on. Again, it may happen (especially with intense currents such as are most easily applied by the use of small electrodes like the ends of Wollaston wire) that ions are liberated in a condition of abnormal activity as, for instance, oxygen as ozone, antimony in its explosive condition, &c. This necessarily means greater expenditure of energy, in proportion to the thermal value of such extra activity, and accordingly a greater E.M.F. is needed to effect decomposition under these circumstances, *i.e.*, the polarisation E.M.F. rises in value, having been forced as high as 3·3 volts, in the case of dilute acid with platinum points, by Buff. If all these circumstances are properly taken into account, I am aware of no experimental reason which need cause us to doubt the general truth of the simple law, $\mathrm{E} = \mathrm{J}\epsilon\theta - \mathrm{J}\Pi$.*

V. Mechanism of Electrolytic Conduction.

Electrolytic conduction is, I suppose we may say certainly, a convection of electricity by the atoms of matter; but concerning the mode in which the atoms make their way through the fluid there are several hypotheses:—

(1) The molecular chain of Grotthus; modified and accepted by Faraday and many others, modified further by Hittorf to explain migration.

(2) The dissociation hypothesis of Clausius and Williamson; virtually accepted by Maxwell, modified by Quincke to explain migration, and shown by Kholrausch to explain the facts of conductivity.

(3) The electrostatic hypothesis of Helmholtz.

1. The Grotthus chain, with its postulated pairings and unpairings, is too familiar to need the smallest description. The only difference between the hypothesis as originally stated and the form in which I suppose Faraday to have held it, consists in whether the direct action of the electrodes be supposed to extend throughout the liquid, affecting and polarising every molecule in it,† or whether the electrodes' direct action be considered as limited to a very minute molecular range, all interchanges beyond this range being conducted on diffusion principles or by inter-actions among the fluid atoms themselves. The only objection that may plainly be urged against the theory is that it seems to require some small force able to effect the necessary initial decomposition, and it suggests that conductivity and tenacity of composition are related to one another in some opposing manner. Facts, however, fail to bear out any such idea; conductivity and chemical tenacity seem independent of one another; and, as has been just said under head "polarisation," no finite force, however small, has ever been found necessary to decompose an electrolyte when really applied to it. In other words, no polarisation exists inside a homogeneous electrolyte; *there is no chemical cling of the atoms there, but only a frictional rub.* Such a fact as this, if well established, renders necessary *some form* of dissociation hypothesis. A Grotthus chain of quite equidistant atoms might serve, or a momentary dissociation would be sufficient, but no hypothesis which involves a tearing asunder of molecules in the *interior* of a homogeneous electrolyte can be permitted. *Herein lies the great distinction between electrolytes and dielectrics.*

2. The form of dissociation hypothesis suggested by Clausius and Williamson is well known. It supposes that the vast majority of molecules in an electrolyte are quite insusceptible to the influence of electrodes, but that a few of them (the number being increased by complexity of composition and by rise of temperature) are, by collision or otherwise, dissociated, and exist in the free atomic state, each atom with its appropriate charge. These alone feel the influence of the electrodes. According to some statements of this hypothesis the direct influence of the electrode is supposed to reach every dissociated atom in the fluid; according to another

what he observed is plainly connected with capillary E.M.F. and endesmose, and in the light of these is natural enough.

* The experiments of Bernstein, as well as some by Beetz and Edlund, have shown how quickly it can rise and decay with make and break of current; so it is scarcely a valid proof of its complete non-existence when a galvanometer switched into a circuit is not deflected. At the same time no sharp distinction can be drawn between temporary and permanent polarisation, any more than between temporary and permanent magnetism.

† Mr. J. Larmer gave a short communication to the meeting, "On the molecular theory of galvanic polarisation," which he has expanded to a most interesting paper, and published in the *Phil. Mag.* for November, 1885. He shows that polarisation, whether natural or artificial, must necessarily diminish surface tension, without any question of exact reversibility; and he calculates the distance apart of the constituent molecules in the electrical layers of the voltameter condenser, whose capacity is becoming incipiently non-constant.

* The simple mode of writing the complete law is

$$\mathrm{E} = \mathrm{J}\epsilon\theta + \mathrm{T}\frac{d\mathrm{E}}{d\mathrm{T}}$$

From this it follows that if heat of combination is independent of temperature, $\frac{d\mathrm{E}}{dt}$ must be constant too; and generally, that

$$-\frac{d^2\mathrm{E}}{d\mathrm{T}^2} = \frac{d(\mathrm{J}\epsilon\theta)}{\mathrm{T}d\mathrm{T}}.$$

Another way of writing it is

$$\mathrm{E} = -\mathrm{T}\mathrm{J}\epsilon\int\frac{\theta d\mathrm{T}}{\mathrm{T}^2}.$$

Mr. Laurie (*Proc.* R.S.E., 1884-5) investigates the heat of combination of zinc and iodine by measuring the E and $d\mathrm{E}/dt$ of a zinc iodine cell.

† Grotthus in 1805 supposed electrodes to attract ions according to an elemental inverse square law.

Digitized by Google

the direct electrode action extends only to those atoms which come within a minute range of its surface, everything else being managed by ordinary diffusion, *i.e.*, by the ordinary chance locomotions common to all atoms in a fluid. Individual atoms, though permitted to recombine as soon as they like, on this theory, are commonly thought of as existing in the dissociated state for a finite time. If there are chemical or other objections to such a view, it need not be held; all that the facts of electrolysis require is the most momentary dissolution of partnership, a temporary but quite perfect freedom, so that the feeblest possible influence may suffice to induce recombination in a definite direction, and with some atom other than its former partner. Provided a sufficient supply of such temporary severances occur throughout the liquid, no individual atom need remain in its uncombined state for a thousandth of a second, so far as the phenomena of electrolysis are concerned. But in proportion as the dissociated atoms are few and far between, the longer must they be supposed to continue in a free condition. Something must here be said concerning the views of Quincke and of Wiedemann on the mechanism of electrolytic conduction.

Theory of Quincke.—Prof. Quincke, adopting the dissociation view of isolated atoms, supposes the electrical charges of opposite ions to be not only opposite in sign but specifically unequal in quantity. He considers the direct action of the electrodes to reach every atom, and to propel the one set one way and the other set at a different speed the other way, according to simple electrostatic laws, and thus explains at one step both decomposition and "migration." Moreover, since the charges of opposite ions are not equal they do not neutralise each other; the resulting molecules are therefore charged with a balance of one or other electricity, and get propelled either with or against the current—thus accounting for electrical endosmose. Evidently the hypothesis is very elastic, and, if granted, explains the facts; but I must confess to an invincible repugnance to the idea of numerically unequal charges existing in the dissociated atoms of a molecule, as well as to the corresponding idea of all the molecules of an electrolyte being similarly charged.

The laws of Faraday seem to me to point so distinctly to a definite charge for every ion, depending solely on its valency in the compound from which it has just been liberated, that it would require very strong necessity to render palatable any other view. And I find no necessity at all. The inequality of charge is postulated only in order to account for the facts of migration as provisionally understood by Hittorf, *i.e.*, for the assumed inequality in pace of opposite ions. Now, without pressing unduly the prejudices I have ventured to suggest against such inequality in pace, I may claim to have proved that the facts of migration do not at any rate *necessitate* such inequality; and the facts of migration are all that the theory is based upon. And as to endosmose: it seems to me very doubtful whether any tendency to electric endosmose exists except in the immediate neighbourhood of a surface; one can only *observe* it in capillary tubes and porous partitions, and it seems allied to surface phenomena in general. It has indeed been elaborately considered by Helmholtz from this point of view, along with the reciprocal phenomenon of the E.M.F. generated by the flow of liquids along tubes.

Theory of Wiedemann.—Prof. Wiedemann's theory of electrolysis is not unlike Prof. Quincke's, but it is based on contact electricity. He supposes the atoms charged by contact with each other, and the molecule charged by contact with the vessel; and, having thus obtained the needful electrifications, decomposition and endosmose naturally follow; moreover, endosmose comes out properly connected with the existence of liquid and solid contact, or surface-action. But how does this theory explain migration? For the atoms in a molecule, if they electrify each other by contact, necessarily do so with equal quantities; and this is where the theory differs from Quincke's. Wiedemann explains the unequal rate of travel postulated by Hittorf, not by inequality in the propelling force, but (more satisfactorily as it seems to me) by a difference in the resistance met with. He would say that a hydrogen atom slips through the liquid more easily than an oxygen atom, and so gets along faster; moreover, he has conjectured, and experimentally verified within certain limits, that the ease of travelling of a given ion is inversely as the ordinary viscosity of the liquid: so that conductivity and viscosity are inverse to one another. He has further established the important and convenient fact that migration and endosmose are totally distinct things, having apparently no sort of relation to one another. Wiedemann's theory thus chimes in beautifully with that of Kohlrausch, who postulates a specific velocity for every ion; a velocity which depends only on the nature of the liquid in which it has to travel, and the $\frac{dV}{dx}$ which drives it.

That part of his theory which asserts a connection between conductivity and limpidity is curiously illustrated by the behaviour of water (or saline or acid solutions) at different temperatures flowing through a capillary tube. It is known that hot water flows some five times as fast as cold water through a given tube. It is also known that hot water conducts much better than cold. Further, it is known that if terminals connected to an electrometer are immersed in the liquid at either end of such a tube, an E.M.F. is discovered between them, depending on the rate of flow. Now, J. W. Clark has discovered that, notwithstanding its vastly greater rate of flow, the E.M.F. of hot water is almost identical with that of cold. His untimely death has prevented his publishing this result, but when he told it and showed it to me, some year or so ago, I conjectured that the observed E.M.F. must be a sort of residue of the whole generated E.M.F., being the part unable to leak back through the liquid; and I accordingly hunted up data to see whether the extra leakiness or conductivity of hot water might so nearly neutralise the E.M.F. generated by its more rapid flow as to give the same residue of E.M.F. Whether this be the true account of the matter or no, the fact is so. The empirical formula in Naumann giving the conductivity of the liquor used in Clark's experiment (it was salt and water, I think), at different temperatures contains practically the same coefficients as that giving the viscosity of the same liquid, measured by its flow through a capillary tube. The observation thus agrees perfectly with the theory of Wiedemann, connecting electrolytic conductivity with mechanical limpidity. The decrease in liquid viscosity with increase of temperature is remarkable. On any kinetic theory of viscosity, as due to diffusion, one would have expected it necessarily to increase with rising temperature. In a gas it does so, as is well known, but in a liquid it does just the reverse. I am unable to suggest any reason for this.

Circumstances affecting Conductivity.—There are two ways of increasing conductivity; increase of dissociation would seem to be the main cause when a weak solution is made stronger; diminished viscosity is probably the main cause when a cold solution is made hotter. But whether the remarkable change in viscosity caused by rising temperature is essentially the same thing as what appears in electrolysis to be extra dissociation I am not able to conjecture. Cases where the conductivity reaches a maximum at a certain stage of concentration, and afterwards diminishes as the strength of solution still further increases, are easily explained on Wiedemann's view of viscosity, combined with that of dissociation; for at first the percentage of dissociation may increase faster than does the viscosity, and so conduction be on the whole easier; while at last viscosity must increase fast enough to neutralise the advantage of whatever extra dissociation there may be. Indeed it is probable that dissociation itself may ultimately diminish, notably so for instance with nearly strong sulphuric acid, for it seems roughly to depend on heterogeneity of constitution. It may be plausibly argued that the experiments of Kohlrausch and Grotrian support the following view. Dissociation, and therefore also conductivity, falls to a minimum whenever the proportion of ingredients present are such as to make a very simple typical compound, such as (markedly) H_2O, or H_2SO_4, or even H_2SO_4, H_2O; but, with intermediate proportions, a certain number of semi-detached radicles are mixed along with these more stable compounds, and high conductivity is the result.

(To be continued.)

NOTES.

PATENT LAW IN NORWAY.—A new patent law is about to be promulgated in Norway.

THE WEST AFRICAN CABLE.—Telegraphic communication has now been established with Bonny, West Africa.

THE BIRKBECK INSTITUTION.—The sixty-fourth session of this institution will commence on Monday, the 4th of October.

TELEGRAPH CABLES REPAIRED. — The cables between Rangoon and Penang and between Madras and Penang are repaired.

THE "VOLTA."—The electric launch "Volta" left Dover on Monday for London, after her accumulators had been re-charged with electricity.

TELEGRAPH CABLES INTERRUPTED.—The cables between Jamaica and Colon and between Libertad and San Juan del Sur are interrupted.

SUBMARINE TELEGRAPH ACT (1885) AMENDMENT BILL.—On Tuesday last this Bill was read a third time in the House of Lords and passed.

FRANKFORT-ON-THE-MAINE.—The large railway station at this town is now lit by electricity. Power is obtained from the water mains, which were already provided for working the cranes and turn-tables.

CAST-IRON TELEGRAPH POLES.—We understand that a large order for cast-iron telegraph poles has just been placed with Messrs. Cochrane, Grove, and Co., North Ormesby, Middlesboro', by a Birmingham firm.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th inst. are £1,848, as compared with £2,051 in the corresponding period of 1885.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 17th inst. were £3,036, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

TUNGSTEN STEEL FOR MAGNETS.—M. Heppe states that the combination of tungsten with steel in the proportion of a one-hundredth part produces a steel capable of retaining its magnetisation unaltered for a much greater length of time than the ordinary qualities.

EGYPT.—Messrs. Crompton and Co. are supplying a No. 8 Crompton dynamo and 6 D D arc lamps, with about 100 incandescents, to Dr. Tweddle, for export to Egypt. We believe that Dr. Tweddle has carried out a large amount of engineering work for the Government in Egypt.

COBALT.—M. Berson, describing some experiments upon the influence of temperature upon magnetisation, in the *Annales de Chimie et de Physique*, states that the magnetic moment of a bar of cobalt *increases* continuously with the temperature up to 318°C., which is as far as the experiment has been carried.

IPSWICH.—The proprietor of the *East Anglian Daily Times*, Ipswich, who is building new offices and printing works, has decided to install the electric light, tenders for which will be opened next week. The lighting will consist of above 120 incandescent lamps, and three arcs of 2,000 candle-power each.

RENEWED EARTHQUAKE SHOCKS IN AMERICA.—Since the great earthquake which destroyed the city of Charleston upon the 31st August, shocks of minor severity have been continually experienced in Georgia and South Carolina. On the 21st inst. a shock of some violence occurred, which was felt as far north as Bridgeport, Connecticut.

THE SANDWICH ISLANDS.—It is stated that a representative of the Hawaiian Legislature, which has recently passed a Bill authorising the raising of a loan of 2,000,000dols. for public works, is now on his way to London to negotiate its issue. Among the objects for which the loan has been authorised is the laying of telegraph cables connecting the various islands.

SHIP LIGHTING.—Messrs. Dorman and Smith, of Manchester, have just completed an installation of 140 lamps on board the "Euterpe," a vessel which has been built at Sunderland for the Austro-Hungarian Lloyd's Steam Navigation Company of Trieste. The "Heraclides," a vessel recently launched at the same port, has been lighted with electricity by Mr. R. Miller, of Glasgow; this vessel is intended for the River Plate trade.

NEW BOOK.—We observe from the current number of the *Academy* that among forthcoming books is one by Messrs. Emile Garcke (of the Anglo-American Brush Corporation) and J. M. Fells on "Factory Accounts; their Principles and Practice, being a handbook for Manufacturer and Accountants." The book is to be published by Messrs. Crosby Lockwood and Co.

TELEGRAPHIC COMMUNICATION WITH AUSTRALIA.—In the House of Commons on Tuesday last, Sir H. Holland stated, in reply to a question, that during the last six years, upon only one occasion, namely, from the 7th to the 16th of the present month, has telegraphic communication between this country and Australia between dependent solely upon the line passing through Russia.

THE ELECTRIC LIGHT IN SPAIN.—*A Correction.*—Under this heading Mr. L. E. Caine writes to us from Algarve, Portugal, to the following effect:—"The letter in your number of the 10th inst. under the above heading necessitates a correction, which did not appear to me to require correction earlier. In sending the 'note' I omitted to mention that the town referred to is in Portugal."

THE LIGHTING OF THE PALAIS DE L'INDUSTRIE.—The French journals are making bitter complaints as to the working of this installation, which is said to compare very unfavourably with previous exhibitions of the electric light in Paris under similar circumstances. On the whole it is tolerably safe to congratulate ourselves upon the fact that electric lighting is not one of those things which they do better in France.

TRAIN LIGHTING.—On the Wurtemberg State Railway an attempt is being made to utilise electricity for train lighting. Storage cells are employed, charged by means of a dynamo which is driven from the axle of the guard's van. A very simple form of coupling has been devised for making the electrical connections between the carriages, and no trouble has hitherto been experienced in this matter, though only one train has yet been fitted up.

"NOTIONS ELÉMENTAIRES SUR L'ECLAIRAGE ELECTRIQUE." This is the title of a small pamphlet which we have received from M. Nelson Cherrill, electrical engineer of Lille, and which very clearly explains the principles of incandescent lighting, and the practical details to which attention should be chiefly directed in carrying out an isolated installation. The book is intended to give those not familiar with the science clear and simple ideas upon the subject of the electric light, and this it is well fitted to do.

THEATRE LIGHTING AT PARIS.—The lighting of the Palais Royal Theatre, to which we recently referred as being likely to be carried out by electricity, is now an accomplished fact. The total number of Edison lamps which are employed is 560. A compound engine of 35 horse-power, running at 300 revolutions, drives an Edison machine giving 450 amperes at 55 volts.

Digitized by Google

Considerable difficulty was experienced in getting the machines into the confined space which was alone available. Nevertheless, to ensure safety the whole of the plant has been duplicated.

AN ARC LAMP INDICATOR.—Mr. Statter has devised a clock-work attachment for the purpose of "indicating" the feed of arc lamps. A pencil is attached to a convenient part of the positive holder, and the point makes a trace upon a paper which is folded round a cylinder. The clockwork causes the cylinder to rotate once in an hour, and in this way a complete record of the amount of each separate feed, the time at which it took place, and the total consumption of carbon is obtained. In *Industries* some curves obtained in this way for the Crompton, the Statter, and the Pilsen lamp appeared last week.

THE AMERICAN BELL TELEPHONE COMPANY.—The statistics recently issued by this company show that on 1st January, 1886, the number of telephone exchange systems in operation in the United States was 747, the number of offices open 1,175, number of circuits 112,067, number of miles of wire 114,046, number of *employés* 5,438, number of subscribers 137,750. Of the total number of exchanges no less than 512, or more than two-thirds of the entire number, were situated in towns having a population of less than 10,000. We cannot at present recall a single instance of a town of this size in our own country which is provided with a telephone exchange.

AN INCANDESCENT LAMP OF HIGH CANDLE-POWER.—At the recent meeting of the American National Electric Light Association at Detroit, a small exhibition for decided novelties was organised. Amongst the most interesting of these exhibits was an incandescent lamp of 400 candle-power, which is said to require only 425 watts. It is to be hoped that these statements will bear further investigation. A lamp fulfilling such conditions is certainly a desideratum. We do not understand that it is intended to claim an efficiency of the watt per candle for lamps of all sizes; this figure is in all probability only attainable in those of high candle-power, such as the one exhibited.

EDISON'S NEW CARBON FOR TELEPHONE TRANSMITTERS.—Edison has recently devised a modification of the carbon button in his telephone transmitter, which is said to greatly increase the efficacy of the instrument. He takes a textile or woven fabric, preferably that known as "veiling;" he forces lampblack or powdered carbon into the meshes under a strong pressure, and then carbonises it. Or, instead of this, he employs a disc of thin paper perforated with a large number of very fine holes, and treats it in the same way. It is evident that if this is a real improvement, it might with equal advantage be employed in the Blake transmitter, which is so largely used in this country.

TAUNTON PUBLIC LIGHTING.—A special meeting of the Town Council was held last week to consider the question of the lighting of the town. Tenders were received from Mr. H. G. Massingham, who has introduced the Thomson-Houston system into the town, as well as from the local gas company. The former offered to light two districts for £1,375, or for £725 each, the gas company tendering for the supply of gas at 3s 4d. per 1,000ft. It was estimated on this basis that the gas would involve an outlay of £1,200 a year, including another district not provided for in Mr. Massingham's tender. After some discussion the Lighting Committee was instructed to present a more exhaustive report.

SPIRAL LIGHTNING.—We recently recorded the fact that in some photographs of lightning flashes obtained in France the discharge has assumed a spiral, or, more strictly, an helicoidal form. M. Canastrini now states that in mountainous countries it is a well known fact that pine trees which have been struck by lightning are usually marked with an helicoidal furrow. He also quotes from a book published in 1867 (*Eclairs et Tonnerre*) by M. Fonvielle to show that the observation, though not new, is fully substantiated. It is even suggested that the fact was familiar to the ancients, for "the thunders of Jupiter" are frequently represented in spiral form.

SECONDARY GENERATORS AT THE PALAIS DE L'INDUSTRIE.—Messrs. Gaulard and Gibbs will shortly have an extensive installation of their secondary generators at work at the exhibition now being held in Paris. The *Bulletin Internationale de l'Etectricité* states that they have discovered in a corner of this exhibition an apparatus precisely similar in every respect to that of Messrs. Gaulard and Gibbs, which the inventor or constructor asserts to have been made long before the date of their patents. It would have been a remarkable exception to the established order of things if the priority of a *successful* electrical invention had been allowed to pass unchallenged, but it remains to be seen what value, if any, is to be attached to the statements of this particular claimant.

THE ELECTRIC LIGHT IN SPAIN.—The town of Gerona will shortly be illuminated throughout by the electric light. The motive power will be supplied by two turbines, situated about the centre of the town. The available water force is equal to about 90 horse-power, of which only 25 will be required. The installation will consist temporarily of 200 incandescent lamps, which will be lighted for 10 hours a night, and for each of which the town will have to pay 75 centimes. Besides these, 10 Gramme arc lights are already in use. These are fed by the secondary currents of four Zipernowsky transformers. The distributing circuits, which are of plain copper wire, are carried overhead upon wooden poles. In case of accidents to the turbines the dynamos will be worked by a steam engine, which is kept in reserve.

ELECTRO METALLURGY.—The large plating companies are at last waking up to the fact that the modern dynamo is far ahead of the machines of the older type that have been in use for many years for electro deposition. Messrs. Vivians, who are some of the largest copper workers in South Wales, have recently given orders to two or three of the best known electric light companies and firms for large dynamos to be used in their process. We understand that, among others, Messrs. Crompton and Co. supplied one of their "No. XL." machines, which gives 10 volts and 500 amperes. It is safe to say that within a very short time all the large companies engaged in the business of electric deposition will have discarded the old type of machines (which in some cases give no more than 40 per cent. efficiency) and adopted the more modern and efficient form of dynamos now to be obtained.

APPARATUS FOR RECORDING EARTH CURRENTS.—Prof. Shida, of the Imperial College of Engineering, Tokio, Japan, has devised a modification of the siphon recorder, by which the instrument may be employed to register the intensity, direction, and duration of earth currents. To the coil of the instrument, which moves under the influence of the currents, he attaches a light metallic arm; and by means of an ingenious arrangement of contacts, consisting of acidulated water maintained between a succession of insulating partitions arranged in a circle this arm is made to close one of a number of distinct circuits. The current in the circuits so closed causes a horizontal line to be traced upon a strip of prepared paper, after the manner of the Bain chemical telegraph. Each circuit when closed by the needle registers its own trace at a

Digitized by Google

different height upon the strip. In this way a complete record of the earth current is obtained.

THE COMMERCIAL CABLE COMPANY.—The New York *Electrician and Electrical Engineer* says :—"If the Commercial Cable Company fails to achieve success, it will not be for lack of advertising. The *Herald* surrenders valuable space daily in both editorial and news departments to booming the enterprise. A quarter of a column in italics, kept standing on the editorial page, devoted to the details of a "race message" with the old companies, is a favour which no other company would be likely to obtain at any price. The other dailies, with certainly one exception, also give editorial endorsement to the Mackay-Bennett cable, and as the advertising of such companies is not freely indulged in when it must be paid for at regular rates, it is evident that it must be more than ordinarily effective." The English of this seems to be that the newspapers do the advertising in consideration of preferential advantages afforded them over this particular company's cables.

LIGHTNING AND LINEMEN.—It will be remembered that on Saturday, the 4th instant, a very heavy thunderstorm passed over the south-west of England, visiting Bridgenorth with great severity. It happened that at the time the Post Office was erecting near the town a new line of four wires to Wales. The men employed on the work were engaged in wiring, and two of them had a very narrow escape. One of the men was drumming out a wire, when it was struck by lightning, and the man was thrown violently on his back, the drum barrow being cast across the road. The other was running out the wire, and, having hold of it at the moment the lightning struck it, was also thrown upon the road and rendered speechless for a few minutes. Happily, neither of the men was seriously injured. This is only another illustration of the thoughtlessness of workmen in persisting in handling wires during a storm of thunder and lightning, which might easily result in much more serious consequences.

CHARTERHOUSE SCIENCE AND ART SCHOOL AND LITERARY INSTITUTE.—The winter session of this, one of the largest science and art schools in the United Kingdom, will commence on Saturday, October 2, 1886, under the presidency of the Rev. Henry Swann, M.A. During the late session about 850 students, mostly elementary teachers, availed themselves of the privileges afforded by this institution, and of this number upwards of 600 presented themselves from examination and were successful in obtaining a large number of first class certificates, as well as several honours certificates, from the Science and Art Department. Of the thirteen national scholarships granted by the Government three were carried off by London candidates, all of whom were students of this institution. Instruction of a practical character is given in most of the sciences, while the art school is under the direction of five competent instructors. There is also a well-fitted chemical laboratory, capable of accommodating sixty students.

AN ELECTRIC RAILWAY IN THE PYRENEES.—The electric railway, which is described in the following extract which we take from an article on the Lartigne single rail system of railway lines in the current number of *Engineering*, would appear to be one of the most interesting applications of electricity which has been heard of for some time :—"At the Ria Mines, Pyrénées Orientales, there is a very curious Lartigne railway, over which iron ore is carried for a distance of six and three-quarter miles. The line is worked by electricity, on a system designed by Messrs. Siemens, the full trains running down generating a current of electricity sufficiently powerful to haul the empty train up. The details of the system have not reached us, but we believe they consist in using the motor on the descending train as a dynamo, which generates sufficient current to work the motor on the ascending train, the difference between the weights of the two trains being enough to compensate for the loss of electrical efficiency."

A THERMO-ELECTRIC EXPERIMENT.—Prof. C. G. Knott, in the course of a paper on the electrical properties of hydrogenised palladium, which has been read before the Royal Society of Scotland, describes the following curious experiment :—Let a palladium wire be hydrogenised throughout one half its length. This is done by dipping one-half the wire into an electrolytic cell, and liberating hydrogen upon its surface. Attach the ends of the prepared wire to a galvanometer, and let a flame play gently upon the central point of the wire. A large current is at once obtained, which grows to a maximum, and then, as the temperature approaches a red heat, diminishes to zero, owing to the hydrogen having been expelled from this portion of the wire. If the flame be now shifted slightly towards the hydrogenised section the experiment may be repeated, and this may be done until the whole of the hydrogen has been driven from the wire, or until the gas has become equally distributed throughout its length. At the same meeting Mr. Thomas Andrews communicated a paper on the electro-chemical relations between metals and fused salts.

CAPITAL PUNISHMENT BY ELECTRICITY.—There is now being exhibited at Leipzig an apparatus for putting criminals to death by electricity. So long as it is found necessary to retain capital punishment upon our statute books it may well be that the electric method is the most merciful and least repulsive process that could be devised for carrying the sentence into effect. But if such means are ever adopted in this country the details will certainly not be carried out in the theatrical manner which commends itself to the Leipzig amateur. In this apparatus, behind the chair in which the condemned man is to take his seat—and by means of which, as we need not explain in detail, his body is placed in circuit with a powerful coil—there stands a conventional figure of Justice with bandaged eyes, holding the balance in her left hand and the sword in her right. The criminal having taken his seat, the proper functionary is supposed to read over the record of his crimes and the sentence of the law. This ceremony completed, he folds up the document and places it in the scale pan, the arm of the balance descends, closes the circuit, and all is over.

THE INSTITUTE OF MECHANICAL ENGINEERS.—The annual report of the Institute of Mechanical Engineers for the year 1885-6, which has just appeared, contains the usual list of subjects upon which the Council are willing to receive original communications during the ensuing twelve months. It may not be universally known that the Institute does not restrict the communication of papers upon these subjects to its own members alone, and in the distribution of the various premiums which are awarded for papers of substantial merit "no distinction is made between any person, whether native or a foreigner, whether belonging to the institution or not." There are five electrical subjects in the present list, which are classed as follows (the number given is that of the Institute list) :—41. Electromotors; their theory, practical construction, efficiency, and power. 42. The Construction and Maintenance of Secondary Batteries. 43. The Distribution of Electric Currents for the Electric Lighting of Towns. 44. Thermo-Electric Batteries, and their Application to Electro-Plating and other purposes. 45. The Application of Dynamo-Electric Machines to the Electro-Deposition of Metals from their Ores.

THE ST. LOUIS TELEPHONE CONVENTION.—A convention of the companies owning or working the Bell patents in the

Digitized by Google

United States has just been held at St. Louis. The presidential address spoke very hopefully of the prospects of telephony in the immediate future, anticipating that the revival of trade, which seems at length to have become fully established in the States, will greatly stimulate telephonic activity. Elaborate statistics were quoted, which tended to show that up to the present time the average return upon capital invested in this direction has not exceeded 6 per cent. The address also contained a summary of the long roll of legal decisions by which the Bell patent has been upheld, and concluded with a facetious dialogue supposed to take place upon matters telephonic between President Cleveland and his private secretary, somewhat after the manner of Landor's "Imaginary Conversations." In this case, however, the necessary expletives were given in full. After several reports had been presented, Mr. Lockwood read a paper upon the employment of lightning protectors, expressing a preference for those which depend upon electro magnetic action over the fusible metal varieties. Several other papers of interest were to be read, notably, one on long-distance telephony, and one on cables and underground work, but the reports have not yet reached this country.

THE INDIAN TELEGRAPH SERVICE.—The *Indian Engineer* of 21st August has the following remarks upon the Indian Telegraph Service:—"The grievances of the Telegraph Department have elicited sympathy and support far and wide. They are a scandal to the State. The *Times of India* well observes that men of university education and scientific training were induced by the Secretary of State by certain promises to join the Telegraph Department. These promises have been shamefully broken. The least they had a right to expect was that their pay and prospects would be equal to those of men appointed to the Forest Department. They are far inferior. A man having entered the Telegraph Department by competition, finds after twelve or fifteen years' service that his pay and prospects are even inferior to those of lads who have without examination been appointed by local Governments to the salt or police. An anomaly and iniquity of this nature ought not to be allowed to exist. It ought not to be allowed to exist on economic grounds, for the most useless and expensive article that a State can possess is a discontented public servant, and the members of the Telegraph Department would not be human if they were not thoroughly discontented."

FURTHER TELEPHONIC SQUABBLES IN THE STATES.—The New York *Electrical World* says:—"A despatch from Washington announces that a bill in equity has been filed in the District Supreme Court by C. G. Beryman for Henry C. Strong, of Chicago, against Robert B. Vance, Acting Commissioner of Patents, and Elisha Gray, for an injunction to restrain the issuing of a patent to the latter. The complainant states that he is the inventor of the railway electric telegraph and telephone, and applied for a patent May 18, 1877; that this application has been kept alive by amendment to claims, &c., that Gray subsequently filed an application for a patent for 'multiple telegraph,' which, he alleges, was by trickery and deceit stolen from him, and is nothing but a reproduction in principle and design of his machine and invention. He charges that by undue influence and by complicity with the examiners, Gray is about to receive a patent; that the issuing of a patent to complainant is delayed by Gray's influence, and the patent to Gray is about to be issued by fraud and collusion with the officers of the Patent Office, and if so issued, will greatly injure and delay him, and necessitate long and tedious litigation on his part. He further alleges that he is entitled to official action on his claim, and asks an injunction and relief. Judge Hagner set the first Monday in September, at 12 o'clock, for a hearing."

"THE JUDICIAL WARPING OF PATENTS."—*The Times* of Sept. 22nd contains a further letter upon this subject from Prof. S. P. Thompson, of which the following is the concluding paragraph:—"To sum up the whole question I have pointed out that there exists a practice of judicially stretching patents so as to make them include more than the inventor claimed, and I maintain that such a practice is essentially unjust. Mr. Imray admits the practice, and defends it in the case of what he calls fundamental inventions. Prof. Forbes has explained how the machinery of the courts is such that wealthy owners of patents can avail themselves of this practice to crush inventors of small means. I have also pointed out that there exists a practice in the law courts of representing a mere improvement in detail to be a fundamental invention, in order to gain the advantage of having the patent stretched. This also Mr. Imray does not dispute; but retorts that the opinion of a mere professor is not worth that of six judges. When I narrow down the issue to particular cases he tries to evade the issue by coining definitions that beg the question, and parables which omit the facts. I submit, then, that my main propositions remain unshaken; and, in closing this discussion, I can only thank Prof. Forbes and Mr. Imray, whose letters have respectively helped to expose and illustrate this blot in the administration of patent law."

THE CHANDLER SYSTEM OF TELPHERAGE.—At Philadelphia last year an overhead wire road for the electric transport of moderately heavy loads was exhibited by a Mr. Chandler. The arrangement is a modification of the well-known system of overhead transport which has been elaborated in this country by the late Prof. Fleeming Jenkin and by Profs. Ayrton and Perry. In Chandler's arrangement there are, however, two cables for each line; these are placed vertically one underneath the other, and the cars or skeps run upon four wheels, two on either cable. The driving wheels are naturally placed upon the upper cable. This method has certainly the advantage of simplifying the electrical connections, and it seems probable that the additional cost is not great. The system is now to be introduced upon a commercial scale by the Suspension Transportation Company, of Boston. At their experimental works at Greenville, several lines have been laid down, and it is said that very satisfactory results have been attained. The employment of the double cable permits the details to be carried out upon a somewhat heavier scale than has hitherto been aimed at in this country. Some of the cars weigh when empty as much as 1 ton each, the upper cable is 2in. in diameter, and the lower 1in. Daft motors are used. It is suggested that the system might be employed for transporting life-saving apparatus along the coast. In this way miles of dangerous coast might be efficiently patrolled, and assistance might be rapidly brought to any required point.

A HINT TO CONSUMERS OF THE ELECTRIC LIGHT.—As the electric lighting season is just now commencing it would be well for those who contemplate electric lighting to place their orders without delay. We believe that in the matter of lighting, manufacturers and others requiring it are very remiss in giving their instructions in time. We have been told by one of the best known electric lighting firms that on speaking to their customers on the subject of electric lighting, they were informed that the "time was too early, they were not requiring lights yet, and that people did not buy candles before they were wanted." This system of procedure will scarcely do with regard to electric lighting. In most cases estimates have to be prepared, and the work of erection has to be

Digitized by Google

carried out at the cost of much time and labour, and in some cases it is no easy matter to get the whole system at work in a few weeks. Nevertheless, there are numerous cases in which large and important installations have been carried out with remarkable rapidity. As an instance of this, we are informed that some large mills in the north of England requiring nearly 900 lights were wired throughout and fitted ready for the machinery to be placed in three weeks. It must be remembered, however, that this very quick work entails greater expense on the part of the contractors, and it is to be hoped that those who are intending to use electric light will go into the matter without delay, and by doing this they will possibly save themselves considerable inconvenience and extra expense later on.

THE LANARK SCHEME.—Last week the Town Council of Lanark received a deputation whose object was to request the countenance and influence of the council in favour of a proposal to procure by purchase or lease the water power of Stoneybyres Falls, to be used as the motive power in generating electricity for illuminating the town of Lanark and other places in the vicinity of the falls. Mr. Andrews, of the Woodside Electric Works, Glasgow, explained the project. He also stated that the promoters of the scheme had concluded a bargain with Mr. Walker, proprietor of the land on the south side of the falls, both for obtaining the land they might require, and also for his share of the water power; but they had not yet succeeded in obtaining the consent of the proprietor on the other side of the falls, viz., Sir Simon M'Donald Lockhart. The company, Mr. Anderson said, were prepared to treat with that gentleman in the same spirit in which they had met Mr. Walker, and from Sir Simon's well-known anxiety to promote every good and laudable object, especially when the same would be beneficial to the neighbourhood, he was sure they would not require to wait long before concluding a fair and honourable arrangement with the hon. baronet. Mr. James Symington, Markgreen, and Mr. Hunter, electrician, Lanark, spoke in support of the scheme, as did also Mr. James Chalmers, architect, Glasgow. The council, after a short consultation, agreed to give the scheme all the support they could, and a committee was appointed to aid the promoters.

THE EVOLUTION OF THE TELEPHONE.—At the recent meeting of the American Association for the Advancement of Science Prof. Dolbear read a paper on "Early Telephone Apparatus," and quoted the following passage describing the Bourseul telephone from the *Didiskalia*, September 28, 1854:—"Suppose that a man speaks near a movable disc, sufficiently flexible to lose none of the vibrations of the voice, and that this disc alternately makes and breaks the current from a battery, you may have at a distance another disc which will simultaneously execute the same vibrations. An electric current traversing a metallic wire changes a piece of soft iron in the vicinity of which it passes into a magnet. As soon as the current ceases, the magnetic quality ceases. This magnet (the electro-magnet) can thus alternately attract or let go a metallic plate. It would be possible to so arrange this second metallic plate that it repeated simultaneously exactly the same vibrations as the first plate, and it would then be exactly the same as if one had spoken in the immediate vicinity against this second plate, or the ear would be affected precisely as if it had received the tones directly through the first metallic wall." Prof. Dolbear also gave another quotation on this subject, which has not, we think, appeared in this country. In an article in the *Deutsche Klinik*, 1863, Dr. Clemens, writing on "Disorders of the Spinal Marrow and their Treatment by Electricity," appended the following footnote:—"This most wonderful phenomenon of the transmission of sound in the electrified wire I have observed once before, about ten years ago, in the following manner: A strong induction coil was operated by one cell of battery, and the current conducted above ground through a copper wire several hundred feet long from my study to a distant garden house. As soon as the wire thus extended was attached at the further place to a strong coil, one could hear in the farther coil quite distinctly the running of the machine and likewise perceive at the second coil any sound which was able in any way to set up strong vibrations. Shouting into a funnel, blows upon a metallic plate, &c., if directed towards the induction coil, were heard distinctly in the farther coil, like the tones of an Æolian harp."

THE CHROMIC ACID BATTERY.—We have been favoured with the following copy of results which have been obtained in the course of some experiments with a chromic acid cell:—"The tests described had as their object the measurement of the E.M.F. of the chromic acid cell, firstly, on open circuit when no work was being done, and secondly, when furnishing a relatively large current. The local action due to osmose was also observed. The materials used for these experiments were those usually met with in regular commerce, namely, commercial zinc, carbon, sulphuric and chromic acids. As a preliminary experiment, a cell was made up and left standing for a fortnight, in order to observe the action of any osmose, which happened to be considerable, the zinc being eaten entirely through before ten days had elapsed. The zinc had been amalgamated, but no mercury was left in the cell, as in Fuller's arrangement. The E.M.F. of the cell was measured after it had been made up ten days, and was found to be 2·12 legal volts, and notwithstanding the very bad state of the cell, the recovery of the E.M.F., after being short-circuited, was very rapid, and the measured E.M.F. subsequently showed considerable constancy. Another cell had in the meantime been put together with the same carbon and a similar piece of zinc, the electrolyte being precisely as in the former cell. This was tested immediately it was made up, and the E.M.F. was found to be 2 22 legal volts. It was then short-circuited, and the current passed was about 1·5 ampere; the E.M.F. fell about 2½ per cent., but recovered its normal value in about six minutes. This experiment and several others of similar nature showed the rapid depolarisation effected by the chromic acid. This cell was left for two days in order to observe any action on the zinc, and as it seemed to be considerably affected some mercury was put in the porous pot for continuous amalgamation. Directly after the mercury was added a test was taken, which showed an immediate rise in the E.M.F. of about 2 per cent. The tests made afterwards from day to day during a week showed a remarkably close agreement amongst themselves, amounting to about ± 0·6 per cent. in the E.M.F. The mean E.M.F. obtained from the whole series of experiments was about 2·18 legal volts. From the above tests the following conclusions may be drawn:—(1) The E.M.F. is high and very constant. (2) The depolarisation is very good, and, consequently, the cell can be used for lighting purposes with advantage for small installations. (3) The local action is apt to be rather great, so that it would be advisable to use a solution of different strength in those cases where the zinc has to be left continuously in the solution, as, for example, in telegraphic uses (later experiments with weaker solutions gave better results). (4) It is very readily cleansed, there is no smell, and the solutions are easily made up and no solid salts are formed. The tests were made with a Thomson reflecting galvanometer, and a standard condenser. The standard of E.M.F. used was Clark's element. Each observation was made usually five times, and the values calculated from the arithmetic mean of those observations."

THE ELECTROLYSIS OF SILVER AND COPPER
AND
Its Application to the Standardising of Electric Measuring Instruments.*

BY THOMAS GRAY, B.Sc., F.R.S.E.

This paper contains an account of a large number of experiments on the electrolysis of silver and copper and its application to the standardising of electrical current and voltmeters which have been made during the past year in the Physical Laboratory of Glasgow University; it forms a summary of the reports made from time to time to Sir William Thomson on this subject.

In the earlier experiments pure silver sheet and solutions of pure silver nitrate were used for the electrolytic cells. The results obtained with these cells confirmed those obtained by Kohlrausch, Lord Rayleigh, and other observers as to the great accuracy obtainable with silver, and also as to the nature of the deposit and the care required in the manipulation of the experiment.

* Paper read by J. T. Bottomley, F.R.S.E., before the British Association at Birmingham. Revised by the Author.

The cathode plate consisted in almost all cases of a sheet of pure silver placed with its plane vertical between two parallel sheets of the same metal. In a few experiments a platinum bowl was used, very much in the same manner as that described by Lord Rayleigh in his paper to the Royal Society, but generally the plates of sheet silver were preferred. The mode of treating the plates both before and after the deposit was upon them is fully described, and it is pointed out that when the plate is made thoroughly clean and its size properly proportioned to the strength of the current to be measured, the deposit is finely crystalline and adheres very firmly to the plate. The best results were obtained when the current density at the cathode was between the $\frac{1}{200}$th and the $\frac{1}{600}$th of an ampere per square centimetre of the surface on which the deposit was taking place, the solution being supposed to contain 5 per cent. of silver nitrate. It is also pointed out that the loss of silver from the anode can be used satisfactorily as a check on the amount of silver deposited on the cathode, but that the current density at the anode must be considerably smaller than that which will give good deposits on the cathode. About $\frac{1}{400}$th of an ampere per square centimetre is stated as the maximum current density at the anode which can be safely used if the loss of silver is to be weighed. A

somewhat greater current density may be used at the cathode if the strength of the solution be increased, but the deposit becomes more roughly crystalline and less adherent. The current density cannot be increased in nearly the same proportion as the increase in the amount of silver nitrate in the solution, and hence when sheet silver cathodes are used the most economical and most satisfactory method is to use weak solutions and large plates. Rolled silver gives unsatisfactory results until the outside skin has been removed by use, polishing, or scraping. The later experiments described in the paper refer, for the most part, to copper and, include experiments on the uncertainty likely to arise from the oxidation of the plate in drying and while in the solution; the effect of the loss of weight due to direct chemical corrosion of the plates; the effect of density of solution; of size of plate or current density; and of the addition of acid to the solution. It was found that there is no difficulty in washing and drying a plate without oxidising it sensibly, and methods are described for doing this. The loss of weight by corrosion in the liquid introduces an error which is nearly proportional to the surface of the plate exposed, and, judging from Dr. Gore's experiments, it is also no doubt influenced by the temperature, if that be not constant; but the effect of temperature was not investigated. The amount of corrosion is also influenced to some extent by the density of the solution, and appears to be least when the density is between 1·15 and 1·10; it is diminished by the addition of free acid to a strong solution.

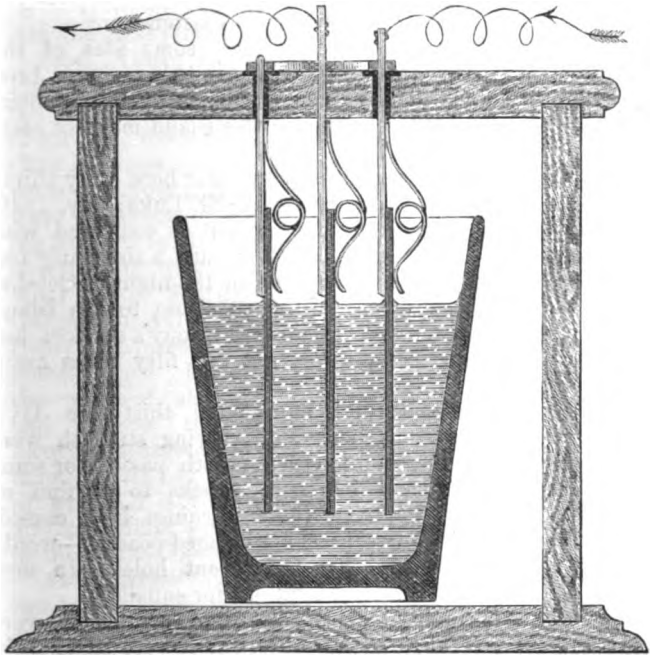

FIG. 3.—Sectional View of Electrolytic Cell.

It is concluded that in the use of copper for standardising purposes, the current density and the density of the solution must be known, and the proper correction made on the electro-chemical equivalent to suit the particular circumstances. If this be attended to copper is capable of giving results within a tenth per cent. of accuracy, and is much more easily managed than silver. Silver is preferable for the highest accuracy, but the accuracy which copper is capable of giving is easily obtained, and it seems sufficient for most practical purposes.

Experiments on the ratio of the electro-chemical equivalent of copper to that of silver were also made, and led to the conclusion that when the proper correction for corrosion in the liquid is introduced, the ratio is very nearly 0·2942, which, on the assumption of ·001118 as the mass in grammes of the silver deposited by 1 coulomb of electricity, gives as the corresponding number for copper ·0003290. When a nearly saturated solution of copper sulphate is used and a current density of $\frac{1}{30}$th of an ampere per square centimetre of the cathode, the amount of copper deposited by a coulomb of electricity is ·0003287 gramme.

It is pointed out that if the solution does not contain free acid there is a danger of obtaining too great an increase of weight, due apparently to the oxidation of the copper as it is being deposited. The same remark as that made above with regard to the silver anodes, namely, that they must be considerably larger than the cathode, applies to the copper anodes if they are to be weighed. If the copper anodes are so small as to give a current density exceeding about the fortieth of an ampere per square centimetre, the current is liable to stop almost completely, even when an electromotive force of as much as 25 volts is used to produce it; this is apparently due to excessive resistance at the surface of the anode. After a few minutes the current again resumes nearly its old strength, and gases are given off freely at the anodes.

These gases are readily dissolved by the liquid, and generally as the final result the gain and loss of copper do not differ very greatly, although they always do differ from those obtained when no gases are given off.

The arrangements of one of the standardising tables in Sir William Thomson's laboratory are illustrated, and the different pieces of apparatus and the mode of using them described. The method of standardising instruments which are designed to measure either very weak or very strong currents is also illustrated and described. In the former case a multiple, and in the latter case a sub-multiple, of the standardising current is passed through the electrolytic cell.

DISCUSSION.

Prof. SILVANUS THOMPSON desired to know what galvanometer was employed for keeping the current constant.

Mr. BOTTOMLEY replied that any instrument that was sufficiently sensitive might be used.

Prof. THOMPSON said he supposed all the measurements assumed H constant.

Mr. BOTTOMLEY said H remains nearly constant during the hour. He did not know whether he had been misunderstood. The object of the whole thing was to standardise a current measuring instrument by electrolysis. The value of H did not enter into the result.

Prof. THOMPSON was afraid H would not remain constant for an hour in his laboratory among dynamos, &c.

Lord RAYLEIGH said he supposed the constancy of the galvanometer was not an essential part of the apparatus. In point of fact, when he wanted to obtain the highest accuracy he found it was best to leave the current alone, and take the mean of the current readings at the beginning and end of the time. Of course it was far more convenient for calculation to control it in the way Mr. Bottomley had described, by means of the galvanometer and rheostat.

Mr. BOTTOMLEY: That is quite so; it is simply for convenience.

Lord RAYLEIGH said he would like to know whether Mr. Bottomley did not find, in using a vertical arrangement of plates, whether of silver or copper, that he was troubled with the necessary tendency of the liquid to assume unequal density. It might be that with large masses of liquid the effect was not important; but in his experiments with silver he had found it decidedly an advantage to keep the plates horizontal, having the anode horizontal near the surface so that the liquid which collected there might circulate itself by gravitation about the plate. He questioned whether it was really the best plan to pass such very heavy currents as Mr. Bottomley spoke of—from 50 to 100 amperes—through voltameters at all. It would not be very difficult to contrive apparatus, a sort of shunted galvanometer, which should show with precision when one current was exactly twenty or thirty times another. In that case the heavy current to be dealt with would be passed through the instrument to be standardised at the same time that the current twenty or thirty times smaller passed through the voltameter. That occurred to him as the best way of measuring very great currents with great accuracy rather than to pass the great current itself through the voltameter.

Mr. BOTTOMLEY said, with regard to the density question, they had not been troubled with the change in density. They had a large number of plates; there were in all nineteen in their instruments, nine cathodes and ten anodes, and an electrolytic vessel containing perhaps 30 or 40lb. of solution. They were brought close to each other, and no doubt current must be circulating in them. He thought large currents, 200 amperes or more, a method of graduating somewhat similar to that Lord Rayleigh had referred to, would be useful. Sir W. Thomson has occasionally graduated two or three instruments with smaller currents, then putting these in multiple arc, taking the whole current from them through an instrument to be graduated with a strong current, and has had very good results

Prof. BLYTH wished to know something more respecting the rheostatic interference with the current strength during the period of measurement. Was it exactly the same thing in measuring the quantity of electricity going through the electrolytic apparatus if it were applied for ten alternate periods of one minute, and then for ten consecutive minutes? He could not quite see why it should not be, but it was quite possible that it might not be exactly the same thing. If it were, the rheostatic interference with the current strength during the time of measurement would require to be seriously looked into.

Mr. SHAW said he had seen a number of experiments on the comparison of silver and copper electrolytic cells, and he would like to remark upon one point introduced by Mr. Bottomley, who had spoken of the determination of the quantity by the loss of weight of the anode as well as by the gain of weight of the cathode, and mentioned a difficulty which those who worked with copper voltameters were perfectly familiar with, that was to say, that after a current had passed for some time it very rapidly fell. It might recover again two or three minutes afterwards, but there was that sudden drop in the current which sometimes seriously interfered in experiments with standardising instruments. That seemed to him to be due to the oxide in the copper, or whatever the anode might be; but, as a matter of fact, it wiped the layer off, and a rehabilitation of the current was at once obtained. Even in the case of silver, although the oxide did not occur there, the current in its action upon the anode seemed to be selective; it did not take a uniform layer, but disintegrated the metal as it took off the silver, and that, although it might be reduced to a minimum in certain particular experiments, could never by any arrangement of the apparatus, so far as he could make out, be actually avoided. A particular experiment might succeed in consequence of the peculiar molecular construction of the silver, but generally the result was greatly interfered with by reason of this disintegration and consequent falling away of the metal. The hard or oily layer on the surface of the silver was very apparent, but even when they got below that and used surfaces originally left by electrolytic action—even there, there was a selective action of the current upon the anode, and it was only when the anode was of considerable size that any satisfactory weighing of the anode could be obtained. The current he had worked with was very much smaller than the currents Mr. Bottomley had mentioned, being about half an ampere or less. This difficulty must be very considerably increased in this case, owing to the proximity of the plates.

Prof. ARMSTRONG asked Mr. Bottomley what method of drying he had employed. Of course chemists now obviated the difficulty in this respect by drying very rapidly, usually by washing first of all with distilled water, and then with ether, possibly to dry the plates after the washing. He spoke of this because chemists were in the habit of using electro-deposition for a very large number of determinations.

Lord RAYLEIGH supposed Mr. Shaw's remarks related rather to the anode than to the cathode.

Mr. SHAW: Yes.

Mr. BOTTOMLEY did not know if anybody had made any experiments on a subject mentioned by Prof. Blyth, that of starting and stopping the current. He did not see why stopping and starting should make any difference, though it would make instruments difficult to read. With regard to weighing the anode plates, it was only used as a check upon the other method; they really went by the cathode. If the anode were to give a bad result it would be put aside. It was mentioned only as a matter of interest, and as showing that the anode could be used if the dimensions were properly arranged. With regard to drying the plates, they simply put them between two folds of blotting paper, squeezed the water out, and then exposed them to the fire or to the hot current of air over a spirit flame.

Prof. OLIVER LODGE said he had always found the copper come out 1 per cent. higher than the silver result. He supposed, however, the method was sufficient for rough graduation. The difficulty in drying copper and weighing it before oxidation occurred was very much too considerable for accurate working; silver was very much easier to deal with.

Prof. SILVANUS THOMPSON said that checking the current after first turning it on could to some extent be avoided by using small current density. An experiment given in the first chapter of "Planté's Researches on Secondary Batteries" was admirably calculated to show the three stages of the process occurring at the first turning on. The phenomenon was most marked when two copper wires were used as electrodes with a very considerable current density.

Mr. BOTTOMLEY said he should be very sorry if it was supposed that the experiments described in the paper were merely for the purpose of rough graduation. They considered that the experiments were good to $\frac{1}{10}$th per cent., and it was not a matter of being sure to 1 per cent. or anything like it. He thought if the precautions which they had discovered to be necessary in the course of these experiments were adopted no very serious difficulty would be found in the way of washing or drying the plates. The plates obtained and treated in the way described were obviously not oxidised; after drying them they could leave them for hours, and the weight was not perceptibly different. The great thing was, perhaps, with regard to avoiding the oxidation during the time when the current was flowing, and that was accomplished by making the solution of the proper density, and keeping it slightly acid. In neutral solutions they always found oxidation, and to a very serious extent.

Mr. SHAW said he could corroborate Mr. Bottomley's statement with regard to the oxidation of the anode when the current density was adjusted with sufficient carefulness. For other current densities the oxidation was equally marked as soon as the plate began to dry. This was a point upon which he was having some communication with Prof. Lodge for the purposes of the Electrolytic Committee, and therefore he would say no more about it at present.

EXPLOSIONS OF ELECTROLYTIC GAS AND VOLATILE CARBON COMPOUNDS.—Signor A. Pizzarello contributes a paper to *Il Gazetta* showing that when electric sparks are passed through electrolytic gas saturated with the vapour of a volatile carbon compound, such as ether, ethyl and methyl alcohols, or ethyl formate, a coloured flame is noticed during the explosion, and a small quantity of carbonic oxide is produced.

THE EARTHQUAKE IN GREECE.—Special Report.

(FROM A CORRESPONDENT.)

ZANTE, SUNDAY, AUG. 29, 1886.

If the unfortunate inhabitants of the Ionian Islands and the Morea had been led to hope that the unusually long immunity from earthquake shocks indicated that they had possibly taken another direction, the illusion has been most rudely dispelled by an earthquake of a character more general and extending over a wider area than Greece has ever previously been visited by.

Many local phenomena as far back as last January, including the stoppage of the ooze from the pitch wells here, subterranean rumblings of a most pronounced character, unusually prolonged calms, and high water, prepared us for something extraordinary.

The whole of the past week had been peculiarly strange. Heavy clouds, which generally discharge their accumulated electricity at this season, remained stationary over certain points of the horizon. The temperature varied but one degree between noon and midnight, averaging 85 F., and by the observant sounds and noises of an unaccountable nature were noticed during the still small hours of the night. The news which had just reached here of the reported volcano some hundred miles south of this island tended to increase our alarm, as former experience (about which I will inform you presently) led us firmly to believe in its existence.

In order that your readers may form some idea of the idiosyncrasies of earthquakes, especially in this region, a brief history of those which have come under my personal notice during a thirteen years' residence in this island may not seem out of place.

It is a tradition that serious shocks occur here every thirty or forty years, and the strong shock of St. Luke's day, 1840, is cited as the last one severely felt, and it is compared with the present one. The Greeks, however, are a singularly forgetful people, and do not now remember the night of October 26th, 1873, when a subsidence of the sea close to the island caused far more damage *locally* than last Friday's shocks; but its area was very limited, and was not felt fifty miles away from its centre.

After that shock the earth moved for thirty-five days, and from five to ten shocks of varying strength were daily registered by me, and never a month passed for some years after without one or more shocks to remind us to beware. Latterly, however, these warnings have ceased, and that true historian of real facts—the aged peasant—would shake his head and declare that the "vent holes were now stopped, and we must therefore look out for squalls."

As a rule, hitherto any local shocks, however distinct, were rarely felt in neighbouring islands, and were classed in the same category as those I have described, viz., strong shocks occurring periodically after an interval of a number of years when the frequent small shocks had ceased.

On the 28th of March, 1885, at 8:25 p.m., whilst sitting at dinner, a violent undulation of a peculiar nature, and of a decided though distant force, occurred in Zante.

In a few days it was fully proved that a most extensive subsidence of the sea's bottom had taken place some eighty-five miles to the south of Zante. In certain places, where a depth of 800 fathoms previously existed, 1,500 and 1,900 were then found, and in others, hitherto measurable, no bottom could be found.

In one place, where the bottom had been previously quite level, a difference of 350 fathoms existed between the bow and stern soundings of the "Volta," the Eastern Telegraph Company's repairing ship, engaged in the repairs of the cable broken by this subsidence. It was generally considered advisable that a surveying man of war should take fresh soundings, as those marked on the Admiralty chart of 1864 must now be a very long way out.

How far this subsidence extended it is difficult to form an idea, but that it was volcanic is undoubted from the following

Digitized by Google

event which took place some few years before :—In the month of August, 1880, a huge black cloud about two miles in height, shaped like a great pine tree, extended over the south of t Island of Zante. The origin of this smoke was within 150 miles of us, in a position where the chart shows 1,200 fathoms of water.

As the smoke gradually extended calcined leaves of a putrid nature, hot ashes, and fine fibrous matter fell all over the place. One charred, but perfectly formed, leaf fell right upon my own arm, and was kept for some time as a curiosity. Some readers may remember these facts, for an account of them was telegraphed home by me at the time, and gave rise to all kinds of conjecture.

There can be no longer any doubt that the upheaval there, the subsidence of the sea's bottom, and the earthquake of last Friday all originated from the same source, and it is a most unpleasant thing to know we have such a dreadful neighbour ready to engulf us at any time.

When the earth began to rock at twenty-seven minutes past eleven last Friday night, the movement was perfectly equal, undulatory and unaccompanied (fortunately for us) by any "kicks." It was in a pronounced direction from the south-east, and was preceded by a noise which we took for a steamer close at hand. It is variously estimated that the shock lasted from 15 to 40 seconds, but seconds are centuries in such supreme moments, and who can think of counting them? For my own part I should say 20 seconds was about the duration. The consternation was, of course, general; but my thoughts were far away where I knew the centre of that shock had its origin, and the next morning our fears were fully confirmed.

From Kastro Tornese, the prominent ruined castle in the Peloponesian shore, opposite Zante, that gloriously fertile tract, the real Arcadia of the ancients, stretches itself away to the southward, towards the Gulf of Calamata, the storm beaten Cape Matapan, and the opposite Island of Crete, the first place we come across is Katacolo, the port (and connected by a railway) of Pyrgos, one of the greatest and richest currant growing districts in all Greece, the average produce amounting to nearly forty thousand tons. Further to the south are the other rising, flourishing, and at this season busy towns of Gargaliano, Aghia, Kyriaki, and Filiatra, and the limit of this richly cultivated part of Greece ends at Calamata. All these places have been most seriously damaged, Filiatra the worst of all, not a single house remaining standing, and up to the time of writing 120 dead bodies have been extracted from the ruins. At Corone, close by, many houses fell, and thirty people were killed. The number of wounded is very considerable at both places. Calamata and its vicinity suffered proportionally less, being too far south of the earthquake's centre.

At the larger town of Pyrgos, a place of some ten thousand inhabitants, with many fine and apparently strong houses, it seems a simple miracle that there were few or no victims, as the houses have been so generally and seriously damaged that the whole place is unrecognisable. The damage alone at this place is calculated at about two million francs.

All the Ionian Islands felt the shock most severely, especially Corfu, where the high stone houses render such visitations particularly dangerous — in fact, earthquakes were hitherto unknown there, and consequently it is an exception to find in that island the low built houses we have here and in the Morea. Athens and Patras sensibly felt the shock, as also several towns in the south of Italy, and the same appears to have been experienced at Malta. It is calculated with the greatest degree of certainty that in a circle of 300 miles radiating from its centre the whole of the earthquake's effects can be traced.

There is not the slightest shadow of doubt that this centre was in the sea and pretty close to the reported position of the supposed volcano, for the nearest place in a direct line between it and Malta is this unfortunate town of Filiatra.

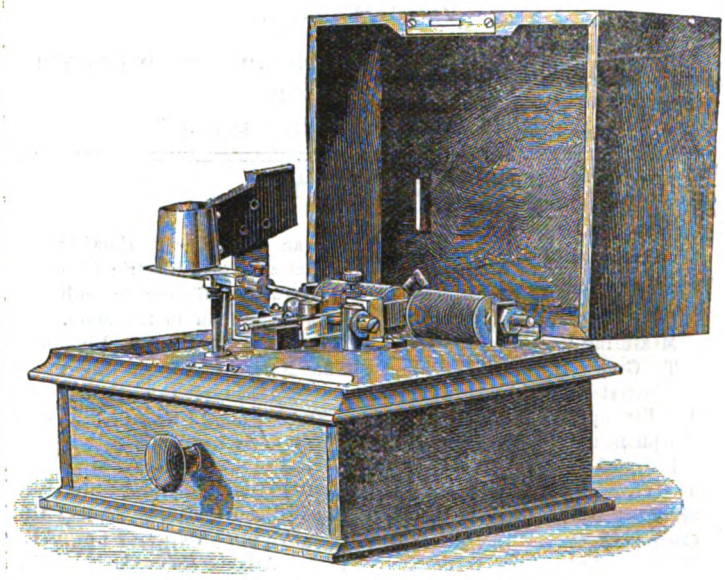
I am fully persuaded that if the whole sea between Zante, the islands of Strofades down to Cape Matapan, were surveyed, it would be found that the sea bottom, for some ten to thirty miles, has regularly given way.

None of the phenomena peculiar to regular magnetic disturbances accompanied this earthquake. It was precisely as you would see the waves roll overlapping each other, if a mountain were steadily lowered into the sea. Nothing else can be compared to the movement we experienced. Had, however, the swaying stopped half way, to begin again with the usual "kick," I am persuaded that the western coast of the Morea and the Ionian Islands would only now exist as places "that were."

The Greek Government immediately sent doctors and supplies to those places where help was most needed, and the misery will be less severe if the weather, hitherto menacing, keeps fine, to enable the currant crop to be collected, as the only income of two-thirds of the Greek population is derived from that source.

TELEPHONE CALL APPARATUS.

The privilege granted by the late Mr. Fawcett, as Postmaster-General, to the Telephone Companies to open public Telephone Call Stations where anyone could use the Telephone Exchange by paying a small amount, has resulted in a further development of telephonic apparatus in the shape of telephone "toll" instruments, and the first in the field in this country is that known as the Crossley, Harrison, and Emmott call box.



The Crossley, Harrison, and Emmott Call Box.

In this instrument (shown in the figure) a slit at the top of the box enables the person wishing to use the telephone to deposit the necessary amount, which is usually 3d. for inter-town communication.

The coins roll on to the table shown at the end of the lever, and, overbalancing it, they fall into the drawer seen in the lower part of the figure. The movement of the lever thus obtained puts the telephone in connection with the exchange by means of a contact which is maintained so long as the operator at the exchange shall permit, the specified time being three minutes, at the expiration of which time a current is sent from the exchange, which throws the needle of the relay to its normal position, and until a second toll has been deposited no further communication can be made. The movement of the lever has been used to start a train of clockwork, and thus take the regulation of the time out of the hands of the operator; but in many cases this is considered unnecessary, and it is preferred to keep the apparatus in the form shown, as the call boxes are often placed in remote country districts, where the number of calls are insufficient to maintain a telephone exchange or attendant, and simplicity, with non-liability to get out of adjustment, is the first thing to be considered.

A counter attached to the lever enables the number of calls to be registered, in order to keep a check on the cash.

THE VOYAGE OF THE "VOLTA."

Although no exaggerated value, either scientific or technical, is said to be attached by the owners to the experimental trip of the "Volta" across the Channel last Monday week, the feat is one which they may well be proud of, and the notice it has attracted in the press cannot fail to add greatly to the reputation of Mr. RECKENZAUN, who was responsible for all the electrical arrangements of the expedition. If the good people of Dover really imagined that the "Volta" was about to be put in competition with the "Calais-Douvres," these modest disclaimers on behalf of the electric launch are perhaps not uncalled for; but the voyage was not made for nothing, and Mr. RECKENZAUN is probably more confident than he cares to own that the propulsion of boats by electricity will soon cease to be a day's wonder, and will eventually take its recognised place among the practical modes of marine locomotion. At all events, there are several ways in which already it may be conjectured that electrical navigation will establish its superiority over steam; and some of these are indicated by the results of this voyage from Dover to Calais and back.

In the first place the "Volta"—which may be taken as a type of what boats of her class will be—is undecked, and her accommodation for passengers or merchandise is, therefore, greater than that of any boat of similar dimensions driven by steam power, and carrying the requisite supply of coals. At the same time it is needless to say that an open boat of this description is not adapted for the sea except in very calm weather. Her batteries are stowed away where fuel could not be accessible; and her motors take up far less room than the engine, boiler, and funnel of an ordinary steam launch. Next, there is the avoidance of all those annoyances to passengers which are the invariable attendants of steamboat travelling, even when the journey is short and the water smooth. The "Volta" makes progress without any disagreeable vibration, and with no smoke or bad smells. The noiseless way in which she glided on the water the other day was demonstrated by one of the crew laying hold of a sleeping seagull, whose slumbers had not been disturbed by the approaching boat. And, lastly, the speed at which a launch of this description would be propelled on ordinary occasions is as great as that of the average steam launch, but can be increased beyond anything a fast sailing steamer is capable of if special occasion call for it.

When the steamboat was first constructed, its employment seems to have been confined to inland waters or narrow streams; and even as late as 1812, some fourteen years after MILLER'S first experimental boat on Dalswinton lake, Dumfriesshire, the more ambitious designs of FULTON in America were only employed as ferry boats, their speed not exceeding seven miles an hour. Probably for some little time to come the electrical boat will confine itself to the same narrow sphere of operations, its usefulness being at present limited by the necessity of plying between fixed points, not very remote, where fresh fuel—or more exactly a fresh charge of electrical energy—may be taken in. Subject to this condition, however, an objection which effectually hindered the progress of steam navigation on rivers and canals will not apply to the electrical boat. SYMINGTON'S steamboat was interdicted on the Clyde Canal in 1801 on account of the motion destroying the banks. The modern steam launch has gained an ugly notoriety on this very account, as well as for its obtrusive ugliness on rivers devoted chiefly to pleasure. The "Volta" might navigate any canal in the kingdom, or the most crowded part of the Upper Thames without provoking a single imprecation, and her "wash" is said to be comparatively harmless.

If the expense of working can be kept within reasonable limits we believe there is a wider sphere of usefulness open to electrical boats of the "Volta" type; and her passage across the Channel will firmly establish public confidence for journeys of more limited extent. In some cases the water power of rivers to be ferried might be utilised for charging the batteries, and the expenses reduced to a minimum; but under even less favourable circumstances the capacity of the secondary battery is being so greatly enlarged that we may confidently anticipate a speedy reduction in the cost of this description of motive power. Mr. CROMPTON'S remarks on this head at the British Association meeting were most encouraging. The batteries on board the "Volta," weighing only two tons, enabled her to do the double journey, occupying more than eight hours; and probably it could have been easily extended to ten. If this is a fair measure of her travelling capacity the utilisation of such boats for the navigation of certain rivers is almost a matter of certainty. Competition with steamboats may be out of the question; but it is easy to see that the many advantages of electrical navigation will establish it where steam has hitherto

Digitized by Google

been inadmissible, and in some cases may supersede the existing steamboat service, at all events for ferrying purposes.

To the more serious business of propelling torpedoes by electricity a good many people are now devoting their serious attention, and probably this recent performance of the "Volta" will give an impetus to the idea. When steam navigation became a practical reality it was sagely predicted that its adoption would diminish the chances of war by increasing the certainty of destruction, and "proportionally lessening the desire for battle." It is certain that naval engagements have been fewer since the general application of steam; and there is a widespread suspicion that the modern iron-clad will be very shy of coming to close quarters. If there is any truth in this "the desire for battle" will be still further cooled by the perfecting of the torpedo as a swift and deadly implement of naval warfare. Electricity as a mode of propulsion would undoubtedly add much to the terrors of this silent messenger of death, and if certain difficulties were overcome in regard to the storing and charging of the batteries, their obvious superiority over steam power would insure their adoption for torpedo warfare. Possibly these difficulties may gradually disappear through the growing application of electricity on board ships of war for electric lighting purposes. Once establish the storage battery as part of the ship's equipment, its transfer to the torpedo boat will be rendered perfectly easy and trustworthy.

SIXPENNY TELEGRAMS.

The newspaper reports of the reply made by the POSTMASTER-GENERAL to Mr. SHAW-LEFEVRE'S question on Wednesday night with reference to the increase of Telegraph business, and the financial results of the change of tariff, varied so considerably that we have been at some pains to ascertain the exact figures given by Mr. RAIKES. It appears that for the six months ended the 31st March last, the number of telegrams under the new rate was 16,787,540, as compared with 11,314,423 during the previous six months of the financial year, when the old tariff was in operation. The income derived under the new tariff, together with the additional amount received in respect of the registration of abbreviated addresses was £22,000 less than that of the corresponding period of the previous twelve months. During the five months of the present financial year—that is to say, up to the end of August last—the number of messages was 17,369,161, as compared with 11,125,794 for the corresponding period last year, the revenue being £3,000 less. As Mr. RAIKES reasonably pointed out, this small deficiency might be made up in the present month—September. It is well to remark, however, that these figures refer only to the number of and receipts from messages, and in no way take into account the extra cost of transmitting the large number of telegrams in excess of those sent under the old *régime*. This item, which naturally must be very considerable, cannot, as the POSTMASTER GENERAL observed, be ascertained for some time. Briefly analysed, the results of the change from the one shilling to the sixpenny tariff are that the increase for the five months has been at the rate of 56 per cent., and for the six months 48 per cent., while the amount received per message has been $8\frac{1}{16}$d. as compared with $12\frac{1}{17}$d., or nearly 1s. 1d. These figures amply testify to the accuracy of the calculations made by the officers of the department who had charge of the scheme; and go far to bear out their expectations that in a short time the accounts will show a balance on the right side.

CORRESPONDENCE.

LITHANODE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reference to the letter under this heading from Mr. Walker Moseley, that gentleman is labouring under an unaccountable misapprehension in supposing that he "unwittingly" manufactured the substance in question when running down a voltaic couple, in which sulphate of lead was the depolarising agent. His lead sulphate was "in process of electrolytic conversion," not into *peroxide of lead*, but into the well-known, though somewhat complex, compound—containing lead sulphide, basic lead sulphate, and metallic lead—which constitutes the "spent" depolariser in the sulphate of lead battery. "A hard, black lump" of *peroxide of lead*, "resting on a layer of minute bubbles of *hydrogen gas*," would, indeed, be an extraordinary phenomenon! No wonder Mr. Moseley objects to the term "lithanode," as being a "dubious title," if he imagines that peroxide of lead can be produced at the *cathode* within a voltaic cell.

Mr. Moseley, as well as other practical electricians using batteries for working electric bells and for many other purposes, has yet to make the acquaintance of *lithanode*. Anything less resembling the residue from the sulphate of lead battery, whether from a physical, chemical, or electrical point of view, it would be difficult to imagine. If he can manage to obtain—there, perhaps, is the difficulty, which I may be able to overcome for him—a plate of lithanode, and if, with a fine saw, he will cut from the plate a narrow strip of the material, he will be able to realise what can now be done in the direction of "small size and cleanliness," as well as in that of general efficiency, in the construction of voltaic batteries. I speak only of the negative element of the couple; but this, as Mr. Moseley knows, is considerably more than "half the battle." With this negative, a fragment (say) of an old meat-tin as a positive, and a little dilute acid—sulphuric or acetic—as electrolyte, he would be able to astonish the good people of Scarborough with a battery presenting a far greater contrast, in bulk and weight, to the sulphate of lead battery, than does even the Leclanché cell.—Yours, &c. DESMOND G. FITZGERALD.

6, Akerman-road, Brixton.

NAVIGATION BY PRIMARY BATTERY POWER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the very interesting account given in your journal of the 17th inst. of the "first occasion on which the Channel has been traversed by electric power," it is stated that the "Volta" was provided with 61 accumulator cells, each containing 39 plates, and that the cells have a capacity of about 240 ampere-hours, which, at 120 volts for that number of cells, is equal to $4\frac{1}{2}$ horse-power for a maximum of $8\frac{1}{2}$ hours when discharging at the rate of 28 amperes. The cells were charged by a dynamo on shore at Dover, and the trip to Calais and back occupied eight hours and five minutes.

Whilst very heartily rejoicing at the success of so notable an expedition, and with a wholesome dread of the consequences which may befall me for venturing to make so bold an assertion, will you permit me to state that the same electrical power would be obtained in a very much more lasting form from 61 cells of a certain primary battery with which I have had some little experience, in each cell of which the 39 lead plates would be replaced by four carbon and five zinc plates? In the 61 accumulator cells there were 2,379 plates, whilst in the primary battery of equal working power there would be only 549, or less than one quarter the number; but, nevertheless, the duration of the voyage, instead of being limited to eight hours, might without difficulty be extended to eight consecutive days and nights, or to eight weeks or more, without its being necessary to return to the shore to re-charge the battery.

During a voyage of eight days and nights (192 hours), if using the same electrical power, viz., 3,360 watts per hour, such a primary battery would require to be from time to time refreshed with liquid, the storage of which need not occupy more than two cubic yards of space; while the steadiness.

Digitized by Google

constancy, and freedom from noise would be precisely the same as with accumulator cells. The only difference in working the batteries would consist in using preferentially with the primary double the quantity of current and half the E M.F.—Yours, &c., O. C. D. Ross, M.I.C.E.

East Dulwich, September 18, 1886.

CAPTAIN CARDEW'S METHOD OF TESTING THE EFFICIENCY OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your note on this subject hardly explains the most useful form of this excellent method. It is not necessary to have three machines of identical size and type, but any two dynamos from the stock of more or less antiquated patterns which most makers have the misfortune to hold will do for testing a third.

Let A be the dynamo to be tested. Take B and C, two others of about the same output, so that A be tested to its full load.

Couple B and C together with a belt or coupling, and run them from A as a generator, using B as a motor and C as a secondary generator, and then C as a motor and B as a secondary generator. These tests will probably be identical; if not, the mean may be taken. The ratio of the output of the secondary generator to the output of the primary will, of course, be the efficiency of the pair B C. Call this E_1.

Perform the same with B and C as primary generators, making three pairs of tests.

Then $E_1 = B C$; $E_2 = A C$; $E_3 = A B$.

Therefore $$A = \sqrt{\frac{E_1 E_2}{E_3}}.$$

This system is, as you observe, absolutely beyond suspicion of error, and the most accurate one that can be adopted.

It would be interesting to test some of the much-talked-of mechanical dynamometers by means of dynamos and electrical instruments; and it would not be surprising if the dynamos told tales about the dynamometers in less complimentary terms than these instruments tell when used to pass judgment on dynamos.—Yours, &c., Alex. P. Trotter.

Bull Green Works, Halifax, Sept. 20, 1886.

ELECTRIC LIGHTING IN ITALY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of Sept. 10, under the heading "Electric Lighting in Italy," taken from *Industries*, appears a statement which is liable to a false interpretation by your readers, and I take the liberty of pointing out its inaccuracy.

The plant at Turin referred to in the above article is not an Edison plant, nor was it installed by the Edison Company, nor under its direction. The Edison Company furnished only the dynamos for this installation. The material which has given trouble, including underground lead cables, lamps, &c., was furnished by other parties and installed by the Turin firm holding the concession from the municipality.—Yours, &c.

Milan, Sept. 13th, 1886. J. A. Lieb, Jun.

THE INCANDESCENT LAMP.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I ask through your valuable paper why it is that the makers of incandescent lamps will not give more than approximate figures of the current or resistances of the lamps they send out? They will only give, I am informed, the E.M.F. and candle-power. Surely they charge enough for them to warrant the purchaser in expecting to know what actual current each lamp requires relatively to its E.M.F.

I am a great lover of the light, and I believe the method by which it is now obtained is almost perfected, with the exception of the lamps; but here there is not that accuracy and reliability which there should be if economy in the incandescent system of lighting is to be attained.—Yours, &c.,

T. D. C. W.

A CORRECTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On page 381 of last week's issue it is stated, in connection with the Sunderland Telephone Exchange, that the "multiple" switch-board has just been introduced there, and that only two other exchanges in this country, viz., Liverpool and Glasgow, have adopted this principle.

Will you permit us to say that the "multiple" switch-board has been in use in the Sheffield Telephone Exchange since February of the present year.—Yours, &c,

Tasker, Sons, and Co.

Sheffield, September 21st, 1886.

ELECTRIC INDUCTION BETWEEN WIRE AND WIRE.*

BY W. H. PREECE.

Along the Gray's Inn-road, in London, the United Telephone Company has a line of wires over the roofs of the houses, and along the same road, for a distance of 2¼ miles, the Post Office has a line of telegraph wires buried in iron pipes about 2ft. 6in. beneath the street. The telephone company stated that they observed certain disturbances upon their wires, and on one occasion had been able to read a message that was sent from London to Bradford. Now, inasmuch as the Bradford wire passes through those pipes, it was clearly evident that the disturbance, such as it was, was due to some action between the underground wires and the overground wires. I took every possible pains to determine to what this was due. It might have been due to some accidental contact somewhere between the wires. It might have been owing to conduction through the earth, but by grouping the wires in every possible way it was quite clear that by eliminating the earth and by adopting every precaution that we knew to avoid contact, there was induction between the telegraph wires underground and the telephone wires overhead, the wires being separated from each other by a distance of 80ft. We little anticipated that inductive effect was experienced at such a distance, and I had a series of experiments tried by Mr. Heaviside on the Town Moor, in Newcastle, to determine how far induction between wire and wire could be traced, and there it was found that distinct evidences of induction were felt at a distance of 3,000ft. Having got from 80ft. to 3,000ft., it was then thought that we would see what effect could be found on an actual line. Between Durham and Darlington there is a line of six wires 18 miles long. Between Castle Eaton and Stockton there is a line of 12 wires 10¼ miles to the east. Between Bishop Auckland and Piercebridge there is another line of 12 wires at a distance of 5¼ miles. We took this central line of six wires and 18 miles long and grouped them into one primary wire, and transmitted currents through this primary wire by means of a Wheatstone automatic transmitter—a transmitter that sends reverse currents—and at each of these corners which I mark A B C and D observers were placed with telephones. The effects of rapid transmission of alternating currents at the rate of about 500 or 600 per second were heard distinctly at these four corners; and the notion was that inductive effect was experienced between these lines, the one being 5¼ and the other 10¼ miles away. This experiment took place on Sunday. The lines were isolated at each end, and while everything was perfectly quiet—while the distinctive currents produced by the transmitter on this central line were absent, the observers received distinct indication of Morse signals being sent elsewhere. There was no line near, there was no place where these Morse signals could be obtained but from a line on the other side of England, 49 miles away from this particular place. On the subsequent Sunday we took the lines from Gretna to Shap, a length of 49 miles, and from Jedburgh to Newcastle, a length of 55 miles. On the one line there were 17 wires, on the other 10 wires. I went myself with Mr. Heaviside to Gretna. We had another observer at Shap, one at Jedburgh, and one

* Paper read before the British Association at Birmingham.

Digitized by Google

at Newcastle. Now, in order that there should be no possible mistake between the sounds obtained by working the telegraph, a special commutator was used that sent rapid intermittent currents increasing and decreasing so that the sound produced was a rising and lowering wail [imitating with the voice] something like that. However, the sound was so perfectly distinct that, if it were transmitted, it would certainly be evident at Gretna. The experiment was to take place between the hours of eleven and one. At a given time, 11:15, the transmitter was to be put on at Gretna, and at that time I heard a distinct and clear wail. Well, the conclusion that we came to is that an inductive effect took place across this country forty miles broad. But I am bound to say that there are many reasons why the evidence must not be taken as conclusive. Every possible precaution was taken by isolating the lines, but we were still compelled to use the earth. The whole of the north of England is covered by a network of wires. There are wires going from Glasgow to Edinburgh, then again from Carlisle across the country; and, although the experiment is very interesting, I do not say that it is conclusive that inductive effects can be transmitted across such an extent of country. At the same time the evidence is quite sufficient to justify our pursuing the investigation as far as we possibly can. At the present moment we are putting up from London to the Welsh coast a line of copper wires 150lb. to the mile—a perfectly distinct line—and there will be many lengths on that line of forty to fifty miles perfectly clear of lines in any other part of the country, and during the next two months I am going to try several more exhaustive experiments of the same kind. Naturally one is very desirous, having got so far, to get some idea of what this effect was, and some notion of the laws with regard to it. Of course it is full of difficulty. We have conduction through the earth, and we have various other causes that make it extremely difficult. But what I have done is this: A gentleman—Mr. Hugh Andrews—gave us the use of his park (Swarland) for some of our experiments. They have been going on for eighteen months, and hitherto we have been able to make many both there and upon the moors. But as regards the latter a difficulty arose—namely, the grouse—which compelled us to go to the park I have referred to, and there we laid out the wires in various forms to try the distance through which this effect was produced. I will not give you all the details, but I will simply give you one of the results that we arrived at. A circuit was made of gutta percha covered wire a quarter of a mile square—that is, a circuit of copper wire covered with gutta percha laid on the ground on a square of a quarter of a mile. Another similar square was laid on the ground, and many other squares of different sizes, forms, and shapes were put apart from each other. The results of those experiments will form the subject of a subsequent paper. Lord Rayleigh has kindly promised to assist me in this matter. It requires a considerable amount of mathematical knowledge to work out the formulæ and conditions that may arise, so that I hope next year I may be able to give you some of the results. But now the result I have got is this—that, with a square fixed at a distance of a quarter of a mile from an exactly similar square, it is quite possible with a telephone in one square to speak to a telephone in the other square, separated by a distance of a quarter of a mile. There is no earth there; there is no disturbance; there is nothing that could possibly enable a listener in one telephone to hear a speaker in the other telephone, except inductive effect across that layer of air a quarter of a mile in length. It is not necessary even that air should be the medium between the two. Since these experiments were made, I have learned from Porthcurnow that our cable to the Scilly Islands was broken down, and half a mile from this Scilly Islands cable there is another cable, belonging to, I think, the Jay Gould Company, to Brest. These cables lie in the water half a mile apart. They do not come near each other, and yet the signals on the Scilly cable were heard distinctly, and the messages transmitted on the French cable half a mile away were read with perfect ease. There we have induction it would almost seem in the sea. I am not quite sure but at the meeting at Southampton I showed how we had spoken with the Isle of Wight from Southampton without any wire across the Solent. This was evidently by induction. Mr. Edison, of America, has been working in this direction, and he has been able to communicate with passing trains. Trains carry induction coils, and they send their inductive influence to the wires along the line, and conversation has been held in that way. There is no doubt that this inductive influence will lead to further inquiries, and probably eventually to a more extensive practical development of the telephone.

Discussion.

Sir W. Thomson said that the question of induction over an area of 40 miles was an interesting one from many points of view, and one which he hoped Mr. Preece would be able by-and-bye to say more about. Mr. Preece, however, had indicated a means by which messages might be communicated, or partially communicated, by the cross telegraph wires that covered the north of England, and they would look forward with the greatest interest to the results of the continued experiments that Mr. Preece had promised. The case of the two squares was something very definite, and he had no doubt that Lord Rayleigh and Mr. Preece would follow it up and bring it to a mathematical certainty. Nothing could be more interesting from a purely scientific point of view, and it was obvious that it might be of practical use. When one spoke into a telephone it seemed now as if one spoke over the length and breadth of the land. The discovery might be taken to show the necessity for taking means to insure secrecy in telephonic communication. Now that they had that wonderful tale-tell or eaves-dropper—the telephone—they could hear what was going on all over the country, and if secrecy was to be obtained, it must be by adopting a thoroughly secret code.

Prof. Silvanus Thompson said he desired to protest against the somewhat general use of the word induction to explain away every phenomenon of the kind described. He knew that telegraph engineers were for ever attributing to induction everything that disturbed their work, when the fact might be simply due to dirty insulators. He himself could not believe that the experiments conducted by Mr. Preece gave an illustration of an effect of induction at all, for this simple reason. They knew that a current in returning through the earth did not, as some people imagined, run straight along the ground underneath the wire, but spread out into a current sheet and flowed round in curves from one earth plate to the other, very much as the lines of force of a magnet curve round from pole to pole. The result of this was that if a neighbouring line, or even one many miles away, had its two ends put to earth anywhere on one of the curving lines of flow, a portion of the return current of the first line found its way through the second line. But this was not induction at all. A case occurred not long ago in a telephone installation which he knew something about in the North of Ireland, where the telephone wires were laid parallel to an electric tramway. The engineer of the line reported that it was hopeless to work it, there being such an amount of induction on the line that it kept on ringing the bell. But that could easily be obviated by putting in a return wire, which was the cure he suggested, and which was found to be perfectly satisfactory. He took exception to Mr. Preece's remarks with respect to the two cables at the Scilly Islands. If there was one thing that would prevent induction it was to have a piece of metal or other good conductor between the primary coil and the secondary wire in which currents were being induced. The surrounding conductor absorbed all inductive effects into itself. In the case of the Scilly Islands there was one cable entirely surrounded by the sea, which was a comparatively good conductor, and, therefore, he entirely declined to believe that induction was going across from one cable to the other. What happened was that some of the current was going along the earth, and a portion of it found its way by conduction to the other cable. He wished to enter a mild protest against the somewhat miscellaneous use of the word induction.

Prof. Blyth quite agreed with Prof. Thompson that the phenomena described might to a great extent be due to conduction through the earth, but at the same time he looked upon the results of these two square experiments as deciding the question that induction between them did take place, and when they called to mind the experiments of Prof. Tait, which were made shortly after the invention of the telephone, and which showed that the telephone could be sensitive to extremely small currents provided they were interrupted with a sufficient degree of frequency, he thought the inductive effect between those two squares ought to be sufficient to work a telephone according to Prof. Tait's calculation. Prof. Tait's calculation was like this—that the telephone was quite sensitive to a current from three Grove cells through the resistance of a wire represented by the distance between this and the sun.

Prof. Thompson said he did not refer to the squares. There was no possible explanation of the experiments from square to square save true induction, but where they had the earth between he believed the far greater part was simply leakage, otherwise conduction, through the earth.

Mr. Traill said that in the remarks Prof. Thompson had made about the electric tramway in Ireland he had no doubt that that gentleman referred to the Newry and Bessbrook electric tramway. He (the speaker) could cite another case—namely, that of the Giants Causeway tramway, where they ran for six miles alongside the Post Office telegraph wire, which was distant only 28ft. from the conductor rail of the tramway, and where there were very great variations in the current of the conductor rail, which was worked with heavy potentials, and yet during the few years that they had been working with the Post Office wire alongside of them, they had never had a single complaint of interference with the messages on the part of the Post Office. He mentioned this as

Digitized by Google

an example where induced action did not take place to any appreciable extent upon a telegraph or telephone wire. With judicious forethought the Post Office, when the tramway company he referred to went to Parliament for their Act, put upon them very great restrictions with regard to the electric conductor rail—so much so, in fact, that if those restrictions had been carried out the company would have been put off the road altogether. But when the facts were put before the Post Office authorities, their original stipulations were altered, and the company received permission to run within a certain distance of the telegraph wire, provided their large current would not affect the transmission of messages, which it did not appear to have done.

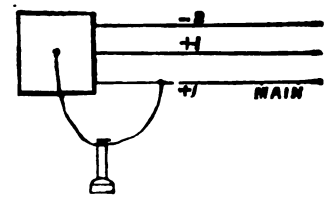
Prof. POYNTING wished to ask whether it would not be possible to arrange a circuit so as to decide between induction and return earth currents?

Mr. PREECE, in reply, desired to disabuse everybody's mind of any idea that there was the slightest chance of secrecy not being maintained. There was a possibility, perhaps, on a Sunday morning, when only one message, say, was being sent from Birmingham to London, and within a region covered with miles of wire, of reading what was going on. But it must not be forgotten that their safety lay in the multitude of messages that were sent, the results being that there was produced on the telephones an incessant patter like that of rain against a window pane. Moreover, it was only possible to read Morse signals on a line that was worked with a single current with dots and dashes. He had explained in Section G that they were going to introduce Delany's multiplex system, which would remove the slightest chance of overhearing anything that might be passing. The cure for these disturbances between telegraphs and telephones was as simple as possible, namely, to invariably use a metallic circuit. Why telephone companies had been so foolish as to exercise the false economy of depending upon single wires was one of those puzzling things which were not possible of explanation. In the Post Office, as soon as they were perfectly satisfied that induction was the main cause of the disturbances, they decided to use double wires, and they never used anything else anywhere. He agreed with Prof. Thompson's remarks. He did not say that the effects he had described were absolutely due to induction, because there were so many things to be taken into consideration. But he had determined to pursue the investigation in a way similar to that which had been suggested by Prof. Poynting between London and the Welsh coast. He would use metallic circuits everywhere, and thrash the question out, for it was really a very important one, for few people had any idea that inductive effects could extend to such an enormous distance.

ON AN EXPERIMENT SHOWING THAT A DIVIDED ELECTRIC CURRENT MAY BE GREATER IN BOTH BRANCHES THAN IN THE MAIN.*

BY LORD RAYLEIGH.

The experiment here described is one that I need not say much about. It has, perhaps, a paradoxical title, and I thought that in that way I might bring out the points really involved in it. The question is, How do conductors in multiple arc or parallel behave when subjected to alternating or periodic currents? The paradox is involved, I think, in the silent introduction of the idea that the currents are steady. If the currents are intermittent, then there is no reason for supposing that the current in the main is the arithmetical sum of the currents in the branches. It must be the alegraic sum under all circumstances. The question of the behaviour of two conductors in parallel, of course, is a very easy one if we suppose that the currents are steady. We then have the law, familiar to electricians, of a division of the current between the two in proportion to their conductivities. But if the currents are alternating, and if the conductors placed in parallel have the property of self-induction which they must have in some degree, and still more if they have a sensible mutual induction one upon the other, then the case becomes a great deal more complicated. In a paper that I published a few months ago in the *Philosophical Magazine* I gave a general calculation of what the resultant resistance of the two conductors placed in parallel to alternating currents would be, and what the resultant self-induction of the two would be—that is to say, I gave what would be the self-induction of any single conductor. In examining that closely I saw what looked to be very curious things involved in it, and which would be brought out, supposing that the two currents placed in parallel were composed of wires laid side by side so as to travel very nearly along the same course, and that will best explain what I have to say. Suppose, too, that you have three wires laid side by side together, and made into a coil of a considerable number of convolutions; and suppose that you have two of those wires in series and combined in such a fashion that the current will circulate in the same way round both those in series, and take that as one of the conductors in parallel, and as the other conductor in parallel take the third wire, and then submit the system composed of those three wires forming two conductors in parallel to alternating currents, what will be the condition of the currents between the two conductors, and how will they be related to the current in the main? The theory shows that when the rapidity of alternation is sufficiently great the endeavour is, as it were, to cause the magnetic effect of the combined currents to be as small as possible at points which they influence—in fact, to neutralise as far as possible magnetic effects; and that tendency more and more asserts itself as the rate of alternation increases, so that ultimately the distribution of the current comes to be independent almost completely of resistance, and to depend solely upon the inductive coefficients. In this case the energy of the field of magnetisation at various points not in the immediate neighbourhood of the three wires may be a suitable index of the distribution of the current neutralised, because we have only to suppose that the current of the two wires joined in series is just half of that, and in the opposite direction to that in the single wire, in order to have at all points complete neutralisation of effect. So that under the influence of rapid periodic currents that is the state of things. You see what is involved in that, namely, that the current in one conductor—in the two wires placed in series—should be represented by +1, the current in the single wire by −2, and the current in the main would be represented by +1, numerically less than one of the currents



in the branches. That is the easiest form in which to make the experiment. I had a large coil, triply wound, and I tried the experiment in the form in which I have related it, in order to estimate the currents in the three conductors. There was a piece of copper sheeting fastened on to a board, three German silver wires of the same diameter were led from it. This was the main [indicating it] coming in along here, and the two branches here, so that if what I say is correct there ought to be along the main a current represented by +1, and along this one a current represented by −2. The current was tested by a sort of telephonic process. Another wire, soldered to this copper sheeting, went to one pole of the telephone, and at the other pole of the telephone the German silver wires were connected by touching the wires at the second telephone terminal at equal distances, and if the currents had been equal in these three wires then of course by touching the second telephone terminal the sounds would have appeared equal. It was found at once that the current of this wire—one of the branches—was very much louder than the current in the other branch, and more than equal to that in the main. In these investigations perhaps it would not do to trust to oneself, but by putting an assistant at the telephone and trying various places it is possible to feel out the points which give the quality of sound, and so to get a numerical estimate of the current in this way. I was not quite satisfied with that. You see in my title I have said "greater in both branches." I have arranged something else, but the principle of it is the same. It involves iron, and it is most easily understood by having five wires instead of three. I combined them, so that three are in series and two are in series, but the three in series are to be combined in parallel with the other two in series, so that in that way, in order to get neutralisation of magnetic effect at a distance, it is necessary that the currents in the two branches in parallel—that the corresponding currents must be in the opposite proportions taken negatively. The currents

* Paper read before the British Association at Birmingham.

Digitized by Google

must be in the proportion of +2 −3. Perhaps it would be better to make it +3 −2. Consequently both currents are numerically greater than the current in the main, which is +1. I have verified that sufficiently to show that there is no difficulty whatever in so arranging the thing that the currents in both branches are decidedly greater than that in the main. Perhaps I ought to say that, if anybody wishes to repeat the experiment it is a very easy one indeed if you have a suitable coil. I used a scraping contact only, which is sufficient for the purpose. There were certain perceptible differences by varying the lengths of the wires, but they are not such as to interfere with the experiment.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION OF THE UNITED STATES.

The fourth biennial meeting of this association has just been held at Detroit; there was a large attendance of members, and the subjects discussed were of an eminently practical character. Indeed, from the tone both of the papers and the discussions, it is clear that the American electricians are too full of business at present to care very much for any merely theoretical considerations. For the English reader there is a freshness and vigour and general go-aheadness about these proceedings which, although decidedly less dignified than those of our own technical societies, has such a refreshing tone of confidence and self-reliance that one is inclined to condone the general absence of scientific terminology, and even to overlook the intrusion of a good deal of slang and a certain amount of "bunkum." Unfortunately, however, in the abstracts which exigences of space will alone permit us to give, we fear that a good deal of the native flavour will necessarily be boiled out.

Among the most interesting papers was the following, from which we have only cut out a little philosophising as to the bearing of the subject upon the dawn of the millennium.

The Operation of Motors from Electric Light and Power Stations.

BY MR. T. C. MARTIN.

When I find that more than one hundred electric light companies have the words "and power" in their titles, I come to the conclusion that they mean something by it, and the drift of the paper I had the honour to present, as a proxy, before the association last February on motors, was that it is worth the while of electric light men to pay attention to the questions involved in the distribution of power electrically. The "faith" exhibited by a high-sounding corporate name can be profitably seconded by "works." Electric light men, for the reason that they, more than any others, are familiar with the modern problems of heavy electrical engineering, are the best qualified to introduce electric motors to public notice, and the further I investigate this subject the more deeply do I become convinced that there is hardly a locality where an electric light plant exists in which also electric motors cannot be installed remuneratively.

At the present time, the feeling with regard to motors is in many quarters so sanguine that it amounts to a "boom." Now "booms" are just as bad in their way as inflation of the currency, or any abnormal display of high spirits and strong imagination. But in the case of electric motors, the "boom," if there be one, has been slightly delayed. Historically, the electric motor anticipates in practice the electric telegraph, the electric light, the telephone, and the storage battery, yet to-day it has less importance than any of these, except possibly the last. I venture the opinion that in the near future the relative prominence of these applications will be somewhat changed. Perhaps it is well that the greater perfection of the electric motor has been delayed, and even to-day is tardy. Its ultimate success has depended upon improvements in primary batteries, in secondary batteries, in dynamos, steam engines, boilers and furnaces burning cheap fuel, upon improvements in wires and in line construction, upon the development of modern ideas of urban convenience, and in no small degree upon the multiplication of small industries requiring power minutely subdivided, yet like the Eastern genii, ready at beck and call.

At the present time, the application of the electric motor divides itself into two departments, both of interest to electric light men, that of street railways and that of industrial work. A brief glance may be taken at each department separately, and first at that of street railways. As nearly as I can estimate, over a million passengers have already been hauled by electric locomotives in America, while the number in Europe far exceeds that. Such a fact is significant in itself in these days of rapid change of system and greater attention to comfort in travel. The Baltimore Daft Electric Street Railway, over which many of you travelled in heavy slush and rain last February, is now in its second year of operation, without any electrician in charge, and contemplating an extension. The cost of electric power per day is $12, as compared with $18 for horses under the old system; and the cost per passenger last year was ·83 cent, or about half, as compared with 1·55 cent in 1884.

The Daft system is in use at Revere Beach, Mass., and is now being introduced on the street car lines at Los Angeles, Cal., and elsewhere. The Van Depeole system of electric locomotion is in use in or under contract for several cities, among which may be named Minneapolis, Montgomery, Ala.; Windsor, Ont.; Detroit; Scranton, Pa.; and Appleton, Wis. The figures will, I hope, be presented by Mr. Van Depeole himself, showing results of great economy as compared with mule or horse-power traction. In Philadelphia, Mr. H. M. Schlesinger has a good system operating on a half-mile track, and one that will be introduced at more than one point early next year. The Bentley-Knight system that was successfully tried in Cleveland last year, can now be seen in operation at the Providence Locomotive Works, Rhode Island. And last, though very far from least, is the system of Mr. Frank J. Sprague, who has worked out his inventions and plans with a thoroughness and ingenuity that must awaken admiration in every one. I am not at liberty just now to explain the details of the system; they will probably be made public in a short time. Prof. Henry Rowland has expressed a highly favourable opinion of this system. I should add that Mr. Daft is also resuming his work, with heavier motors, on the New York elevated roads.

The second department in which motors are being used to-day is the industrial, although, even already, the industrial work is subdividing itself. The number of small electric motors in use to-day industrially in this country may be put at certainly far beyond 5,000. Of the old familiar Griscom motor, several hundreds have been put in use; of the Stockwell motor, about 1,000 have already been called for; Daft motors are in use in New York, Boston, Worcester, Providence, Coney Island, and other places. Sprague motors are running in New York, Chicago, Boston, Pittsburgh, Des Moines, Elgin, Oskaloosa, Shamokin, York, New Brunswick, Fall River, New Bedford, Milford, Taunton and Lawrence, Mass., and there are also a great many Brush, Baxter, Pendleton, Bergmann, Keegan, Edgerton, Reckenzaun, Ayrton and Perry, Diehl, Roberts, Crocker and Curtis, and other motors in use all over the country, on work of the most varying nature. A few exemplifications of their use by electric light companies will perhaps be interesting. In Philadelphia the Brush Company is running about 250 Stockwell motors and one 1 horse-power motor. The small motors are chiefly on factory sewing machines, but some are on fans and jewellers' lathes. They are generally giving satisfaction, and if the company could only get its wires to the places wanting motors, the number in use would be quadrupled. Mr. M. D. Law, the electrician of the company, who has charge of this department, operates 18 of the small motors with the power required for one arc light, if they all of them run together at one time; but in practice he has no trouble in running from 30 to 40 with the same power, as they are never all on together. The charge for the current is $5 per month for the first four motors and then $1 per month for each additional motor. All motors are wisely sold outright, the company only renting the current for them. At the Brush-Swan Station, Cheyenne, Wyoming, Mr. E. P. Roberts is building his own motors and finding a wide variety of use for them. One runs an evening paper, another a gunsmith's lathe and emery grinder, and two others cut up sausage meat for butchers. In the case of the gunsmith, the charge is ten cents per hour per horse-power. The motors are run from Brush storage batteries on the day incandescent circuit, and at night from the dynamo, the potential being 100 volts. The Brush station at Baltimore has been putting out motors, chiefly of the Baxter and Edgerton types, quite extensively. The Baxter motor there has been running on a great variety of work, on arc circuits, with good profit, and is said to be very economical of power while regulating with the utmost closeness under all variations of load.

At Des Moines, Ia., the local Edison Company is running a number of Sprague motors. One of these motors, of three horse-power, is used in a livery stable to run the elevator for hoisting the buggies and hay, for pumping water, and brushing down the horses. One runs a scissors grinder's outfit, one a drug mill, one a polisher in a plating establishment, and, curiously, one the generator in the Telephone Exchange. Several elevators now run by water will have electromotors this fall. Mr. F. H. Whiting, the manager, says:—"I think that the motors in reasonably large towns can be made to go a long way to the paying of running expenses of those stations that have to run all the time, as in the incandescent business."

At New Bedford, Mass., seven Sprague motors have already been installed within a short time by the local Edison Company, and are now used in silver-plating works, on ice cream freezers, on coffee grinders, bookbinders' cutting presses, on a hydro-extractor in dye works, and on a hair-picking machine. These motors earn easily altogether about $40 a month, on the regular incandescent circuit, the current being supplied at lamp rates, 1¼ cent. per 16 candle-power per lamp hour, and measured by meter.

In Boston, the Sprague Company is running a large motor service on a circuit embracing a three-quarter mile radius from its station in Bumstead-court, the motors ranging in capacity from ½ horse-power to 1½ horse-power. The motors are sold outright to the customers, and $125 per horse-power per annum is charged for the current or power service. The intermittent use by the consumer is found to be an important factor in supplying power, as not more than 37 per cent. of that sold is ever called for at one time, so that, allowing for the loss in transmission, at least double the engine service can be sold, provided the power is distributed in small quantities. From actual tests made by one company it appears that some few of the averages of power consumed run as low as 14 and 15 per cent., and Mr. Sprague tells me that the higher average of from 33 to 37 per cent. will apply not only to small powers, but is absolutely true of large powers, such as 40, 50, or 100 horse, where a number of these are operating together from a central station.

Digitized by Google

As an evidence of the feeling in Boston on the subject of motors, I may mention that the Merchants' Electric Light and Power Company, running 800 Thomson-Houston arc lamps, has voted to adopt, and is now equipping for, the Sprague system. At Springfield, Mass., another actual electric power station will be established. The Springfield Steam Power Company, heretofore transmitting power by belting, shafting, and wire cables, has now decided to distribute power by means of electric current, as giving a better and more economical service, as well as increasing the distance at which it can work. The change is being carried out at the present hour.

In New York a great many Sprague motors are in use. A large number of Daft motors have been in operation there for a considerable length of time, and I know from actual personal inquiry and observation that you could not get these customers to abandon the use of their motors. One instance deserves special mention. Mr. E. B. Stimpson, in Spruce-street, well-known as an inventor and manufacturer of fine machinery for the shoe and stationery trades, has for about a year been running four floors of his workshop with a Daft motor. Some of the machines belted to the shafting on the various floors are quite heavy—drills, lathes, planers, and the like; others are extremely fine and delicate; but for all of them, Mr. Stimpson tells me, the electric power has been sufficiently steady. He had formerly a 10 horse-power vertical engine, with boiler on the top floor of his building, and had the usual trouble with engineers, coal, ashes, dust, oil, vibration and great heat in summer. Now, in striking contrast, a little 6 horse-power Daft motor stands on a small wooden base, close up against the disused boiler and engine, making so slight a noise that it in no way interrupts conversation. The motor runs the day through, and all the attention it gets is a very occasional visit and wipe on the commutator from a motor man, who also has charge of a number of other motors all round the neighbourhood. Mr. Stimpson pays $12 a week, and I doubt if there is a manufacturer in New York to-day better pleased with his power than is Mr. Stimpson with the electric motor he has been using so long and with such good results.

A great many motors to day are operating very successfully with primary batteries, and that field will grow.

In the incandescent business, the plant must be kept running all the time, so that the consumer can always have his light when he wants it. Hence I look upon motors as the most important auxiliary to-day for incandescent lighting, and I think that in many an arc station, too, they will solve the financial problems of day lighting. But whether that be so or not, what I have said shows, I think, that the day of the electric motor is upon us.

A discussion followed the reading of this paper, to which we hope to refer in a subsequent issue.

"ANTI-INDUCTION" TELEPHONE CABLES.

The telephone cables which are manufactured by Messrs. Felten and Guilleaume, at Mulheim-on-the-Rhine, under the name of "anti-induction" cables, have lately come into somewhat extensive use, and their performance seems to give much satisfaction.

The cables are manufactured in one continuous piece of any required length, and are made up with any required number of wires. The standard sizes contain twenty-seven and fifty-two wires respectively. The diameter of the conductors is varied according to the length of the line for which they are intended. For the greatest distances hitherto attempted No. 19 B.W.G. is employed, and for shorter distances either No. 21 or No. 22. Each wire is separately insulated by a "special impregnated fibre," of which further particulars are not at present forthcoming.

The whole cable is enclosed in a sheathing of lead, which is finally served with tape. It is claimed that the impregnated fibre possesses a high insulating power, that its mechanical properties are good, and that it is unaffected either by atmospheric influences or by changes of temperature, so that the cables are equally well adapted for overhead or for underground use. When placed underground, it is also claimed that, owing to the above-described properties, they may be laid in shallower trenches and require less external protection than gutta percha or india rubber covered lines, so that, if desired, they can be placed immediately under the paving stones of the side walks, where additions or repairs are most easily undertaken. An iron trough 4½in. by 7in. will contain 24 of these cables, each of 27 conductors, or in all 648 wires.

The difficulties connected with induction are overcome by wrapping each insulated wire with a separate layer or coating of tinfoil. This may not be a theoretically perfect method, but in practice it has stood the test of actual work under the most unfavourable conditions, and with very excellent results. To lesson the danger of leakage from wire to wire, each cable also contains a certain number of idle wires, which may be connected to earth at either end. The conductors may, of course, be used either with earth or with metallic returns, or by means of induction coils the two systems may, under certain circumstances, be advantageously combined.

In the case of trunk lines from town to town, for instance, it is frequently useful and economial to employ underground cables with either metallic or earth circuits through the streets, and then to connect with aerial wires having earth returns over the intervening country. It is well known that such a circuit is in general peculiarly liable to inductional disturbance, but the method has been found to answer remarkably well with the Felten-Guilleaume cables. A circuit consisting of two overhead sections and one underground section is in use between Liverpool and Birkenhead, where one of these cables, a mile and a half in length, containing twenty-seven conductors, passes through the Mersey Tunnel. Telephonic circuits of a similar character are in use in Berlin, Munich, Nuremberg, Stuttgard, Copenhagen, Christiana, Bergen, Montreal, and Buenos Ayres. At Copenhagen 13 miles of these cables have been laid, of which 10 miles are underground. Inductive effects are not altogether absent in this case, but they have practically no injurious effect upon the articulation. In this exchange all the electro-magnetic annunciators are provided with shunts, so as to avoid the injurious effects of the self-induction of the soft iron cores of the magnets. This is found to be a very great improvement, a result which recent developments of theory have fully prognosticated. In all cases where electro-magnetic annunciators have to remain in the speaking circuit a similar arrangement ought undoubtedly to be provided. It would be a still further improvement if the shunt coils were wound non-inductively, and of course they must have a resistance sufficiently high to allow the annunciators to be worked by the magneto or battery current.

At Copenhagen the shunt coils are made with about four times the resistance of the annunciator coils, and from figures which have recently been published in this journal it is easy to understand that in this case the "virtual" resistance of the annunciator coil may, for the higher tones, be many hundred times as great as that of the shunt coil, so that by the insertion of the shunt, overtones which are essential to distinct articulation and which would otherwise be practically extinguished, are transmitted with comparatively little loss. Messrs. Felten and Guilleaume have recently carried out an extensive series of experiments at their works which still further illustrate the same point. In one case a line was employed consisting of 30 miles of open wire and four miles of cable. The cable was lead cased, the conductors had each a resistance of 39 ohms per mile, insulation resistance 8,000 megohms, with a capacity of 29 microfarads per mile at 0°C. Under these conditions the articulation was perfectly clear and distinct, and little or no difference could be detected whether the four miles of cable were or were not included in the circuit, *but directly an ordinary annunciator was inserted, a very marked deterioration was apparent*, or, to speak more correctly, we should say, was audible.

In some further experiments of a similar character, with a copper resistance of 24 ohms per mile, but with the insulation resistance diminished to 1,500 megohms, the volume of sound was perceptibly diminished when more than two and-a-quarter miles of cable were in circuit, thus showing that high insulation resistance is by no means to be overlooked in telephone work of this description.

Experiments upon the inductive effects between adjacent wires showed that upon lengths of cable of three kilometres and upwards the wires nearest to the one in use suffered a certain amount of inductive effect, but up to six kilometres, which seems to have been as far as the experiment was carried, the conversation could not in any case be overheard. In conclusion, we may add that these cables are not expensive, and from the foregoing description it will be evident that they form a valuable addition to the resources of telephony, especially where large numbers of wires follow the same route.

CHEMISTRY AS A SCIENCE.*

A glance over the Presidential Addresses delivered before this section on former occasions will show that the occupiers of this chair have ranged over a fairly wide field. Some of my predecessors have given a general survey of the progress of chemical science during the past year, some, taking up a technological aspect of the subject, have discussed the bearings of chemistry upon our national industries; others, again, have passed in review the various institutions in this country for teaching chemistry; and in yet other cases the speaker has had the opportunity of bringing before the scientific world, for the first time, an account of some important original researches.

On this occasion I venture to ask your attention to a few thoughts on the very foundations of chemistry as a science—on the nature and the probable, or at least possible, origin of the so called elements. If the views to which I have been led may at first glance appear heretical, I must remind you that in some respects they are shared more or less, as I shall subsequently show, by not a few of the most eminent authorities, and notably by one of my predecessors in this chair, Dr. J. H. Gladstone, F.R.S., to whose brilliant address, delivered in 1883, I must beg to refer you.

Should it not sometimes strike us, chemists of the present day, that after all we are in a position unpleasantly akin to that of our forerunners, the alchemists of the Middle Ages? These necromancers of a time long past did not, indeed, draw so sharp a line as do we between bodies simple and compound; yet their life-task was devoted to the formation of new combinations, and to the attempt to transmute bodies which we commonly consider as simple and ultimate—that is, the metals. In the department of synthesis they achieved very considerable successes; in the transmutation of metals their failure is a matter of history.

But what are we of this so-called nineteenth century doing in our laboratories and our libraries? Too many of us are content to acquire simply what others have already observed and discovered, with an eye directed mainly to medals, certificates, diplomas, and other honours recognised as the fruits of "passing." Others are seeking to turn the determined facts of chemistry to useful purposes; whilst a third class, sometimes not easily distinguished from the second, are daily educing novel organic compounds, or are racking their ingenuity to prepare artificially some product which Nature has hitherto furnished us through the instrumentality of plants and animals. The practical importance of such investigations, and their bearing on the industrial arts and on the purposes and needs of daily life, have been signally manifested during the last half-century.

Still a fourth class of inquirers, working at the very confines of our knowledge, find themselves, occasionally at least, face to face with a barrier which has hitherto proved impassable, but which must be overthrown, surmounted, or turned, if chemical science is ever to develop into a definite, an organised unity. This barrier is nothing less than the chemical elements commonly so called, the bodies as yet undecomposed into anything simpler than themselves. There they extend before us, as stretched the wide Atlantic before the gaze of Columbus, mocking, taunting, and murmuring strange riddles, which no man yet has been able to solve.

The first riddle, then, which we encounter in chemistry is, "What are the elements?" Of the attempts hitherto made to define or explain an element none satisfy the demands of the human intellect. The text-books tell us that an element is "a body which has not been decomposed"; that it is "a something to which we can add, but from which we can take away nothing," or "a body which increases in weight with every chemical change." Such definitions are doubly unsatisfactory; they are provisional, and may cease to-morrow to be applicable in any given case. They take their stand, not on any attribute of the things to be defined, but on the limitations of human power; they are confessions of intellectual impotence.

Just as to Columbus long philosophic meditation led him to the fixed belief of the existence of a yet untrodden world beyond that waste of Atlantic waters, so to our most keen eyed chemists, physicists, and philosophers a variety of phenomena suggest the conviction that the elements of ordinary assumption are not the ultimate boundary in this direction of the knowledge which man may hope to attain. Well do I remember, soon after I had obtained evidence of the distinct nature of thallium, that Faraday said to me, "To discover a new element is a very fine thing, but if you could decompose an element and tell us what it is made of, that would be a discovery indeed worth making." And this was no new speculation of Faraday's, for in one of his early lectures he remarked, "At present we begin to feel impatient, and to wish for a new state of chemical elements. For a time the desire was to add to the metals, now we wish to diminish their number. . . . To decompose the metals, then to reform them, to change them from one to another, and to realise the once absurd notion of transmutation, are the problems now given to the chemist for solution."

Mr. Herbert Spencer, in his hypothesis of the constitution of matter, says:—"All material substances are divisible into so-called elementary substances composed of molecular particles of the same nature as themselves; but these molecular particles are complicated structures consisting of congregations of truly elementary atoms, identical in nature and differing only in position, arrangement, motion, &c., and the molecules or chemcal atoms are produced from the true or physical atoms by processes of evolution under conditions which chemistry has not yet been able to reproduce."

Mr. Norman Lockyer has shown, I think on good evidence, that, in the heavenly bodies of the highest temperature, a large number of our reputed elements are dissociated, or, as it would perhaps be better to say, have never been formed. Mr. Lockyer holds that "the temperature of the sun and the electric arc is high enough to dissociate some of the so-called chemical elements, and give us a glimpse of the spectra of their bases;" and he likewise says that "a terrestrial element is an exceedingly complicated thing that is broken up into simpler things at the temperature of the sun, and some of these things exist in some sun-spots, while other constituents exist in others."

The late Sir Benjamin Brodie, in a lecture on Ideal Chemistry delivered before the Chemical Society in 1867, goes even further than this. He says:—"We may conceive that, in remote time or in remote space, there did exist formerly, or possibly do exist now, certain simpler forms of matter than we find on the surface of our globe—a, χ, ξ, ν, and so on. . . . We may consider that in remote ages the temperature of matter was much higher than it is now, and that these other things existed then in the state of perfect gases—separate existences—uncombined. . . . We may then conceive that the temperature began to fall, and these things to combine with one another and to enter into new forms of of existence, appropriate to the circumstances in which they were placed. . . . We may further consider that, as the temperature went on falling, certain forms of matter became more permanent and more stable, to the exclusion of other forms. . . . We may conceive of this process of the lowering of the temperature going on, so that these substances, when once formed, could never be decomposed—in fact, that the resolution of these bodies into their component elements could never occur again. You would then have something of our present system of things. . . .

"Now this is not purely an imagination, for when we look upon the surface of our globe we have actual evidence of similar changes in Nature. . . . When we look at some of the facts which have been revealed to us by the extraordinary analyses which have been made of the matter of distant worlds and nebulæ, by means of the spectroscope, it does not seem incredible to me that there may even be evidence, some day, of the independent existence of such things as χ and ν."

In his Burnett lectures "On Light as a Means of Investigation," Prof. Stokes, speaking of a line in the spectrum of the nebulæ, says:—"It may possibly indicate some form of matter more elementary than we know on earth. There seems no *à priori* improbability in such a supposition so great as to lead us at once to reject it. Chemists have long speculated on the so-called elements, or many of them, being merely very stable compounds of elements of a higher order, or even perhaps of a single kind of matter."

In 1868 Graham wrote of Sir W. Thomson's vortex-ring theory, as enlivening "matter into an individual existence and constituting it a distinct substance or element."

From these passages, which might easily be multiplied, it plainly appears that the notion—not necessarily of the decomposability, but at any rate of the complexity of our supposed elements—is, so to speak, in the air of science, waiting to take a further and more definite development. It is important to keep before men's minds the idea of the genesis of the elements; this gives some form to our conceptions, and accustoms the mind to look for some physical production of atoms. It is still more important, too, to keep in view the great probability that there exist in Nature laboratories where atoms are formed and laboratories where atoms cease to be. We are on the track and are not daunted, and fain would we enter the mysterious region which ignorance tickets "Unknown." It is for us to strive to unravel the secret composition even of the so-called elements—to undauntedly persevere—and "still bear up right onward."

If we adopt the easy-going assumption that the elements, whether self-existent or created, are absolutely and primordially distinct; that they existed as we now find them prior to the origin of stars and their attendant planets, constituting, in fact, the primal "fire-mist," we are little, if any, the wiser. We look at their number and at their distinctive properties, and we ask, Are all these points accidental or determinate? In other words, might there as well have been only 7, or 700, or 7,000 absolutely distinct elements as the 70 (in round numbers) which we now commonly recognise? The number of the elements does not, indeed, commend itself to our reason from any *à priori* or extraneous considerations. Might their properties have conceivably differed from those which we actually observe? Are they formed by a "fortuitous concatenation," or do they constitute together a definite whole, in which each has its proper part to play, and from which none could be extruded without leaving a recognisable deficiency?

If their peculiarities were accidental it would scarcely be possible for the elements to display those mutual relations which we find brought into such prominent light and order in the periodic classification of Newlands, Mendeleeff, and Meyer. Has not the relation between the atomic weights of the three halogens, chlorine, bromine, and iodine, and their serially varying properties, physical and chemical, been worn nearly threadbare? And the same with the calcium and the sulphur groups? Surely probability of such relations existing among some 70 bodies which had come into fortuitous existence would prove to be vanishingly small.

We ask whether these elements may not have been evolved from some few antecedent forms of matter—or possibly from only one such—just as it is now held that all the innumerable variations of plants and animals have been developed from fewer and earlier forms of organic life? As Dr. Gladstone well puts it, "they have been built up one from another, according to some general plan." This building up, or evolution, is above all things not fortuitous: The variation and development which we recognise in the universe run along certain fixed lines which have been preconceived and foreordained. To the careless and hasty eye design and evolution seem antagonistic; the more careful inquirer sees that evolution, steadily proceeding along an ascending scale of excellence, is the strongest argument in favour of a preconceived plan.

The array of the elements cannot fail to remind us of the general aspect of the organic world. In both cases we see certain groups well filled up, even crowded with forms having among themselves but little specific

* Prof. Crookes's Address to the Mechanical Science Section of the British Association, September, 1886.

Digitized by Google

difference. On the other hand, in both, other forms stand widely isolated. Both display species that are common and species that are rare; both have groups widely distributed—it might be said cosmopolitan—and other groups of very restricted occurrence. Among animals I may mention as instances the Monotremata of Australia and New Guinea, and among the elements the metals of the so-called rare earths.

Now, as these facts in the distribution of organic forms are generally considered by biological experts to rank among the weightiest evidences in favour of the origin of species by a process of evolution, it seems natural, in this case as in the other, to view existing elements not as primordial, but as the gradual outcome of a process of development, possibly even of a "struggle for existence." Bodies not in harmony with the present general conditions have disappeared, or perhaps have never existed. Others—the asteroids among the elements—have come into being, and have survived, but only on a limited scale; whilst a third class are abundant because surrounding conditions have been favourable to their formation and preservation.

The analogy here suggested between elements and organism is, indeed, not the closest, and must not be pushed too far. From the nature of the case there cannot occur in the elements a difference corresponding to the difference between living and fossil organic forms. The "great stone book" can te'l us nothing of extinct elements. Nor would I for a moment suggest that any one of our present elements, however rare, is like a rare animal or plant in process of extinction; that any new element is in the course of formation; or that the properties of existing element are gradually undergoing modification. All such charges must have been confined to that period so remote as not to be grasped by the imagination, when our Earth, or rather the matter of which it consists, was in a state very different from its present condition. The epoch of elemental development is decidedly over, and I may observe that in the opinion of not a few biologists the epoch of organic development is verging upon its close.

Making, however, every allowance for these distinctions, if evolution be a cosmic law, manifest in heavenly bodies, in organic individuals, and in organic species, we shall in all probability recognise it, though under especial aspects, in those elements of which stars and organisms are in the last resort composed.

Is there, then, in the first place, any direct evidence of the transmutation of any supposed "element" of our existing list into another, or of its resolution into anything simpler?

To this question I am obliged to reply in the negative.

I doubt whether any chemist here present could suggest a process which would hold out a reasonable prospect of dissocating any of our accepted simple bodies. The highest temperatures and the most powerful electric currents at our disposal have been tried, and tried in vain. At one time there seemed a possibility at least that the interesting researches of Prof. Victor Meyer might show the two higher members of the halogen group, bromine and iodine, as entering upon the path of dissociation. These hopes have not been fulfilled. It may be said, in the general opinion of the most eminent and judicious chemists, that none of the phenomena thus elicited prove that even an approach has been made to the object in view.

Even if we leave our artificial laboratories and seek an escape from the difficulty by observing the processes of the great laboratories of Nature, we feel no sufficiently firm ground.

We find ourselves thus driven to indirect evidence—to that which we may glean from the mutual relations of the elementary bodies. Such evidence of great value is by no means lacking, and to this I now beg to direct attention. First, we may consider the conclusion arrived at by Herschel, and pursued by Clerk-Maxwell, that atoms bear the impress of manufactured articles. Let us look a little more closely at this view. A manufactured article may well be supposed to involve a manufacturer. But it does something more; it implies certainly a raw material, and probably, though not certainly, the existence of by-products, residues, paraleipomena. What or where is here the raw material? Can we detect any form of matter which bears to the chemical elements a relation like that of a raw material to the finished product, like that, say, of coal-tar to alizarin? Or can we recognise any elementary bodies which seem like waste or refuse? Or are all the elements, according to the common view, coequals? To these questions no direct answers is as yet forthcoming.

And this leads us up to a hypothesis which, if capable of full demonstration, would show us that the accepted elements are not coequal, but have been formed by a process of expansion or evolution. I refer to the well-known hypothesis of Prout, which regards the atomic weights of the elements as multiples, by a series of whole numbers, of unity = the atomic weight of hydrogen. Everyone is aware that the recent more accurate determinations of the atomic weights of different elements do not by any means bring them into close harmony with the values which Prout's law would require. Still, in no small number of cases the actual atomic weights approach so closely to those which the hypothesis demands that we can scarcely regard the coincidence as accidental. Accordingly, not a few chemists of admitted eminence consider that we have here an expression of the truth, masked by some residual or collateral phenomena which we have not yet succeeded in eliminating.

The original calculations on which the most accurate numbers for the atomic weights are founded have recently been recalculated by Mr. F. W. Clarke. In his concluding remarks, speaking of Prout's law, Mr. Clarke says that "none of the seeming exceptions are inexplicable. In short, admitting half multiples as legitimate, it is more probable that the few apparent exceptions are due to undetected constant errors than that the great number of close agreements should be merely accidental. I began this recalculation of the atomic weights with a strong prejudice against Prout's hypothesis, but the facts as they came before me have forced me to give it a very respectful consideration."

(To be continued.)

THE BRITISH ASSOCIATION MEETING.

PRESIDENTIAL ADDRESS.

(Continued from page 396.)

The warm water thrown into the North Atlantic not only increases the temperature of its whole waters, but gives an exceptionally mild climate to Western Europe. Still the countervailing influence of the Arctic currents and the Greenland ice is sufficient to permit icebergs which creep down to the mouth of the Strait of Belle Isle, in the latitude of the south of England, to remain unmelted till the snows of a succeeding winter fall upon them. Now let us suppose that a subsidence of land in tropical America were to allow the equatorial current to pass through into the Pacific. The effect would at once be to reduce the temperature of Norway and Britain to that of Greenland and Labrador at present, while the latter countries would themselves become colder. The northern ice, drifting down into the Atlantic, would not, as now, be melted rapidly by the warm water which it meets in the Gulf Stream. Much larger quantities of it would remain undissolved in summer, and thus an accumulation of permanent ice would take place, along the American coast at first, but probably at length even on the European side. This would still further chill the atmosphere, glaciers would be established on all the mountains of temperate Europe and America,* the summer would be kept cold by melting ice and snow, and at length all Eastern America and Europe might become uninhabitable, except by Arctic animals and plants, as far south as perhaps 40deg. of north latitude. This would be simply a return of the Glacial age. I have assumed only one geographical change; but other and more complete changes of subsidence and elevation might take place, with effects on climate still more decisive; more especially would this be the case if there were a considerable submergence of the land in temperate latitudes.

We may suppose an opposite case. The high plateau of Greenland might subside or be reduced in height, and the openings of Baffin's Bay and the North Atlantic might be closed. At the same time the interior plain of America might be depressed, so that, as we know to have been the case in the Cretaceous period, the warm waters of the Mexican Gulf would circulate as far north as the basins of the present great American lakes. In these circumstances there would be an immense diminution of the sources of floating ice, and a correspondingly vast increase in the surface of warm water. The effects would be to enable a temperate flora to subsist in Greenland, and to bring all the present temperate regions of Europe and America into a condition of subtropical verdure.

It is only necessary to add that we know that vicissitudes not dissimilar from those above sketched have actually occurred in comparatively recent geological times, to enable us to perceive that we can dispense with all other causes of change of climate, though admitting that some of them may have occupied a secondary place.† This will give us, in dealing with the distribution of life, the great advantage of not being tied up to definite astronomical cycles of glaciation, which may not always suit the geological facts, and of correlating elevation and subsidence of the land with changes of climate affecting living beings. It will, however, be necessary, as Wallace well insists, that we shall hold to that degree of fixity of the continents in their position, notwithstanding the submergences and emergences they have experienced, to which I have already adverted. Sir Charles Lyall, more than forty years ago, published in his "Principles of Geology" two imaginary maps which illustrate the extreme effects of various distribution of land and water. In one all the continental masses are grouped around the equator. In the other they are all placed around the poles, leaving an open equatorial ocean. In the one case the whole of the land and its inhabitants would enjoy a perpetual summer, and scarcely any ice could exist in the sea. In the other the whole of the land would be subjected to an arctic climate, and it would give off immense quantities of ice to cool the ocean. But Lyell did not suppose that any such distribution as that represented in his maps had actually occurred, though this supposition has been sometimes attributed to him. He merely put what he regarded as an extreme case to illustrate what might occur under conditions less exaggerated. Sir Charles, like other thoughtful geologists, was well aware of the general fixity of the areas of the continents, though with great modifications in the matter of submergence and of land conditions. The union, indeed, of these two great principles of fixity and diversity of the continents lies at the foundation of theoretical geology.

We can now more precisely indicate this than was possible when Lyell produced his "Principles," and can reproduce the conditions of our continents in even the more ancient periods of their history. Some examples may be taken from the history of the American continent, which is more simple in its arrangements than the double continent of Europ-Asia. We may select the early Devonian or Erian period, in which the magnificent flora of that age—the earliest certainly known to us—made its appearance. Imagine the whole interior plain of North America submerged, so that the continent is reduced to two strips on the east and west, connected by a belt of Laurentian land on the north. In the great Mediterranean sea thus produced the tepid water of the equatorial current circulated, and it swarmed with corals, of which we know no less than one hundred and fifty species, and with other forms of life appropriate to warm seas. On the islands and coasts of this sea was introduced the Erian flora, appearing first in the north, and with that vitality and colonising power of which, as Hooker has well shown, the Scandinavian

* According to Bonney, the west coast of Wales is about 12deg. above the above the average for its latitude, and if reduced to 12deg. below the average its mountains would have large glaciers.

† More especially the ingenious and elaborate arguments of Croll deserve consideration; and, though I cannot agree with him in his main thesis, I gladly acknowledge the great utility of the work he has done.

Digitized by Google

flora is the best modern type, spreading itself to the south.* A very similar distribution of land and water in the Cretaceous age gave a warm and equable climate in those portions of North America not submerged, and coincided with the appearance of the multitude of broad-leaved trees of modern types introduced in the early and middle Cretaceous, and which prepared the way for the mammalian life of the Eocene. We may take a still later instance from the second continental period of the later Pleistocene or early Modern, when there would seem to have been a partial or entire closure of the North Atlantic against the Arctic ice, and wide extensions seaward of the European and American land, with possibly considerable tracts of land in the vicinity of the equator, while the Mediterranean and the Gulf of Mexico were deep inland lakes.† The effect of such conditions on the climates of the northern hemisphere must have been prodigious, and their investigation is rendered all the more interesting because it would seem that this continental period of the post-Glacial age was that in which man made his first acquaintance with the coasts of the Atlantic, and possibly made his way across its waters.

We have in America ancient periods of cold as well as of warmth. I have elsewhere referred to the boulder conglomerates of the Huronian, of the Cambrian and Ordovician, of the Millstone-grit period of the Carboniferous, and of the early Permian; but would not venture to affirm that either of these periods was comparable in its cold with the later Glacial age, still less with that imaginary age of continental glaciation assumed by certain of the more extreme theorists.‡ These ancient conglomerates were probably produced by floating ice, and this at periods when in areas not very remote temperate floras and faunas could flourish. The glacial periods of our old continent occurred in times when the surface of the submerged land was opened up to the northern currents, drifting over it mud and sand and stones, and rendering nugatory, in so far at least as the bottom of the sea was concerned, the effects of the superficial warm streams. Some of these beds are also peculiar to the eastern margin of the continent, and indicate ice-drift along the Atlantic coast in the same manner as at present, while conditions of greater warmth existed in the interior. Even in the more recent Glacial age, while the mountains were covered with snow and the lowlands submerged under a sea laden with ice, there were interior tracts in somewhat high latitudes of America in which hardy forest trees and herbaceous plants flourished abundantly; and these were by no means exceptional "inter-glacial" periods. Thus we can show that while from the remote Huronian period to the Tertiary the American land occupied the same position as at present, and while its changes were merely changes of relative level as compared with the sea, these have so influenced the ocean currents as to cause great vicissitudes of climate.

Without entering on any detailed discussion of that last and greatest Glacial period which is best known to us, and is more immediately connected with the early history of man and the modern animals, it may be proper to make a few general statements bearing on the relative importance of sea-borne and land ice in producing those remarkable phenomena attributable to ice action in this period. In considering this question it must be borne in mind that the greater masses of floating ice are produced at the seaward extremities of land glaciers, and that the heavy field-ice of the Arctic regions is not so much a result of the direct freezing of the surface of the sea as of the accumulation of snow precipitated on the frozen surface. In reasoning on the extent of ice action, and especially of glaciers in the Pleistocene age, it is necessary to keep this fully in view. Now in the formation of glaciers at present—and it would seem also in any conceivable former state of the earth—it is necessary that extensive evaporation should conspire with great condensation of water in the solid form. Such conditions exist in mountainous regions sufficiently near to the sea, as in Greenland, Norway, the Alps, and the Himalayas; but they do not exist in low arctic lands like Siberia or Grinnel-land nor in inland mountains. It follows that land glaciation has narrow limits, and that we cannot assume the possibility of great confluent or continental glaciers covering the interior of wide tracts of land. No imaginable increase of cold could render this possible, inasmuch as there could not be a sufficient influx of vapour to produce the necessary condensation; and the greater the cold the less would be the evaporation. On the other hand, any increase of heat would be felt more rapidly in the thawing and evaporation of land ice and snow than on the surface of the sea.

Applying these very simple geographical truths to the North Atlantic continents, it is easy to perceive that no amount of refrigeration could produce a continental glacier, because there could not be sufficient evaporation and precipitation to afford the necessary snow in the interior. The case of Greenland is often referred to, but this is the case of a high mass of cold land with sea, mostly open, on both sides of it, giving, therefore, the conditions most favourable to precipitation of snow. If Greenland was less elevated, or if there were dry plains around it, the case would be quite different, as Nares has well shown by his observations on the summer verdure of Grinnel-land, which in the immediate vicinity of North Greenland, presents very different conditions as to glaciation and climate.§ If the plains were submerged, and the Arctic currents allowed free access to the interior of the continent of America, it is conceivable that the mountainous regions remaining out of the water would be covered with snow and ice, and there is the best evidence that this actually occurred in the Glacial period; but with the plains out of water this would be impossible. We see evidence of this at the present day in the fact that in unusually cold winters the great precipitation of snow takes place south of Canada, leaving the north comparatively bare, while as the temperature becomes milder the area of snow-deposit moves farther to the north. Thus a greater extension of the Atlantic, and especially of its cold ice-laden arctic currents, becomes the most potent cause of a glacial age.

I have long maintained these conclusions on general geographical grounds, as well as on the evidence afforded by the Pleistocene deposits of Canada; and in an address the theme of which is the ocean I may be excused for continuing to regard the supposed terminal moraines of great continental glaciers as nothing but the southern limit of the ice-drift of a period of submergence. In such a period the southern margin of an ice-laden sea where its floe-ice and bergs grounded, or where its ice was rapidly melted by warmer water, and where consequently its burden of boulders and other *débris* was deposited, would necessarily present the aspect of a moraine, which, by the long continuance of such conditions, might assume gigantic dimensions. Let it be observed, however, that I fully admit the evidence of the great extension of local glaciers in the Pleistocene age, and especially in the times of partial submergence of the land.

I am quite aware that it has been held by many able American geologists* that in North America a continental glacier extended in temperate latitudes from sea to sea, or at least from the Atlantic to the Rocky Mountains, and that this glacier must, in many places, have exceeded a mile in thickness. The reasons above stated appear, however, sufficient to compel us to seek for some other explanation of the observed facts, however difficult this may at first sight appear. With a depression such as we know to have existed, admitting the Arctic currents along the St. Lawrence Valley, through gaps in the Laurentian watershed, and down the great plains between the Laurentian areas and the Rocky Mountains, we can easily understand the covering of the hills of Eastern Canada and New England with ice and snow, and a similar covering of the mountains of the west coast. The sea also in this case might be ice-laden and boulder-bearing as far south as 40°, while there might still be low islands far to the north on which vegetation and animals continued to exist. We should thus have the conditions necessary to explain all the anomalies of the glacial deposits. Even the glaciation of high mountains south of the St. Lawrence Valley would then become explicable by the grounding of floe-ice on the tops of these mountains when reefs in the sea. In like manner we can understand how on the isolated trappean hill of Beloeil, in the St. Lawrence Valley, Laurentian boulders far removed from their native seats to the north are perched at a height of about 1,200ft. on a narrow peak where no glacier could possibly have left them. The so-called moraine, traceable from the great Missouri Coteau in the west, to the coasts of New Jersey, would thus become the mark of the western and southern limit of the subsidence, or of the line along which the cold currents bearing ice were abruptly cut off by warm surface waters. I am glad to find that these considerations are beginning to have weight with European geologists in their explanation of the glacial drift of the great plains of Northern Europe.

Whatever difficulties may attend such a supposition, they are small compared with those attendant on the belief of a continental glacier, moving without the aid of gravity, and depending for its material on the precipitation taking place on the interior plains of a great continent.

(To be continued.)

* As I have elsewhere endeavoured to show ("Report on Silurian and Devonian Plants of Canada"), a warm climate in the Arctic region seems to have afforded the necessary conditions for the great colonising floras of all geological periods. Gray had previously illustrated the same fact in the case of the more modern floras.

§ These views have been admirably illustrated by Von Wœickoff in the paper already referred to and in previous geographical papers.

COMPANIES' REPORTS.

Direct Spanish Telegraph Company.

Report of the Directors for the half year ended 30th June last, to be presented to the general meeting of shareholders on Thursday, the 30th inst., at 3 o'clock:—

The accounts for the half year show, after providing for debenture interest, a balance to the credit of profit and loss of £4,573. 12s 2d. The traffic receipts show an increase of £1,022. 2s., as compared with the corresponding half year of 1885, and a decrease of £89. 10s. as compared with the last half year. The new Bilbao and the Marseilles-Barcelona cable continue in good working order. The Directors have already, by their circular of 16th July last, advised the shareholders of the result of the examination of the original Bilbao cable, and of the opinion of the firm of engineers, Messrs. Clark, Forde, and Taylor, who superintended the operations, to the effect that this line could not be advantageously restored, and the Board have accordingly abandoned it. They enclose a special report on the financial steps which are requisite to be taken in consequence of the loss of this cable as an asset. The Directors propose to put £4,500 of the balance to the credit of profit and loss to the reserve fund, which will then amount to £14,300, and to carry forward £73. 12s. 2d. to next account.

The following special report is to be presented by the Directors at the extraordinary general meeting to follow the general meeting:—

The examination of the original Bilbao cable having resulted in showing that it could not be advantageously restored, the Company has now to adopt one of the alternatives pointed out in the opinion of Sir Horace Davey (to which reference has been made at previous meetings), and either

* Report of Mr. Carvill Lewis in *Pennsylvania Geological Survey*, 1884; also Dana's *Manual*.

Digitized by Google

discontinue the payment of dividend on all the shares (including the preference shares) until sufficient money is accumulated to lay a new cable, or else take steps to write off a proper amount of the existing capital as unrepresented by assets. The Board have considered the position carefully, and find that the former alternative would, with the present revenue, involve the suspension of all dividends for ten years. But, on the other hand, to place the Company in a sound and dividend-paying position by writing off the lost capital, the following step may be taken, viz., reduce the nominal capital by writing off £5 per share on all the shares. If this were done, the arrears of dividend on the preference shares (£2. 10s. per share to the 31st December, 1886), could be at once paid, and the prospects of the shareholders would stand thus from the end of the present year:—

	Per annum.
Taking the average net revenue for the last three years.....	£12,750 0 0
And reserving for renewals and repairs	5,000 0 0
There would remain for appropriation as below	£7,750 0 0
Interest at 6 per cent. £62,000 debentures.....	£3,720 0 0
Dividend at 10 per cent. on £30,000 preference shares ...	3,000 0 0
Dividend at 2 per cent. on £51,724 ordinary shares.....	1,034 0 0
	£7,754 0 0

In the above calculation the reduced ordinary shares are treated as £5 shares with £4 paid on each, thus leaving the £1 liability on the ordinary shares as at present, and the Directors consider that this liability should remain, as the debenture holders might object to the scheme if it were proposed to extinguish it. There is no occasion for calling up the amount at present. It will be borne in mind, with reference to the proposal to reduce both classes of shares alike, that the preference shares confer no priority as regards capital, but in the event of a liquidation would suffer equally with the ordinary shares from the diminution of assets Special resolutions will be proposed to the meeting in the form which is appended to the notice convening it; they will require to be confirmed by a subsequent meeting, and to be afterwards approved by the High Court.

The French Atlantic Cable Company.

The directors of the French Atlantic Cable Company have issued a circular to the shareholders in view of the annual general meeting, which is to be held on October 6th. After referring to the very grave character of the business which is to be transacted at that meeting, and which, in the opinion of the Directors, involves the very existence of the Company *as a French company*, it is announced that, owing to the opposition which was manifested to their policy at the meeting in June last, and to the charges of maladministration which were then freely made, they had taken steps in accordance with the French law to have the position of the Company officially investigated. The report of the commissioners will be presented at the forthcoming meeting, and will be found to contain a complete vindication of the policy of the Directors. Owing to these unfounded charges, and owing more especially to the unfortunate war of tariffs in which they were most unwillingly compelled to engage, the management of the affairs of the Company had, during the last few months been a matter of considerable difficulty. It was, however, abundantly evident from the facts and figures which had now received the confirmation of the commissioners, that their financial position was perfectly sound. "As to the war of rates, we have always kept in view the desirability of bringing the matter to its earliest possible termination. It has been confidently asserted that a return to the tariff first adopted by the allied companies—namely, 2 francs per word—would now be capable of yielding an adequate return upon the capital invested. Notwithstanding our highly unfavourable experience of this rate, which was in force from December, 1884, to May, 1886, we are giving the whole question a fresh and impartial consideration. In the meantime, we are convinced that the experience which is being gained by the allied companies during the continuance of the present low rates will in future prove to be of the greatest value. The lowering of the tariff to 60 centimes per word has produced a total augmentation of traffic upon the cables of the allied companies amounting to 122 per cent., which produces a revenue equal to a charge of 1fr. 33c. per word upon the traffic under the old tariff. This permits our Company at the least to pay its way, while we are enabled at any time, after due examination, to adopt such a course as may seem most conducive to our own interests. In presence of these results it is permissible to affirm that in the event of a revival of trade the present tariff would certainly yield a revenue equal, if not superior, to that previously earned under the charge of 2fr. The facts tend also to show that the future of submarine cables depends as much upon the progress of the art of submarine telegraphy as upon the raising of tariffs." The document concludes with a repudiation of the assertion that the Directors had in any sense subordinated their own interests to those of the English companies, and appeals strongly to the shareholders for their support at the forthcoming meeting.

CRICKET.

The return cricket match between the Manchester and Liverpool centres of the Lancashire and Cheshire Telephone Exchange Company took place at Manchester on the 18th inst. After a pleasant game Manchester were again victorious. Score:—

MANCHESTER.—Beer, b. Martin, 0; Hodgkinson, b. Holmes, 11; Poole, b. Martin, 0; A. Pugh, c. Holmes, b. Uxley, 13; Hibbert, run out, 3; M'Pherson, b. Uxley, 2; Morris, sen., b. Uxley, 4; Morris, jun., b. Uxley, 0; W. Pugh, b. Uxley, 1; Clark, b. Uxley, 2; Partington, b. Uxley, 2; Bennett, not out, 0; extras, 12—total, 50.

UNIVERSITY COLLEGE, BRISTOL.

DEPARTMENT OF EXPERIMENTAL PHYSICS.

Professor J. RYAN, M.A. (Camb.), D.Sc. (Lond.)

The SESSION 1886-87 will begin on the 5th OCTOBER. Lectures and Classes in Physics are given to first, second, and third year students. The Physical and Electrical Laboratory is open daily, and on Wednesday evenings.

Calendar, price 1s. (by post 1s. 3d.)

For prospectus and further information apply to the Registrar.

UNIVERSITY COLLEGE, DUNDEE.

THE SESSION BEGINS OCTOBER 11TH.

In addition to the ordinary Science Subjects, particular provision is made in the Departments of NATURAL PHILOSOPHY (Prof. Steggall) and ENGINEERING (Prof. Ewing) for a course of Theoretical and Practical Instruction in ELECTRICAL ENGINEERING, including Electric Lighting, Telegraph Testing, &c., a SPECIAL LABORATORY having been fitted up for the purpose.—Apply to

SHIELL and SMALL, Secretaries.

CITY AND GUILDS OF LONDON INSTITUTE.

FINSBURY TECHNICAL COLLEGE.

EVENING DEPARTMENT for Apprentices, Journeymen, Foremen, and others. Instruction in Mechanical and Electrical Engineering, Technical Chemistry, Applied Art, Cabinet-making, Metal-plate Work, Builders' and Plumbers' Work, Carpentry and Joinery, Bricklaying, &c.

Fees from 6s. to 30s. for the Session, inclusive of Laboratories and Workshops. The SESSION commences on MONDAY evening, OCT. 4.

Apprentices are admitted at half the ordinary fees.

For further particulars apply at the College, Leonard-street, City-road, E.C.; or at Gresham College, E.C.

PHILIP MAGNUS, Director and Secretary.

NOTES.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 24th ult. amounted to £3,601.

DETROIT.—At Detroit it is stated that there is one telephone in use to every fifty-one inhabitants, and each instrument is employed on the average 13·8 times daily.

A BIG CLOCK.—At Buffalo they are going to light by electricity a clock dial which is said to be the largest in the world. It is 25ft. in diameter, and is placed at a height of 360ft. above the ground.

STOCKPORT.—On the occasion of some recent local festivities at this town, the principal streets were illuminated by means of Jablochkoff lamps. The installation was carried out by Messrs. Durham and Co.

THE ELECTRIC LIGHT AT HELL GATE.—Owing to the numerous and emphatic complaints from pilots and captains as to the dazzling effect of the electric lights at Hell Gate, it is not unlikely that they will be discontinued.

GAS COMPANIES IN THE STATES.—The American papers contain week after week the names of gas companies in all parts of the country who have decided to undertake the supply of electric light upon their own account.

TELEGRAPHISTS' DINNER.—The Metropolitan District Telegraphists held their first annual dinner at the Victoria Mansions Restaurant on Friday last. There were about sixty present, and a very pleasant evening was spent.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended September 24th, were £2,817, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

TELEPHONE V. ELECTRIC LIGHT.—A test case is about to come before the American Courts in order to determine the question as to the right of electric light companies to erect cables in such proximity to telephone wires as to interfere with the telephone service.

TELEGRAPHIC FRAUDS.—Serious accusations are brought against certain of the local officials of the Western Union Cable lines as to systematic tampering with or delaying Stock Exchange messages, whereby it is believed that large sums have been fraudulently obtained.

ERRATUM.—In the second leader of last week there was an evident typographical error. The average cost per message under the old tariff was stated to have been "$12\frac{1}{7}$d., or nearly 1s. 1d." The figures should have read 12·97d. Similarly, in the line above, $8\frac{1}{16}$d. should read 8·16d.

AN ELECTRIC MACHINE GUN.—A resident of Sydney has brought under the notice of the Governor an electrical machine gun invented by him, which he claims is capable of firing 120 rounds every few seconds from any position and in any direction. The gun is stated to be easily portable, and it is attested by experienced officers to be an invention of considerable value.

PERSONAL.—Many of our readers will be interested to know that another member of the profession has recently ventured to become a Benedict. A few days since, at St. Peter's, Bournemouth, Mr. C. J. Wharton, of the well-known firm of Laing, Wharton, and Down, was married to Miss May Sybil Sandys, only daughter of Mr. James Sandys, of Bournemouth.

AMERICAN ELECTRICAL FINANCING.—A company has recently been launched in the States with a nominal capital of $4,000,000 for the purpose of introducing the Campbell Court Conduit. This we presume to be some kind of box for putting wires in, which at the same times makes a decent pavement kerb. It must be an uncommonly good box if it is going to pay interest on £800,000.

COLCHESTER.—That most unhappy episode in the history of the electric light in this country, which is connected with the lighting of the city of Colchester, may be considered to have been finally closed last week, when the entire plant came under the hammer of the autioneer. The total amount realised was £345. It may be added that this is about one quarter of the original cost of the *cables alone*.

BOOKS RECEIVED.—We have received a copy of "Short Lectures to Electrical Artisans," by Dr. J. A. Fleming, published by Messrs. E. and F. Spon. We have also received "Heroes of Science—Physicists," by Dr. Garnett, M.A., which is published by the Society for Promoting Christian Knowledge. The National Telephone Company have issued a new list of subscribers for their "Scottish North Central District."

DISTRIBUTION OF MOTIVE POWER AT BIRMINGHAM.—At Birmingham, a company is being promoted to distribute power by means of compressed air. It is estimated that under the given local conditions power can be supplied at a cost of about 20 per cent. less than steam power. It seems to be anticipated that the facilities to be furnished for running light machinery will have a considerable influence upon the extension of isolated electric lighting installations.

ELECTRICITY IN MINING.—According to the last reports of the Montana Company, the electrical appliances now at their works include one dynamo machine, supplying seven arc lights, and one 30 incandescent lamp dynamo machine, which are employed for lighting two of the stamp mills as well as some of the offices. Electric signal communication is also established between the millmen and the engine driver. Provision will shortly be made for about 60 additional lamps.

THE EASTERN EXTENSION TELEGRAPH COMPANY.—The Eastern Extension Telegraph Company notify that the accounts for the half-year ended 30th June last show, subject to audit, a balance of profit of £66,230 after payment of the interim dividend for the first quarter. The directors have declared a dividend for the quarter ended 30th June of 2s. 6d. per share, free of income-tax, payable on the 15th inst., and decided to carry forward the balance of £34,980 to next account. In consequence of the diminution of revenue the directors do not feel justified in paying any bonus for the past half year.

A SEVERE TEST.—We are informed that on board H.M.S. "Devastation" a "Kapp" dynamo was recently kept running for twenty-six continuous days and nights without cessation, and at the end of that time appeared to be in as good condition as at the beginning. This was not undertaken by way of experiment, but simply because the light was required during the whole of the time to facilitate repairs. The result simply shows that with a thoroughly well designed dynamo there is no limit to the length of time during which the machine may be continuously run, except the eventual and inevitable wear and tear of the commutator.

SUBMARINE PHOTOGRAPHY BY ELECTRIC LIGHT.—Experiments are about to be undertaken by MM. Bonfante and Maisonneuve on deep-sea photography by means of the incandescent light. Upon a smaller scale, and in comparatively shallow water, some success has already been attained in this direction by M. Pinard. In the case, for instance, of a sunken wreck which it might be proposed to raise, it is evident that

Digitized by Google

if a camera could be arranged so as to be placed in the hands of the divers, results of considerable practical value might be attained. As for deep-sea photography, they would probably be more successful if taken with an arc light, and no doubt this could be done with a properly constructed lantern.

POLICE TELEGRAPHS.—A system is now being introduced in the States, and has for some time been in active operation at New Haven, Connecticut, whereby the police stations are at all times enabled to communicate with any of the men while on their beats. This is effected by means of a visual signal, similar to a railway semaphore, which is attached to certain of the street lamps, and is operated by electricity from the superintendent's office. A telephone placed in a locked box fixed to the same part enables the policeman on perceiving the signal to learn what is required. This is very pretty, no doubt, but we confess that it puzzles us to understand how they manage in the States to find the money to pay for all these little luxuries.

THE ESTIENNE TELEGRAPH.—The French Administration has for some time had under their consideration the question of introducing the Estienne system of telegraphy. They have at length determined to give the system a trial upon an extensive scale, and a special staff of operators has been formed to study the method of working. The special feature of the system is the substitution of vertical for horizontal lines in the Morse alphabet, and, so far, we fail to see where it is essentially different from the system long ago proposed in this country by Mr. Richard Herring.

NEW CABLE.—A telegraph cable is to be laid between Cape York and Thursday Island, Queensland. The tender of the Eastern Extension Company for the supply, transportation, and laying of the cable for £10,000 has been accepted. A two-cored brass-ribboned cable of the latest form has been manufactured by the Telegraph Construction and Maintenance Company, and is now on its way to Singapore, where it will be put on board one of the Eastern Extension Company's steamers and thence conveyed to its destination. It is expected the cable will be completed during November.

FORGING A TELEGRAM.—At the Hammersmith Police Court on Wednesday, a servant out of place, named Eliza Davis, was charged before Mr. Partridge with forging and uttering a telegram, purporting to be sent by one H. Newman, of 27, Great Portland-street, to Mrs. Newman, of 173, Portobello-road, on Friday last. It ran as follows :—"Your husband has met with an accident. He is dying. Come at once. Father." Evidence having been given by Mrs. Newman and the Post Office authorities proving that the prisoner had sent the telegram, Mr. Partridge remanded her for a week to consider how he should deal with the case.

TEMPORARY ELECTRIC LIGHTING.—Messrs. G. Binswanger and Company are introducing the Pollak regenerative cell for the purpose more especially of temporary installations of incandescent lighting. This cell, which is one of that very limited class which has a valid claim to be based upon a new principle, has also several features which render it suitable for the purpose above referred to. We have already described and illustrated the cell, but we may add that its "self-regenerative" powers depend upon the action of the atmosphere. Oxygen is continuously absorbed by the upper part of the carbon (which is of a specially porous texture), and is thus brought into intimate relation with the electrolytic hydrogen.

DIELECTRIC FLUIDS.—Prof. G. Quincke, continuing his studies of the properties of dielectric fluids, publishes in the last number of the *Annalen der Physik und Chemie* some results of experiments with very high electromotive forces. By means of a Holtz machine and a long-range electrometer the observations have been carried up to 30,000 volts. Prof. Quincke finds that an apparent exception to the law of Ohm occurs under these conditions, inasmuch as the strength of a steady current through the fluid increases more rapidly than the electromotive force which produces it. It was also observed that with high electromotive forces the dielectric constant (the inverse of specific inductive capacity) is less than with lower forces; in other words, there exists an apparent tendency to saturation in inductive capacity.

ELECTRICITY IN SOAP AND BLEACHING WORKS.—M. Rotondi has discovered that by the employment of suitable vessels, it is possible to effect the saponification of oils by the electrolysis of an emulsion of the oil in a concentrated solution of sodic chloride. This, at least, is the nature of the process so far as we can gather from a not very lucid description in one of the French technical journals. During the process it is said that caustic soda, free chlorine, and glycerine are formed, and it is suggested that at bleaching works it would be found economical to prepare chlorine by this process in order to obtain the soap and the glycerine as by-products. It is also suggested that as the process requires practically no supervision, it would be practicable to employ in this way at night, steam-power already in use during the day-time for other purposes.

WEST AFRICAN CABLES.—The Silvertown Company has received telegraphic advices from Mr. Matthew Hamilton Gray, the engineer in charge of the expedition, announcing the completion of the West African Telegraph Company's system of cables. These cables are laid in 10 sections of a total length of about 3,600 nautical miles, and, in conjunction with the cables just completed for the African Direct Telegraph Company by the Telegraph Construction and Maintenance Company, give telegraph communication with Europe to the principal ports of West Africa as far south as St. Paul de Loanda, and a duplicate communication to Bathurst and Sierra Leone. The cable steamer "Silvertown" is expected to arrive in London about the beginning of November, and the cable steamer "Dacia," which was also occupied in this work, is expected to arrive home on Saturday next.

FLUORINE BY ELECTROLYSIS.—M. Moisson has contributed to the Academie des Sciences a further note upon his recent discovery of a method of obtaining fluorine by electrolysis. His later experiments tend to add further confirmation of the fact that the gas which is obtained by this process is the element itself, and not a hydrogen fluoride, as was at first thought possible. By mixing fluoric acid with potassic fluoride, which greatly increases its conductibility, and also by surrounding it with a freezing mixture capable of reducing the temperature to $-50°$ C., M. Moisson is now able to obtain the separation of the gas with an electromotive force of only 10 Bunsen cells. The liquid is placed in a platinum capsule, which serves as one of the electrodes, and the other pole is formed by a platinum wire, which dips into the liquid. Unless the temperature be kept very low the platinum is attacked with rapidity by the liberated gas.

ELECTRIC BUOYS.—Some experiments have recently been carried out at Asnières with a buoy which carries an incandescent lamp, supplied by accumulators. Although the experiments are described as being highly successful, we certainly do not consider this at all a promising field for the application of accumulators. The Pintsch system of storing gas under pressure in the buoy, and by means of which it may be left without attention for a month or more, is decidedly superior

Digitized by Google

to a battery arrangement for this particular purpose. Upon a less ambitious scale, however, the idea may possibly have some value. It has been suggested that a small battery might be attached to a life buoy with an arrangement by which the lamp is brought into the circuit upon contact with the water. Even here, however, the Silas life buoy, which on falling into the water shows a light by means of phosphide of calcium, is probably very much cheaper.

ARC LAMP EFFICIENCY.—According to the Hartford *Courant*, from certain tests which have recently been made in that city upon an arc lamp circuit, which has a length of over seven miles, with forty-six arcs, the power expended in the external circuit, including that lost in the leads, was equal to 0·58 horse-power per lamp of 2,000 candle-power. It does not, however, appear that any photometric observations were undertaken, and we all know that the ratio between the nominal and actual power of an arc lamp must be taken in the inverse sense to that of a steam engine. The horse power developed was apparently calculated from indicator diagrams, which gave 31·5 horse-power. From this 4·88 horse-power was deducted for friction of engine and dynamo, leaving 26·62 horse-power available for the 46 lamps. The system employed at Hartford is that of the Waterhouse Company, but we fear that more substantial evidence must be adduced before an efficiency of 4,000 candles per horse-power will be accepted on this side of the Atlantic.

THE SS. "ORIZABA."—The latest addition to the magnificent fleet of the Pacific Steamship Navigation Company is named the "Orizaba." She has this week left the Albert Dock upon her trial trip. The electric lighting upon this vessel is provided for by means of two 300 light 16 candle-powder slow-speed Kapp dynamos, which are driven direct from two compound engines, running at 250 revolutions. The four machines are placed in one line, the two engines being side by side in the centre, and by means of a coupling between the engine shafts either or both of the engines may drive either or both dynamos. This arrangement has been adopted at the suggestion of Mr. Brice Douglas, M.I.C.E., engineer-in-chief to the company. The machines are built for an output of 240 amperes at 55 volts, and in order to provide for the very high temperature which exists in the engine rooms of vessels passing through the Red Sea fans have been supplied to cool the dynamos, while at the same time the machines are specially designed to have a very low current density in all the coils, together with a large cooling surface.

"ENCORE CREIL."—Under this title *L'Electricien* reproduces at length a highly amusing article from a French provincial journal, in which Prof. Elihu Thomson's process of electric welding is ascribed to "certain Russian savants," to whom M. Marcel Deprez is said to have lent his laboratory and his advice. This process has, however, been greatly developed since Prof. Thomson has had anything to do with it, for we are assured that a weld can now be effected under water, so that, according to our authority, an ironclad may in future have her plates re riveted beneath the water-line without ever being docked. This is one of the finest examples of the scientific use of the imagination which we have come across for a very long while. Since writing the above we notice that our French contemporary, *Cosmos*, repeats the statement as to experiments upon electric welding carried out by Russian savants at Creil, but without committing itself to the submarine details. Perhaps, therefore, it will be better to wait to hear further who these Russians are, and what they have really done, before joining M. Hospitalier in his chaff at their expense.

SHUNTING ELECTRO-MAGNETS ON TELEPHONE LINES.—In connection with the remarks which we made last week upon this subject, when speaking of the "anti-induction" telephone cables, it is somewhat singular to note that at the Telephone Convention, which has just been held at St. Louis, a self-acting device of a similar character was exhibited under the name of a "reducer." This little apparatus is the invention of Mr. C. D. Wright, of Petersburg, Ill. Under normal conditions the bell or annunciator coils are short-circuited by the armature of a small relay of low resistance; when the call signal is given, this relay opens the short circuit, and throws a portion of the current through the coils of the bell or annunciator. Thus, while the telephone is in use the bell coils are always short-circuited. We have no doubt that this device is a good one, and are not surprised that it was well spoken of at St. Louis by the telephone men who had tried it; at the same time, it does not seem that any of them supposed the effects to be due to anything else than the simple reduction of the metallic resistance of the circuit.

PROPOSED CABLE TO TORY ISLAND.—Tory Island is a lighthouse station lying off the extreme north-west of Ireland. It is the turning point, so to speak, for all vessels coming from the south or south-west, and using the north of Ireland route for Liverpool, Londonderry, Belfast, Glasgow, and other ports. Sir E. W. Watkin, writing to the *Standard*, points out the very great advantage which would accrue to shipowners from the laying of a cable connecting this point with the main land. According to Sir E. Watkin, five hours would be saved in signalling steam ships, and the advantage to sailing ships would be even greater, for it appears that vessels coming eastward are frequently delayed for days, and even weeks, by adverse winds off this part of the coast, without being able to communicate with their owners, who, if informed by telegraph, could at once send tugs to their relief. Sir E. Watkin estimates the cost of the cable at £2,500 if landed at Traymore Bay, or £6,000 if landed at Malin Head. It is, however, to be remembered that the cost of maintaining the cable is in cases of this kind a consideration of greater importance than the first outlay.

A NEW APPLICATION OF THE PHOTOPHONE.—M. Leon Esquille has found it possible to employ photography and electricity together, for the purpose of recording and reproducing speech in a more direct manner than has hitherto been done. M. Esquille's method consists in speaking in the first instance to a photophone transmitter. Our readers will remember that this is merely a diaphragm with a highly polished surface from which a ray of light is reflected. The record of this speech is then obtained by simply photographing the ray of light upon a travelling band of sensitized paper. After having been developed, the articulation may be reproduced by projecting the image of the trace by means of an electric arc or oxyhydrogen light upon a selenium receiver, preferably one of the form due to M. Mercadier. The speech is then heard through the telephone in the usual manner. It seems highly probable that, although this method is certainly more troublesome, it will give results superior to those of instruments which, like Edison's phonograph and Prof. Bell's more recent "graphophone," depend initially upon a mechanically formed trace of the sound vibrations.

TELEPHONE LITIGATION.—We hear that the telephone war is about to break out again in an old quarter. Writs have been issued by the New Telephone Company against the Western Counties and South Wales Telephone Company and against Mr. Lewis, their manager, and their district superin-

Digitized by Google

tendent at Bournemouth, Mr. O'Donnell, for alleged slander of title. The United Telephone Company, who for some time maintained that their patents were infringed by the New Telephone Company, were understood to be about to bring an action for infringment against that company on this ground; but when challenged in Mr. Justice Chitty's court to substantiate their threats, they declined to do so, virtually admitting that there was no infringment by the New Telephone Company. The New Telephone Company, however, allege that the licensees of the United Company have, nevertheless, continued to circulate false statements to that effect, to the damage of the New Telephone Company's business, and the latter have opened fire by serving writs upon the Western Counties Company. As the statements of infringment, rightfully or wrongfully, have been made openly and wholesale, heavy damages will be claimed.

THE LISBON TELEPHONE SERVICE.—On the authority of the *Diario Popular*, of Lisbon, we recently stated that the telephone service in that city was the subject of considerable complaint. Our strict sense of justice now leads us to reproduce the following recantation, which appeared in the issue of that paper on the 17th ult. :—"In justice to the Telephone Company of this city, who, in spite of the many great difficulties they have met with on all sides, have introduced such an important improvement amongst us, we would now make a few remarks regarding a paragraph we lately published concerning the same, in which we complained of the switch room service. Since writing the paragraph in question we have noticed a great improvement in the service, and, having ascertained the reason, find that at the time we complained some of the chief operators at the exchange had recently left, and had to be replaced by others to whom this service was entirely new, and who at the time had not yet learnt the art of operating. Also as regards our statement that many of the subscribers did not intend to renew their subscriptions, we are very glad to learn that we were entirely misinformed, and that it had no foundation whatever in fact."

THE PROPOSED ELECTRIC LIGHTING AT BOURNEMOUTH.—The project for a public supply of incandescent light at Bournemouth is being followed up with some vigour by the townspeople. Since our last "Note" upon the subject a meeting has been held at the Town Hall to consider the question of taking steps to form an Electric Lighting Company. It was estimated that a capital of £3,000 would be required, and several of those present expressed their intention of applying for shares, so that there is very little doubt that the installation will be proceeded with. "A gentlemen in the body of the hall" raised some objection, on the score of the supposed dangers to life resulting from the electric light. Considering that only incandescent lights upon a low tension system are in question, Mr. Shepherd does not appear (according to the newspaper report) to have expressed himself as strongly as he might have done as to the absence of all risk of the kind referred to. He was, however, able to adopt the practical expedient of an appeal to another gentleman present, who stated that at Mr. Shepherd's request, although feeling rather nervous about it, he had actually touched a wire supplying an incandescent light—and had survived the experiment; in fact, as he went on to add—and evidently much to his own surprise—he did not feel the slightest sensation at the critical moment. The public still require a good deal of enlightenment on points of this character.

ELECTRIC PROGRESS IN CANADA.—At Toronto an electric railway has just commenced running, and has so far proved a success. The motor, which was designed and constructed by Mr. J. Wright, of the Toronto Electric Light Company, presents several novel features. We take the following account from the *Electrical World*, of New York:—The armature is built up of removable coils wound in a mould and made interchangeable. A defective coil can thus be replaced in a very short time. An electric light is placed in a powerful reflector in front of the car, and remains constantly lighted, as the current is never interrupted. The power is conveyed to the driving wheels by friction gearing, which admits of the motor being always in operation except at the moment of reversing its direction of rotation. When the motor is released from the gearing for stopping the car, it is prevented from accelerating its speed by the introduction of resistances in the circuit. Part of the resistance is in the form of coils of fine wire encircling an extension of the iron of the brake shoes, which are thus converted into powerful magnets, and bring the car to a standstill without any manual power being applied to the brake at all. There is also a double gong on the upper part of the front of the locomotive actuated by a small quantity of the current in a derived circuit to the main line. While on the grade the current rose from 15 amperes to 25, which was the highest recorded. The E.M.F. of the generator at 750 revolutions is about 2,000 volts.

"LA SUITE DES EXPÉRIENCES DE CREIL."—Under this title the *Revue Industrielle* has the following remarks:—"One of the most surprising results of the late experiments of M. Marcal Deprez for the electric transmission of force between Paris and Creil has been to reduce to silence the journal, *La Lumière Electrique*, which has hitherto been devoted to the glorification of the enterprising academician. This sudden change of attitude has caused no little surprise among those who have not been initiated into the mysteries of financial syndicates. It is said that harmony no longer reigns among the promoters of the enterprise, and rumours are even current as to legal processes involving claims for indemnity, or for damages, amounting to millions of francs. We do not pretend fully to understand the relations of the house of Rothschild with these matters, but it is well known that kissing goes by favour, and, in any case, we shall be very curious to know what foundation there may really be for these rumours of serious disagreements. It is perhaps permissible to believe, in financial circles, that M. Marcel Deprez has made some great discovery; delusions of this character are common even among the first financiers of the world. But, from an industrial point of view, we have still to learn that any practical value attaches to the Creil experiments." The article concludes with some remarks of great severity as to the personal distinctions or advantages which "certain persons" are said to have derived from the business.

CIVIL SERVICE INQUIRY.—*Apropos* of the controversy now going on in the *Daily Telegraph* on this subject, one correspondent from Birmingham writes to that paper as follows:—"I am more than surprised to find that no member of the postal telegraph service has thought fit to join in the controversy now going on in your paper concerning the Civil Service inquiry. Although it is clear that there is to be a big levelling down, it is to be hoped that there will also be a big levelling up with respect to those who were handed over to the tender mercies of the Post Office by the telegraph companies; for, though it may not be publicly known, great dissatisfaction exists among them in consequence of their having been deprived of their legal rights. As one of the number so transferred, it will be sufficient to state my own position. In taking over the property of the telegraph companies the Act of Parliament provided that all clerks retained by the Government were to

Digitized by Google

be, to all intents aud purposes, officers of the Civil Service, and as such were to be entitled to all the privileges of that service, but when the Order in Council gave effect to certain recommendations of the Playfair Commission the telegraph clerks were excluded, and have been excluded to this day, even from the lower division of the scheme, and as a consequence I, like many others, stand in receipt of £130 per annum, after considerably more than twenty years' service. And my duties are, what? To be able to ascertain and determine the nature and locality of interruptions on telegraph lines; to be well versed in the laws of electromotive force; to be competent to remedy faults in electrical appliances—in short, to be an electrician, and to occasionally assist in the control of large bodies of men."

An "All-Round" Battery.—The October number of the Maderia *Monthly Correspondent* contains the following:—"A want has lately been felt of a good 'all-round' battery; one, not only of the *constant* type, but one which will work equally well—(1) On cable circuits; (2) On land lines; (3) On house electric bells and annunciator; (4) As an exciter for recorder vibrators; (5) As a testing battery. With this end in view, we have lately thoroughly tested and have now in constant use on a cable circuit a battery of modified gravity cells of a form suggested by one of M. Hospitalier's books. Circumstances, however, have compelled us to adopt a slight modification, as to form and shape, from the drawing given in the book of the eminent French electrician. Our cell is as follows:—The + pole is a piece of *lead* piping filled with sulphate of copper and slit at the bottom, the slit pieces being opened out so that the lead piping stands up easily in centre of cell. Unfortunately we have to utilise the old Minotto jars, which are of the roughest make, and some of which are not even straight, and with bottoms all on one side, owing to bad manipulation of glass. The edge of glass jar supports the out-reaching lappets of the – pole, a massive ring of *zinc*, through which the lead piping freely passes. We are having all our old refuse zinc recast into zincs of the above form, and all useless old Minotto coppers are replaced by this cheap substitute, lead-piping, which answers very well. Charged with a weak solution of sulphate of zinc, the above battery is about 3ω per cell, but after working for two or three weeks, falls to 2ω per cell, at which resistance it remains. If one set up the battery by filling up with water, and short-circuiting for a short time, the battery is at first about 17ω, and then, as the sulphate of zinc is formed, gradually falls to 2ω per cell. When the cell requires more sulphate of copper a little is dropped into the lead piping. We had a battery of these cells on closed circuit for a week, and every morning rough tests for R and E.M.F. were applied; its behaviour was perfect."

New York Wires.—In order to avoid having to place their lines in the conduit, now being laid down in New York, the Western Union Telegraph Company have concluded an arrangement with the Elevated Railway Company in that city for placing their lines underneath the railway structures. This is now being carried out; we can only wonder that so obvious an arrangement was not long ago adopted. As to the conduit itself, the work proceeds slowly; more than once unexpected difficulties have arisen in the way of large gas and water pipes, which are often found to occupy very different positions from those shown upon the plans. The conduit sections also are not being supplied as rapidly as had been promised by the makers; and, further, there are several lawsuits pending on different matters connected with the action of the Subway Commissioners; among others the latter are themselves bringing an action against the Western Union Company to compel them to place their wires in the subway. As the conduit is not yet complete, this seems rather premature. The following details of the specifications for the material of the conduit have not as yet appeared in this country:—The specifications call for a material which shall bear a crushing strain of 4,000 pounds per square inch, a tensile strain of 300 pounds per square inch, that will not crack at 10° F. or soften below 160°, and that will not lose shape under 200° F. It must also be impervious, and resist the action of illuminating gas, salt water, and organic acids. The sand used to be silicious, clean and sharp, and heated before mixing with the asphalte to the temperature of the latter. The natural bitumen, if used, to be freed from water, and contain in the semi-refined mastic not less than 60 per cent. of pure bitumen. No petroleum refuse or still bottoms to be used for softening it, but preferably paraffin or paraffin oil. The conduits are to be rectangular in section, containing 2½in. ducts, varying in number. The conduit is to rest on a foundation of Portland cement concrete 6in. thick. The method of joining the sections to secure tightness is by the use of paper tubes covered with coal-tar pitch. Manholes are to be built at street-crossings. The specification would seem to be deficient in requiring no test as to expansion and contraction from changes of temperature.

The Phœnix Fire Office Rules.—The eighth edition of these rules has just made its appearance, and contains the regulations which have been adopted for the use of secondary generators. They are as follows:—"Where secondary generators are employed and the alternating primary current is of high electromotive force, it is preferable that neither the secondary generators nor the portion of the primary circuit in connection with them be placed inside any building, but in a fireproof structure apart. When, however, this cannot conveniently be done, the following precautions must be observed: The primary conductors must be heavily insulated with india rubber of the highest quality, or other approved equally good material or materials, and must have a very strong external covering, and the insulation resistance must be very high, and to the satisfaction of the inspector from the fire office. The conductors must be kept at a minimum distance of twelve inches from each other, and be enclosed in separate casing. The casing should be of a non-conducting material and fireproof, and the arrangement must be such that no leakage of electricity can take place to earth from either of the conductors, or any short circuit from one to the other. The primary conductors must be furnished with a double-pole switch, and also double-pole 'cut-outs' which act at 25 per cent. above the normal and placed as near the entrance of the primary conductors into the building as possible. The switch-board must be of slate or other approved non-combustible material, and placed in a secure position The secondary generators must be encased in iron, or be in a fireproof compartment, and placed as near the entrance of the primary conductors into the building as can conveniently be done. They should be in a dry situation and thoroughly insulated. All secondary conductors must be protected by double-pole 'cut-outs' to go at 50 per cent. above the normal, to be approved by the inspector from the Fire Office. Where from the nature of circumstances it is found impossible to follow out any part or parts of these safe-guards, then the inspector from the Fire Office will decide as to what shall be done in each particular case as it arises. The casings for the primary conductors must be fireproof from their entrance into a building up to the 'cut-outs.' Should, however, it be desired to use non-fireproof casing from the 'cut-outs' to the switch and secondary generators, special permission must first be obtained."

CONTEMPORARY PROGRESS.*

ON AMPERE'S LAW.

By P. DUHEM, *Journal de Physique*, 2nd Series, Vol. V., 1886.

Gauss was the first to enunciate the following proposition:—

"There are an infinite number of laws for the action of one current element upon another, such that the action of a closed current upon a current element shall be the same as that obtained from Ampère's law. But of these, Ampère's law is the only one for which the action of one current element upon another reduces to a single force in the straight line joining the two elements."

The following seems to be a particularly simple proof:—

Gauss's theorem will follow immediately if we can show that the action of one current element upon another is completely determined, when the action of a closed steady current upon a current element is known, by the condition that the mutual action of two elements shall be in the direction of the straight line joining them.

Let ds, ds' be the two current elements; i, i' the currents in them. Let us suppose that there are two distinct expressions representing the action of ds on ds', both subject to the assumed conditions. The components of the force exerted by ds on ds' will be for the two expressions respectively:—

$$\begin{matrix} ii'\,X\,ds\,ds' \\ ii'\,Y\,ds\,ds' \\ ii'\,Z\,ds\,ds' \end{matrix} \quad \text{and} \quad \begin{matrix} ii'\,X_1\,ds\,ds' \\ ii'\,Y_1\,ds\,ds' \\ ii'\,Z_1\,ds\,ds' \end{matrix}$$

Let ds form part of a closed circuit; then, since the action of the circuit is the same for either law,

$$\int X\,ds = \int X_1\,ds$$
$$\int Y\,ds = \int Y_1\,ds$$
$$\int Z\,ds = \int Z_1\,ds,$$

the integrals being taken round the closed circuit.

Hence
$$\left.\begin{matrix} (X-X_1)\,ds = d\,F \\ (Y-Y_1)\,ds = d\,G \\ (Z-Z_1)\,ds = d\,H \end{matrix}\right\} \quad . \quad . \quad . \quad (1)$$

where F, G, H are functions of the co-ordinates, x, y, z, of the element ds.

If in each case the resultant action is along the straight line joining ds and ds', we shall have, where x', y', z', are the co-ordinates of ds',

$$\begin{matrix} (y'-y)\,Z - (z'-z)\,Y = 0 \\ (z'-z)\,X - (x'-x)\,Z = 0 \\ (x'-x)\,Y - (y'-y)\,X = 0 \end{matrix}$$

and
$$\begin{matrix} (y'-y)\,Z_1 - (z'-z)\,Y_1 = 0 \\ (z'-z)\,X_1 - (x'-x)\,Z_1 = 0 \\ (x'-x)\,Y_1 - (y'-y)\,X_1 = 0 \end{matrix}$$

Hence from equations (1)—

$$\left.\begin{matrix} (y'-y)\,d\,H - (z'-z)\,d\,G = 0 \\ (z'-z)\,d\,F - (x'-x)\,d\,H = 0 \\ (x'-x)\,d\,G - (y'-y)\,d\,F = 0 \end{matrix}\right\} \quad . \quad . \quad . \quad (2)$$

If we write
$$\begin{matrix} (y'-y)\,H - (z'-z)\,G = F_1 \\ (z'-z)\,F - (x'-x)\,H = G_1 \\ (x'-x)\,G - (y'-y)\,F = H_1 \end{matrix}$$

Equations (2) take the form—

$$\left.\begin{matrix} H\,dy - G\,dz = -d\,F_1 \\ F\,dz - H\,dx = -d\,G_1 \\ G\,dx - F\,dy = -d\,H_1 \end{matrix}\right\} \quad . \quad . \quad . \quad (3)$$

From the first of these we see that F_1, and therefore also its partial derivatives H and G, are independent of x. Applying the same reasoning to the two others we find that

F is a function of x only,
G is a function of y only,
H is a function of z only.

Again, since the left hand members of equations (3) are complete differentials,

$$\frac{\partial H}{\partial z} + \frac{\partial G}{\partial y} = 0$$
$$\frac{\partial F}{\partial x} + \frac{\partial H}{\partial z} = 0$$
$$\frac{\partial G}{\partial y} + \frac{\partial F}{\partial x} = 0$$

Whence
$$\frac{\partial F}{\partial x} = \frac{\partial G}{\partial y} = \frac{\partial H}{\partial z} = 0.$$

Thus F, G, H are constants; and therefore, from equations (1),

$$X = X_1$$
$$Y = Y_1$$
$$Z = Z_1,$$

which proves our proposition.

ON THE ELECTRICAL CONDUCTIVITY OF DOUBLE SALTS.

By E. KLEIN, *Wied. Ann.*, Vol. XXVII., 1886.

The principal object of the author in these experiments, made both with double salts and with mixtures of salts, was to obtain data which would give some insight into the condition in which such salts exist when in solution.

It has generally been maintained that double salts always become dissociated when in solution, but these conclusions do not rest upon direct experimental evidence, but only upon probable suppositions. The author refers to a large number of researches by different inquirers who all agree on the point that dissociation occurs, but the question whether this dissociation is complete or only partial had still to be decided.

The resistance measurements were made by the aid of a Wheatstone bridge of Kohlrausch's form, with sliding contact and alternate currents. The dynamometer was replaced by a telephone, and an induction coil was used to generate the currents.

The bridge wire, the resistance coils, and the thermometers used in the experiments were carefully calibrated, and the errors from all sources were not more than from 3 to 5 per cent.

The salts used were the sulphates of magnesium, ammonium, potassium, sodium, iron, manganese, and nickel, and the chlorides of potassium and sodium, together with their double salts and mixtures. The solutions were prepared, not according to the specific weights, but according to the number of molecules contained in a litre, by which is meant (according to Kohlrausch in the case of simple salts) the number of grammes of the salt in a litre of the solution at 18°, divided by the electro-chemical molecular weight of the salt.

It was in this way that F. Kohlrausch was able to obtain a general insight into the complicated phenomena of electrical conductivity.

This electro-chemical molecular weight is equal to the ordinary chemical molecular weight, divided by the number of "*bonds*" set free during the electrolytic decomposition, as, for example, $K - Cl$; $NH_4 - NO_3$; $\frac{1}{2}(Ba = Cl_2)$; $\frac{1}{2}(H_2 = SO_4)$; $\frac{1}{3}(H_3 \equiv PO_4)$ (*Wied. Ann.*, Vol. VI., p. 146, 1879).

In the case of double salts and mixtures the number of molecules m must be somewhat differently defined, since the number of molecules must be referred to two litres instead of one. Then if two fluids with molecule number m be mixed, the resulting mixture will also have the molecule number m, even although every pair of molecules form one double molecule.

The molecule number will therefore be defined by the expression,

$$m = \frac{ps}{A} . 1000,$$

where p is the weight of the electrolyte per unit weight of the solution, s the specific weight of the solution at 18°, and A the electro-chemical molecular weight.

Some determinations were first made of the resistances of the simple salts, and the results agreed well with those

* Compiled and translated by G. W. de Tunzelmann. Continued from No. 17, Vol. XXVII.

Digitized by Google

obtained by Kohlrausch, who had previously investigated the electrical conductivity of most of the simple salts already mentioned. The measurements of the conductivity k were made at temperatures of 18° and 26°. The mean temperature coefficient at 22° was expressed in the form,

$$\frac{\Delta k_{22}}{k_{18}} = \frac{k_{22} - k_{18}}{k_{18}},$$

k_{22} and k_{18} being the values of k at the temperatures 22° and 18° respectively.

Fig. 1 shows the curves obtained for the conductivity and the temperature coefficient, defined as above, for the sulphates of iron and of nickel, for different values of m, the values of m being taken as abscissæ, and the ordinates being the values of R and $\Delta k_{22}/k_{18}$ respectively.

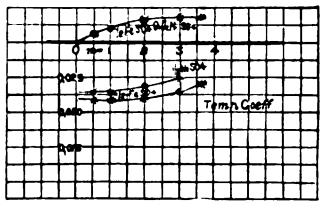

FIG. 1.

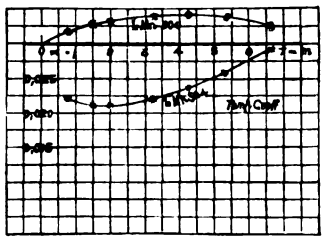

FIG. 2.

Fig. 2 gives the same curves for sulphate of manganese.

It will be noticed that the curve giving the temperature coefficient is in each case a sort of distorted reflection of the conductivity curves.

Conductivity of the Mixtures.

The mixtures may be divided into two classes.

1. Those which cannot undergo double decomposition, viz., when two salts contain either the same base or the same acid, excluding such mixtures as form double salts; they must therefore be of the form $AB + AB_1$ or $AB + A_1B$.

2. Those which can undergo double decomposition, viz., when the two salts contain different acids and different bases, being therefore of the form $AB + A_1B_1$.

There are two ways of comparing the electrical conductivities of the mixtures with the conductivities of the simple salts.

One way would be to measure the conductivities of equal volumes of solutions of the two simple salts, and then to measure the conductivity of the same volume of the mixture, and see whether in the latter case the conductivity is the sum of the two separate conductivities. Or, the two liquids may be mixed, and it may be determined whether the conductivity of the mixture be equal to the arithmetic mean of the conductivities of the components.

The two methods are not identical, and it is easy to see that the latter is the one which must be used.

The electrical conductivity of liquids is no simple phenomenon, but depends on the most widely differing factors; on the number of molecules, on their separate velocities, on the viscosity and frictional resistance between the molecules of the salt and of the medium in which it is dissolved, and finally on the chemical constitution of the solution.

The conductivity k may be defined as that strength of current due to a unit E.M.F. in a conductor of unit length and section. The current strength is, however, that quantity of electricity which crosses a section of the conductor in unit time. Now, in electrolytes the electricity is carried by the molecules of the salt, and therefore the current is proportional to the number of molecules crossing a section in unit time, and this number is itself proportional to the number m of molecules in the liquid, and to the velocity with which they cross the section. But this velocity is equal to the sum of the separate velocities of the constituent portions of the molecule, which leads to the known relation,

$$k = (u + v)m.$$

The velocity $u + v$ depends on the medium of solution, the degree of concentration, &c.

In the case of very dilute solutions $u + v = \lambda$, where λ is the molecular conductivity; and therefore the influence of the separate molecules of the salt on their motion can be neglected, and there remains only to take account of the frictional resistance of the medium. If to the very dilute solution of a salt there be added another, which if dissolved alone in the same would have a conductivity $k_1 = (u_1 + v_1)m_1$, the two salts will not interfere, provided they do not act chemically on each other. Since the solvent is in large quantity compared to that of the salts, therefore the molecules of either salt are able to pass a section as well as though the other were not present. It follows, then, that the conductivity of the mixture must be $k^1 = \phi(m)(m + m_1)$ where $\phi(m)$ is the velocity of the different molecules, having the constant value $u + v$ for one salt, and $u_1 + v_1$ for the other, so that $k^1 = k + k_1$, a law which Arvhenius (*Wiedemann's Beiblätter*, Vol. IX., p. 437) expressed as follows: "If two (or more) salts be dissolved in the same non conducting solvent, the conductivity of the solution is equal to the sum of the conductivities which the solution would have if in the first case one of the salts only were in solution, and in the second case the other only."

This law no longer holds for less dilute solutions, because there are then so many more molecules in a given volume of the solution.

If, however, the two salts be dissolved in such a way that the number of molecules per unit of volume is the same in each case as in the case of two solutions containing the same number of molecules, then the conductivity will be the mean of the two separate conductivities. In the experiments, therefore, with mixtures and double salts the solutions were so prepared that the number of molecules per unit of volume was the same as in the case of the simple salts.

The law of the arithmetic mean does not hold for very highly concentrated solutions, for even if the number of molecules be the same the specific weight and the fluidity of the mixture will be different.

Besides, with highly concentrated solutions the encounters of separate *ions* take place more easily and more frequently, and can no longer be neglected. Besides, it is probable that in concentrated solutions (as Hittorf has shown to be the case with iodide of cadmium) the single molecules collect into larger groups, and act electrolytically like ordinary molecules, the result being a smaller number of molecules, and a diminution in their velocity due to their increased size.

Possibly this may hold good for all simple salts, in which case the nature of the curves of conductivity would be perfectly accounted for.

The accompanying table A gives the results obtained with some of the mixtures experimented upon. The values of k in the second column are at the temperatures 18° and 26° respectively. The third column gives the arithmetic mean values of k for the two salts separately. D stands for the difference between the observed value of k for the mixture and its mean value for the two salts, expressed as a percentage of the mean. The sixth column gives the arithmetic mean value of $\Delta k_{22}/k_{18}$ for the two salts separately.

The figures for the first two mixtures show that for moderately concentrated mixed solutions of two salts having either the base or the acid in common, the conductivity is very nearly equal to the arithmetic mean of the conductivities of the two salts separately, but the mean is always slightly in excess.

In the case of the last two mixtures, which are of a kind capable of double decomposition, the conductivities are nearly the same, leading to the conclusion that two solutions of the form $AB + A_1B_1$ and $AB_1 + A_1B$ respectively, are identical,

Digitized by Google

a result obtained in an entirely different manner by Ostwald (*Wied. Ann.*, Vol. VIII., p. 154, 1878), and also by Rüdolff (*Pogg. Ann.*, Vol. CXLVIII., p. 574, 1873). Since the conductivity of the mixture is more nearly equal to the mean conductivity of its constituents in the case of the mixture $NaCl + \frac{1}{2}K_2SO_4$,

		$NiSO_4 + K_2SO_4$.			
0·5	246·4	256·2	−3·8		
	290·5	301·6	−3·7	0·0224	0·0225
1	424·4	455·6	−6·8		
	501·5	533·4	−6·0	0·0227	0·0214

it may be inferred that though all the four possible salts exist in each of these two mixtures, NaCl and K_2SO_4 exist in larger quantity than the other two,

Conductivity of Double Salts.

The double salts experimented on were $MgSO_4 + (NH_4)_2SO_4$, $MgSO_4 + K_2SO_4$, $FeSO_4 + (NH_4)_2SO_4$, $FeSO_4 + K_2SO_4$, $NiSO_4 + (NH_4)_2SO_4$, $NiSO_4 + K_2SO_4$, and such mixtures as were capable of forming these double salts. The accompanying table B gives some specimens of the results obtained.

These figures show an essential difference between double salts and mixtures, as with the double salts the value of D may attain as high a value as 11 or even nearly 12. This distinction exists even in cases where the dissociation is admitted to be complete, but is most marked in the case of double salts which can exist as such in solution.

This difference must depend on the chemical constitution, and it is simply explained by the hypothesis of a partial dissociation. Also as in the case of simple salts and mixtures it was found that when the strength of the solution increased complex molecules were built up, which in their electrolytic action resembled single molecules; and naturally this will occur still more in the case of double salts.

The fact of the variability of D, generally speaking proportional to *m*, shows that in the mixtures there was a partial and not a complete formation of double salts. In the case of double salts which do not undergo decomposition it would be expected that the values of D would be much higher. The example selected by the author is the double salt $CdI_2 + 2KI$, which has been shown by Hittorf not to undergo decomposition in solution unless the solution be very dilute, and he gives the accompanying table, calculated from the results of Grotrian (*Wied. Ann.*, Vol. XVIII., p. 177, 1883) and those of Kohlrausch already referred to. The last number in the third column was not an observed value, but was obtained by interpolation :—

M.	10^6k_{18}	Mean.	D.
0·5	228	291	−21·6
1	415	559	−25·9
2	758	1059	−28·4
3	1070	1484	−27·9
4	1341	(1830)	−26·7

When the solution is fairly strong D remains pretty constant, but when very dilute, complete dissociation takes place, and Grotrian estimates the molecular conductivity of K_2CdI_4 to be very approximately the sum of the molecular conductivities of KI and $\frac{1}{2}CdI_2$.

Conductivity at Higher Temperatures.

It was generally found that the deviation D of the conductivity from the arithmetic mean at the temp. 26° was slightly smaller than or equal to the value of D at the temp. 18°. In some cases, however, there was a greater difference, but not enough to warrant any inferences being drawn from it. A special determination was therefore made of the conductivity of a solution (m = 3) of ammonio-sulphate of iron at a temperature of 40°, and the value of D was found to be 9·5, its value at 18° being 11, leading to the conclusion that dissociation increases with increase of temperature, as was to be expected for mechanical reasons.

Mixtures of Simple and Double Salts.

Observations were made on some mixtures of simple and double salts in which the solutions were not in equivalent proportions. If the previous conclusions be correct, a small deviation would be expected from the arithmetic mean between the conductivity of the simple and that of the double salt. This was found to be the case, as is shown in the original paper, by a series of tables analogous to the previous one, of which examples are given above.

Results of the Research.

1. The conductivity of a dilute solution formed by mixing two salts, whether these salts be capable of double decomposi-

Digitized by Google

tion or not, is approximately equal to the arithmetic mean of the conductivities of the two salts whose existence in the solution is most probable.

2. Inversely, from the conductivity of the mixture, the two salts chiefly existing in it may be inferred.

3. The conductivity of a dilute solution of a double salt is very slightly less than the arithmetic mean of the conductivities of its two constituents. This difference increases with the concentration of the solution, being very nearly proportional to the number of molecules.

4. Double salts are completely dissociated in dilute solutions, and more or less in concentrated solutions. The dissociation always increases with the dilution.

5. Dissociation is favoured by heat.

ON THE ELECTROLYSIS OF SALTS.

By A. RENARD, *Comptes Rendus*, Vol. CII., February, 1886.

In a note to the French Academy (*Comptes Rendus*, Vol. CI., p. 747) in October, 1885, the author called attention to the fact that if solutions of various degrees of concentration containing quantities of metal proportional to their equivalent atomic weights are subjected to a current of the same E.M.F., there is in general no simple relation between the quantities of metal deposited; and described experiments, which led him to the following conclusions:—

1. In sufficiently dilute solutions the quantity of metal deposited is proportional to the strength of the solution.

2. The quantities of metal deposited are in the same ratio as their equivalent atomic weights.

3. According to Faraday's law, the quantity of metal deposited being proportional to the strength of the current, the conductivity of the solutions containing equivalent atomic weights of the metals is the same, as M. Bouty has shown by a direct method (*Ann. de Chim. et de Phys.*, Vol. XIII., p. 433).

The current was obtained from a thermopile, by which a constant E.M.F. could be maintained for several hours. The electrodes were formed of two discs, having a surface of 226 square mm., immersed vertically in the liquid, and having their non-opposed faces covered with an insulating varnish, which was not acted on by acids. The positive electrode was made of the same metal as that in the solution, and was provided with a screw adjustment, by which it could be moved backwards or forwards through a measured distance. The negative electrode was of platinum, and was fixed to the hammer of an electric bell in order to give it a rapid backward and forward motion with the object of always having it in contact with a fresh surface of the liquid, and more particularly to ensure that the deposits should not be pulverulent, as is the case in dilute solutions where the electrodes remain fixed.

The length of an experiment varied from one to five hours, according to the quantity of metal deposited. After each experiment the electrode was taken out of the bath, washed, dried, and weighed, the increase in weight giving the amount of the deposit. Throughout the experiments the distance between the electrodes, when at rest, was 2cm., the temperature was 16 degrees, and the electromotive force of the current was 3·65 volts.

The solutions contained equivalent atomic weights of the different metals, varying in strength from 1/10,000 to 1,024/10,000 parts of metal to 100 of liquid. Salts of silver, copper, zinc, and cadmium were used in the experiments.

In the present paper the author describes the results of some further experiments made with the same apparatus upon some solutions of the same metallic salts as previously, varying in strength from 2/10,000 to 64/10,000, and containing, as before, equivalent atomic weights of the different metals. Using the same E.M.F. as before, with the same electrodes at the same distance, the author found that when the temperature varied the quantity of metal deposited increased proportionately to the temperature, according to the formula,

$$P_t = P_o (1 + Kt),$$

in which K increases as the concentration diminishes, attaining a maximum value of about ·052 when the solutions become so dilute that the quantity of metal deposited at a constant temperature is proportional to the strength of the solution.

When the distance between the electrodes was varied it was found that as the distances of the electrodes were successively doubled, the quantities of metal deposited diminished in a geometrical proportion having for its common ratio $r = 1{\cdot}237$. For distances beyond 32cm. this law is no longer applicable, as the values of r then increase with considerable rapidity.

Some experiments made with nitrate and sulphate of copper, and with copper discs as electrodes, with diameters of 10cm., 20cm., and 30cm. respectively, at a fixed distance of 2cm., led to the conclusion that when the two electrodes are identical the quantities of metal deposited are proportional to their diameters, and therefore to the square roots of their surfaces.

REPORT OF THE COMMITTEE ON STANDARDS OF LIGHT.*

BY PROF. G. FORBES.

The first communication that I have to make is the report of the Committee on Standards of Light. The Committee on Standards of Light have met repeatedly during last winter. It had been proposed in last year's report to carry on experiments on electrical standards in the hope of arriving at an absolute standard of light. One of the first steps was to discover a means of reproducing a definite temperature, and certain experiments were proposed for this purpose. At one of the first meetings of the committee Captain Abney announced that he had already found a means of doing this in a different manner to that proposed in the committee's report, depending only on the change of the resistance of the carbon filament with temperature. Under these circumstances, the committee left this part of the experimental investigation to be reported upon by Captain Abney. His further researches, however, have led him to believe that the law which he had announced to the committee does not hold with all qualities of carbon filaments. He has, however, been engaged upon further experimental researches in the same direction, which are ready for publication, and which have an important bearing on the labours of the committee. (I may here mention, however, that he has been prevented from putting these into a form ready for publication, and that must be delayed for the present.) In the last year's report attention was drawn to the value of the pentane standard of Mr. Vernon Harcourt as a practically reproducible standard of illumination. Mr. Rawson has been engaged during the past winter, under the direction and with the assistance of Mr. Vernon Harcourt, in a further examination of this standard, and his results will be made known in a separate paper. Sir James Douglass has also made some experiments which are not quite completed, but they have gone so far as to give great promise. Some account of those experiments in this report had been expected by the committee, but the absence of Sir James Douglass on official business prevented him from completing it. At one of the first meetings of the committee the secretary showed what he had done in the way of improving thermopiles, such as it was hoped would be of use in the investigation recommended in last year's report, and he was instructed by the committee to proceed with the construction of the instrument, which has been completed, and is placed before the section and described in a separate paper. The committee respectfully request to be re-appointed, with a grant of £25.

THERMOPILE AND GALVANOMETER COMBINED.*

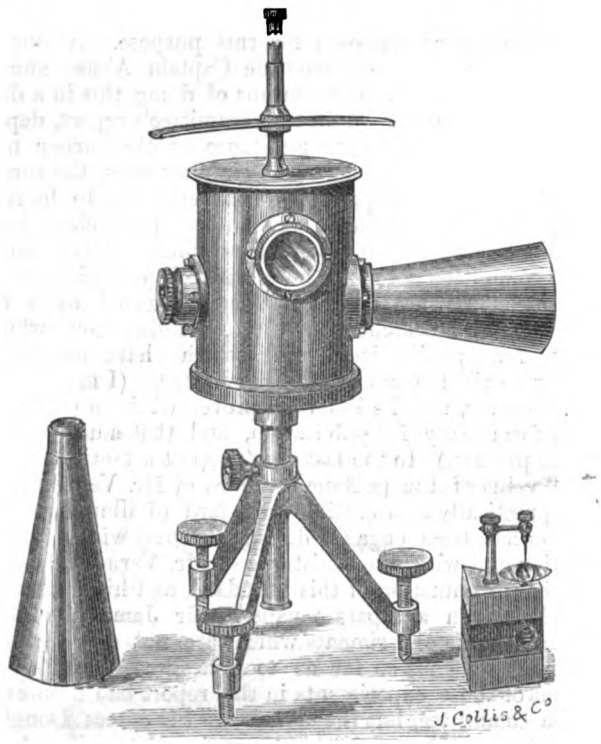
BY PROF. G. FORBES.

My next duty is to bring before the section some account of an apparatus, a name for which I have not succeeded in fixing upon, but which I have spoken of as a combined thermopile and galvanometer, and that represents accurately what the instrument really is. A "thermal galvanometer" might perhaps be a suitable term for the instrument, the object of which is to measure the radiation of heat in the manner which has been accomplished by the ordinary thermopile. The instrument was designed more particularly for use in spectroscopic work—that is to say, to replace

* Paper read before the British Association at Birmingham.

Digitized by Google

what has been generally known as the line thermopile, a thermopile which measures the intensity of light forming a linear image. Some account of the first forms of this instrument was given to the Royal Society last spring. Since then the instrument has been modified, with the intention of making it more sensitive. The first apparatus which was constructed was extremely simple, and consisted merely of a very short tube made of two different metals. One half of the circular section was of bismuth, and the other half was of antimony. The two edges were filed down, so as to be very thin, and covered with a carbon surface which absorbed radiation freely. The difference of intensity of radiation on the one junction or the other determined the direction of the electric current which circulated round the composite tube. The circuit needle had an extremely low electrical resistance, and the compass needle, or magnetic needle, like those employed in Sir William Thomson's galvanometers, was inserted into the tube, and acted directly upon this circuit of low resistance carrying the electric current. It was hoped by thus lowering the resistance enormously that we should get an increased effect, and the result of the experiment seems to support the theoretical conclusion. In the ordinary thermopile



Prof. Forbes's Combined Thermopile and Galvanometer.

as used we have a number of junctions—a number of pieces of antimony and bismuth—joined together in series, and consequently they offer a much larger resistance than the composite tube which I have spoken of. Moreover, they have the resistance of the galvanometer in the circuit, and in the communication to the Royal Society it was pointed out that one would expect *à priori* that the combination of the galvanometer and thermopile would be about equal in efficiency to this combination if the galvanometer were made specially of a proper resistance and construction for the thermopile, a thing which is seldom attained in actual practice. The form of instrument which was most complete, which I showed to the Royal Society, consisted of a wedge of antimony and bismuth combined. This [showing instrument] is not an exact representation of the wedge, but it is near enough to it to show you the type. You see this is a wedge with a hole passing through very close to the narrowest surface of the wedge. In that hole the magnetised needle and suspended mirror were placed. The upper half of the wedge consisted of antimony, and the lower half of bismuth, and the heat striking the junction of these two determined the electrical current which influenced the needle. That apparatus was found to be very sensitive indeed, and probably as sensitive as any arrangement could be for use as a line thermopile. There was one very great point about it—that it was very dead beat in its action. This large mass of metal, with its low resistance, acted as a damper on the motions of the magnetic needle, and rendered it extremely stable, and caused it to come to rest very rapidly. That was assisted, of course, by my employing in that instrument one of the mirrors of Mr. White, of Glasgow. And speaking of mirrors, I cannot conceive of anybody using any other kind in galvanometers, though in England there seems to be a delight in those heavier mirrors which are supplied by London makers. But I must say—it may be that I have had more experience of them than others—I cannot conceive anybody using others when they can get Mr. White's. Since then I have modified the instrument to make it more sensitive by making it astatic. Instead of having one set of magnets inside the circuit I have another set outside on the same suspension. The instrument is rendered much more sensitive, but it is not so dead. This wedge is enclosed in a brass covering, and it has a cone to reflect the heat on to the surface of the junction of the two metals, and it has also a controlling magnet like the ordinary Thomson galvanometer that we so often see. In the present arrangement I have put the magnet down as low as possible to give it very great directive influence, because in this room there is so much tremor that it is almost impossible to see the action of the apparatus. At this moment you notice that the spot of light has gone to the far side of the scale, and I hardly like to move it, because in doing so I should set up vibrations which would last a long time. The heat of my hand, placed beside it, is sufficient to move it over a very considerable range, but in this present shaky condition I am afraid it must be left for a limited number of gentlemen to examine it when the conditions are more favourable. I will not take up the time of the section longer than just to add that this apparatus has been made by Messrs. Nalder Brothers, Westminster, and it strikes me as being very much more beautifully made, and much more delicate, than the apparatus which I showed originally.

DISCUSSION.

Prof. FITZGERALD said he would like to ask a question as to the relative delicacy of thermopiles and bolometers. Prof. Langley, he thought, had given the preference to the latter for the purpose of measuring the current Was that the opinion of Prof. Forbes ?

Prof. FORBES said he quite agreed in that respect with Prof. Langley, believing that there was not the slightest doubt that the bolometer was very much more accurate than any thermopile arrangement. It was simply in comparison with thermopiles that he considered his instrument the most sensitive.

Lord ROSSE thought that this was a most important question to raise. He had directed his attention to it, and had endeavoured to ascertain the respective merits of the bolometer and thermopile. It seemed to him, however, on looking over Prof. Langley's paper on the subject, that the advantages attributed to the bolometer by him were rather exaggerated. Prof. Langley did not draw sufficient attention to the fact that he took immense pains to make his galvanometers. He made the needle very much lighter upon the same principle that Prof. Forbes was very anxious to make it lighter, and he made it particularly dead-beat by a very simple and ingenious contrivance, using dragon flies' wings, and thus getting a very stiff and light damper. He (Lord Rosse) tried the same thing himself on a galvanometer ; he stuck two dragon flies' wings on the back of the reflector by means of a small piece of wax ; he then stuck two more wings at the ends of the others, and found that the galvanometer was driven to the end, stopped, and returned very fast to zero. It was extraordinary how it was brought to rest after two or three oscillations. Prof. Forbes used a modified form of thermopile, but the ordinary thermopile had a number of advantages. It struck him that probably the E.M.F. was proportional to the elevation of the temperature, and by sending all the heat into one solder ten times the temperature would be obtained for the same E.M.F. By this arrangement the resistance of the thermopile was very much reduced at once. He thought that the subject wanted fuller consideration. The plan by which he collected all the heat into one solder was by fixing one solder to the other by a thin sheet of copper coil, and he believed that very rapidly carried all the heat of the disc on to the central solder. As regarded the combination of the the two which Prof. Forbes had shown, it depended upon circumstances whether the arrangement would be a successful one or not. He himself used a thermopile placed in the focus of his reflector, and employed very large wires. For his purpose it was much more convenient to read the galvanometer in the observatory, and to have it more generally used by moving the telescope.

Lord RAYLEIGH said that he would like to offer a word or two on the comparison between the thermopile and bolometer. He was very much of the opinion shared by Lord Rosse, that a great part of the important results that Prof. Langley had obtained was due more to his galvanometer and the other part of his arrangement than to the substitution of the bolometer

Digitized by Google

for the thermopile. He would not say that the thermopile was as good as the bolometer as a general proposition. Taking the case in which interest was probably greatest, where a linear element was wanted to investigate the spectrum with, in the nature of the case, even where the apparatus was capable of taking in a considerable area or section, the ground of the spectrum would prevent it being done. They must make a comparison between what E M.F. would result from change of fine wires and the E.M.F. which would be generated by the induction at the same temperature of a single thermal element formed by putting together two equally fine wires in such a manner that the junction came into the field of action. The comparison could not be made in any absolute way, because theoretically the sensitiveness of the bolometer might be increased without limits, if they could indefinitely increase the limits passing through it. Prof. Langley did not give any definite data to enable one to fix the limit of the current that passed. In the thermopile the E.M.F. was proportional to the increase of current absolutely ; in the bolometer it was proportional to the varying influence of the platinum or whatever might be used. But, taking such data as Prof. Langley gave, it did not appear that much more E.M.F. was got out of the elements forming the bolometer than might be done out of the German silver and iron connection formed of two correspondingly thin wires. He had also tried the plan of using a comparatively small disc, and he thought that as good a result was got in that way.

Lord Rosse said he would like to add that Prof. Langley contrasted his experiments with his (Lord Rosse's), but that gentleman overlooked the fact that he (Lord Rosse) had a much larger mirror to work with, and worked in the open air in varying atmospheric conditions, whereas Prof. Langley worked in his observatory, completely sheltered from draughts of air. This fact made such an important difference that one could hardly compare the two sets of radiation experiments.

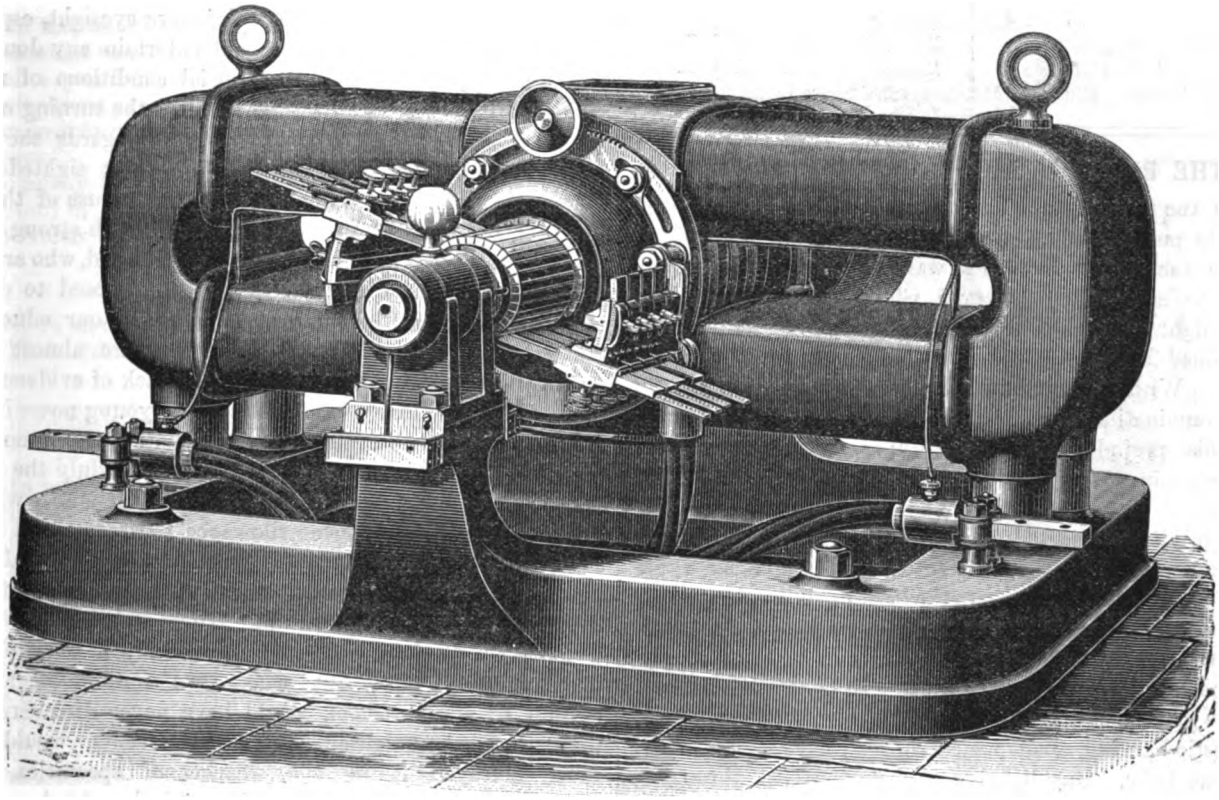
THE CHAMBERLAIN AND HOOKHAM DYNAMO.

We have already described the electric lighting of the Bingley Hall Exhibition, which was very successfully carried out by the Gülcher Company. Among the most interesting of the electrical exhibits in the body of the hall we noticed a dynamo machine of a new type, which has been designed and constructed by Messrs. Chamberlain and Hookham. The general construction of this machine will be understood from the accompanying engraving, which represents a 30-unit type. The heavy yokes and pole pieces are of cast iron, the magnetic circuit is well isolated from the frame, giving as a result great symmetry of field. The armature is of the drum type, with slots and projections similar to those of the Pacinotti ring. The armature resistance is remarkably low, being less than three per cent. in a 10-unit and less than two per cent. in a 30-unit machine. The slots and ribs of the armature are so proportioned that the sum of the sectional areas of the ribs at any time opposite the pole pieces are equal to the magnetic section of the armature, so that but for the small clearance necessary between the ribs of the armature and the pole pieces the magnetic circuit is complete through iron producing a great intensity of field.

The brushes, which are of a new type with end pressure, only require the readjustment of a spring at long intervals to compensate for wear. A brush of this kind has been on one of the company's plating machines in daily use for six months without touching. Each machine has two or more brushes side by side, and each brush is capable of independent movement, both in the direction of its length and also round the axis of the commutator.

The bearings of these machines are exceptionally long, and the steel spindles very strong and heavy, and in all other mechanical respects the machines seem to be thoroughly well designed.

The 10in. by 13in. 25-unit nominal is the largest machine on view. It is shunt wound. The resistance of the armature is ·003 ohm hot, of the magnets 8 ohms. The speed is 960 revolutions per minute, and the E.M F. 57 volts. The total energy converted is 26,635 watts. 610 watts are absorbed in the armature coils, thus giving a loss of 2·28 per cent. in the armature, 1·4 per cent. in the magnets, and an electrical efficiency of 96·3 per cent. This particular dynamo is one of a set made for use in copper refining. For ordinary electric lighting its speed would be 1,000 revolutions per minute, and we are informed that it would then develop 30 units with a still higher efficiency. A 7¼in. by 9in. 9-unit nominal dynamo is shown running as a motor by current from the Gülcher Company's dynamos which are lighting the hall. This machine is identical with the one the company have just used in their installation at the Birmingham Art Gallery. The machine has an armature resistance of ·01 ohm hot, and at 1,250 revolutions per minute gives an E.M.F. of 57 volts at terminals, and has an electrical efficiency of 94·5 per cent.



Chamberlain and Hookham's Dynamo.

The firm also exhibit their patent interchangeable wall couplings and lamp holders, which are extremely simple, and make at the same time a thoroughly good electrical and mechanical connection.

An automatic switch for use in charging storage batteries and heavy current switches of novel design are also shown.

THE ELECTRIC LIGHT AND EYESIGHT.

One of the first objections to the Electric Light when introduced into public buildings was on the score of its being so trying to the eyes. Even its warmest admirers were constrained to admit that however wholesome might be this artificial light in regard to the atmosphere, the natural eye was strained and rendered somewhat uncertain under its influence. With the gradual disappearance of arc lights for indoor illumination, and the substitution of incandescent lamps, this prejudice is rapidly dying away. It is kept alive in certain places, such as the British Museum Reading Room, whose late visitors pay the penalty of a headache for the privilege of studying after ordinary hours. But in the Theatres, where the more agreeable and steadier application of electricity was adopted, the light has been always very popular, and, so far as we know, has never been objected to either on the ground of its being defective as a light, or prejudicial to the complexion considered as a decorative adjunct. The same may be said of it wherever it has been introduced for domestic lighting, about which we shall have more to say in our next issue. Gas lighting probably passed through a similar experience before burners and globes were interposed to regulate and modify the coarse and turbulent flame of blazing gas. The arc light is to the incandescent light what the flare of a gas tube is to the glow of a well-fitted gaselier. And, as regards the eyesight, unprejudiced observers have uniformly given their verdict in favour of the improved electric lamp over the best form of gas burner.

We are led to making these observations on perusal of a paper read by Dr. Oakley at the Congress of the Sanitary Institute held at York last week on the Prevalence of Defective Eyesight. Not that Dr. Oakley made any special reference to the Electric Light in relation to what he testifies is a growing defect among the people of this country. But the importance of the subject and its connection with the question of lighting are obvious; and in the solution of this question we believe the Electric Light will in the future take a conspicuous place. Defective eyesight is in part produced by insanitary conditions and hereditary tendencies transmitted under their influence. One at least of these baleful conditions would be removed by the relegation of gas to the place where we have already banished the arc light, namely, out of doors. Dr. Oakley speaks very precisely as to the effects of vitiated atmosphere and high temperatures in crowded places as the predisposing causes of defective sight and hearing; and most people can corroborate him to some extent from their own experience. Hot eyelids and aching head, followed by chill and slight catarrh, are commonly the effects of incautious enjoyment of pleasure where a dazzling blaze of gaslight forms part of the evening's attractions; and this form of attack, often repeated, is, we are told, far more prejudicial to the eyes than any ordinary cold, however severe, could possibly be. On the other hand, insufficient light is a fruitful source of impaired eyesight. But insufficiency is of two kinds; either it may be inadequate in quantity or defective in quality. Young people are never discriminating in these respects, and sustained exertion of the eyes is often persevered in without suspicion of harm. Upon their elders devolves the obligation to guard against permanent injury to the most precious of all human possessions; and Dr. Oakley gives some very useful hints well worth attending to in these days of educational high pressure.

Of the growing prevalence of defective eyesight, especially of myopia, nobody, we imagine, will entertain any doubt. It is due partly, no doubt, to the artificial conditions of modern civilisation, among which we must reckon the turning of night into day one of the foremost. But as regards the rising generation, Dr. Oakley attributes its short sightedness to increasing pressure of schooling, to excessive use of the eyes for near objects, and to close application with strong mental effort in early life. On children already debilitated, who are badly nourished, and who are hereditarily predisposed to disease, the effect of schooling under the latest of our educational crazes is simply disastrous. Medical men are almost agreed on this point; and there is certainly no lack of evidence to go upon. The prevalence of spectacles on young noses in these days is a fact which cannot escape the notice of the most careless observer. We have no desire to press unduly the natural inference to be drawn. No doubt it is very generally what the doctors say it is; but some allowance must be made for the equally undoubted fact that a great number of children are now undergoing a course of education who formerly would have had no education at all. These scholars are mostly of the lowest orders, who are presumably most subject to the hereditary taint, but who, save for the legal compulsion to attend school, would have never discovered that they were short sighted—or, at all events, would have never betrayed it by the wearing of spectacles. They are probably made worse in this particular by learning to read and write; and the hereditary defect will be transmitted forward by them in an aggravated form. Whether we gain much by filling the brain and emptying the eyes is a question which is open to dispute; but there is no denying the fact that the general tendency is to create and perpetuate a blind race, who left to themselves might have preserved their eyesight, and under less artificial conditions might recover its full enjoyment.

As a nation we are better sighted than the French, and immeasurably superior to the Germans, though we cannot pretend to be the superiors of the latter in physique. The case

Digitized by Google

of Germany confirms the doctors' view. We hardly exaggerate when we say that too much learning has made the Germans blind. It is rather a distinction to wear spectacles—or, rather, a mark of inferiority not to wear them. But the practice is more common among the better classes than among the lower. The village youth becomes a "somebody" if he can anyhow make believe to need the assistance of a pair of *pince-nez*, which is a sign of learning as irrefragable as the goggles of an Oriental. Something, however, must be laid to the charge of a barbarous type when accounting for Teutonic myopia; and this is perhaps the reason why the educated classes—by which we mean the student classes—are more grievously afflicted than are the artisans and rustics. We are better off in this respect than our German neighbours, but their experience ought to be a warning to us against undue pressure of the very young at our Board Schools. Home lessons, Dr. OAKLEY states, are a fruitful cause of impaired eyesight; and the Germans are excessively exacting in home lessons. It will be long before the Electric Light will help the ordinary scholar with his books; but everything that tends to establish a higher standard of illumination will gradually improve the national health, and is calculated to preserve the people's eyesight.

CORRESPONDENCE.

THE TELEPHONE IN SMALL TOWNS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In last week's impression (page 400) it is mentioned that you cannot recall a single instance in this country of a town with a population of less than 10,000 being provided with a telephonic exchange. I am pleased, however, to be in a position to inform your readers that there are several such "exchanges."

My company has opened three (Ormskirk, Skelmersdale, and Huyton) in Lancashire, and several others in the little towns of North Wales.—Yours, &c.,

KENNETH MACIVER,
Secretary and General Manager.

Lancashire and Cheshire Telephone Company,
Manchester, 25th September, 1886.

EFFICIENCY TESTS OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reference to the note in your issue of Sept. 17 on the testing of dynamos, I wish to remark that a method of testing, *only by electrical measurements*, was already indicated by me in my letter of March 15, published in your issue of March 19, 1886.

I think my method is preferable in respect to accuracy and simplicity, as it does not depend on the assumption that the efficiency of a dynamo is the same as a motor or as a generator, which is certainly *not* "absolutely beyond suspicion of error."

In my method *two tests* are sufficient, no matter if identical or different size or type of dynamos are used, while in the manner as indicated by Mr. Trotter, in your issue of Sept. 24, *six tests* must be made.—Yours, &c., C. L. R. E. MENGES.

The Hague, Holland, September 27, 1886.

[We would point out that the method described by our correspondent in his letter of March 19th can scarcely be said to depend *only upon electrical measurements*, inasmuch as the efficiency of the motor must in this case be previously determined by means of a dynamometric brake. The formula contained in the letter of Mr. A. P. Trotter upon this subject, and which appeared in our last number, owing to a slip of the pen on the part of the writer, stands in need of correction. It should read

$$A = \sqrt{\frac{E_2 E_3}{E_1}}.$$

—ED. *E.*]

A NEW SCALE FOR TANGENT GALVANOMETERS.*

BY W. H. PREECE, F.R.S., AND H. R. KEMPE.

Tangent galvanometers are much used for the exact quantitative measurement of currents of considerable strength, such as are measured in amperes, but they are not so generally used for the measurement of smaller currents in milliamperes. This arises from a notion that they are not sensitive enough, although the most sensitive instrument in practice—Sir William Thomson's mirror galvanometer—is really a tangent instrument. The ordinary forms, Joule's, Gaugain's, or Helmholtz's, are not very sensitive. Their constant is about 3; that

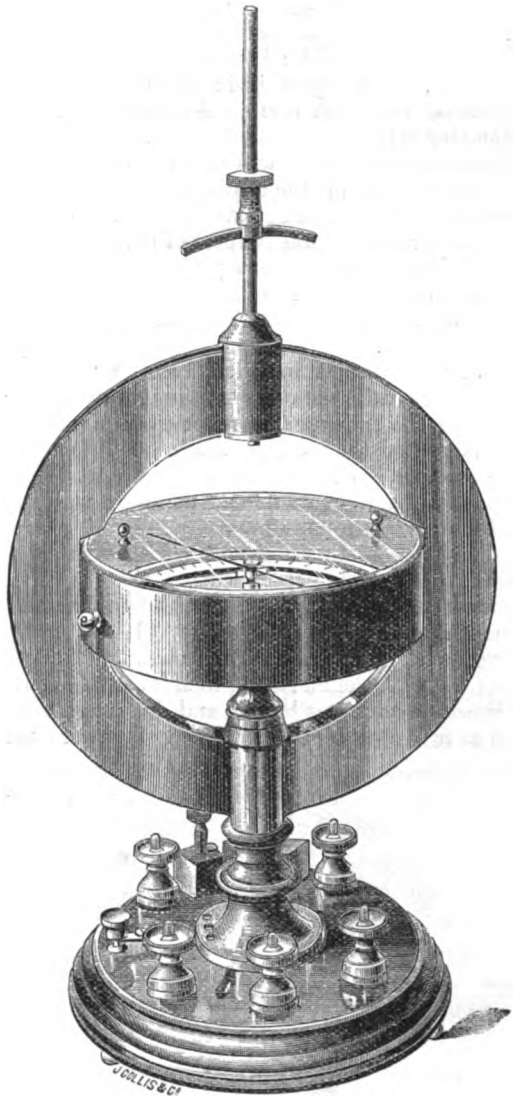

FIG. 1.

is, 3 amperes are required to produce the unit deflection of 45°. The Post Office has for many years used a more sensitive and portable form, having a constant of ·00214, for testing wires, batteries, and apparatus Fig. 1 shows in elevation the

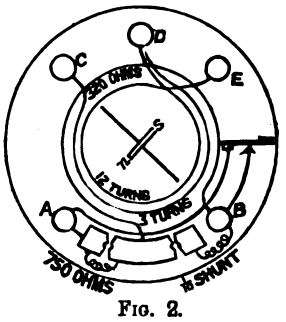

FIG. 2.

general form of the instrument; Fig. 2 is a general plan of the arrangement of the coils, &c.

* Paper read before the British Association at Birmingham.

Digitized by Google

The ring, which is 8in. in external diameter, has three coils of wire wound on it. The one nearest the needle is of No. 35 wire, and is wound to a resistance of 320 ohms approximately. The other two coils are of No. 18 gauge; the one between C and D making three turns, and the one between D and E making 12 turns in the opposite direction. The latter coils are for testing batteries; by using terminals C D, D E, or C E, respectively, relative degrees of sensitiveness of approximately 1, 3 and 4 can be obtained. An adjusting magnet, similar to that used on the ordinary Thomson mirror galvanometer, is set on the upper part of the ring, as shown. In testing the strength of a current in milliamperes by means of the instrument a standard Daniell cell is connected between terminals A and B; both plugs being removed from the plug holes, *a*, *b*, there is in circuit a total resistance of 1,070 ohms, viz., 750 + 320. As the electromotive force of the standard cell is 1·07 volt, the resulting deflection (30°) of the galvanometer needle will be due to a current of 1 milliampere. By means of the adjusting magnet this deflection can be increased or diminished as required. In practice, the adjustment is such that 1 milliampere of current gives a deflection of 80 divisions on the ordinary tangent scale. When the measurement of a current is to be made the plug in *a* is usually inserted so as to cut out the 750 ohms resistance. Plug *a* inserts a $\frac{1}{10}$th shunt.

Hitherto *two* scales have been engraved on the dial, the one divided in degrees and the other in tangent divisions; and to avoid parallax the indicator is reflected in a mirror, so that when the image and the indicator are in one line no error from this cause occurs. Where observations are made by reading deflections serious errors arise from parallax, especially where the law of tangents is followed.

Mr. Eden—one of the assistant electricians of the Post Office—discovered, while experimenting, that the galvanometer could be made more sensitive to increments of current for high deflections if it were given a false zero. In fact, if the instrument be "slewed" round so that the plane of the coil makes an angle of 60° with the meridian, then the instrument becomes twice as sensitive as it was before, and he suggested a double scale such as is shown in the following figure to utilise this

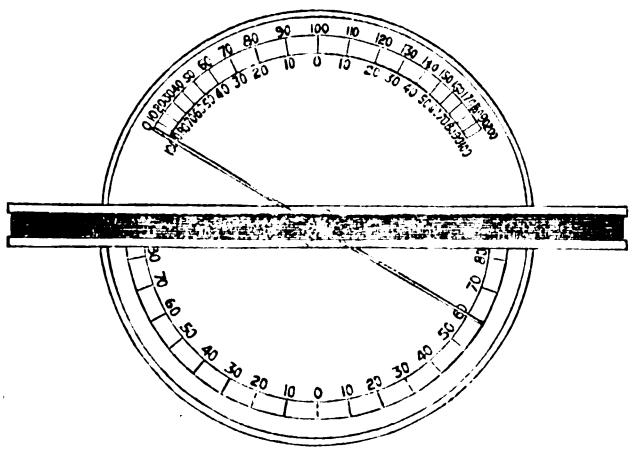

Fig. 3.

fact. This plan has been adopted, and all tangent galvanometers in the Post Office service will be gradually altered to the new scale.

It is quite clear that the instrument owes its increased sensitiveness to the fact that when the needle reaches its maximum deflection, its angle to the lines of force of the field is the one most favourable for the deflection of the needle by the current. In fact, the plane of the coils becomes parallel to the plane of the needle, which is then in the most *uniform* portion of the field

It becomes most desirable to know if the divisions of deflection under these conditions are still proportional to the current strengths.

Let the dotted line A, B, represent the plane of the coil ring, and let a_1, b_1, be the needle which has been deflected from the normal position, *a*, *b*, the angle which the needle normally makes with the coil being $\beta°$. Let $\alpha°$ be the angle to which the needle has been deflected to the other side of the coil, then

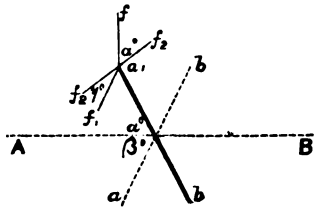

Fig. 4.

deflective force, *f*, of the coil resolved at right angles to the needle is

$$f_2 = f \cos \alpha° \, k$$

where *k* is a constant.

Also force f_1 of earth's magnetism, which acts parallel to *a*, *b*, resolved at right angles to the needle is

$$f_2 = f_1 \cos \gamma° \, k$$

therefore $$f \cos \alpha° = f_1 \cos \gamma°$$

or $$f = f_1 \frac{\cos \gamma°}{\cos \alpha°}$$

but $$\gamma° + 90° + \alpha° + \beta° = 180° \therefore \gamma° = 90 - (\alpha° + \beta°)$$

from which $$\sin \gamma° = \sin (\alpha° + \beta°)$$

therefore

$$f = f_1 \frac{\sin (\alpha° + \beta)}{\cos \alpha°} = f_1 \frac{\sin \alpha° \cos \beta° + \sin \beta° \cos \alpha°}{\cos \alpha°} \text{(A)}$$

$$= f (\tan \alpha° \cos \beta° + \sin \beta°) = f \cos \beta° \left\{ \tan \alpha° + \frac{\sin \beta°}{\cos \beta°} \right\}$$

$$= f \cos \beta° (\tan \alpha° + \tan \beta°)$$

so that cos β being a constant quantity the strength of a current is directly proportional to $(\tan \alpha° + \tan \beta°)$, which is the reading on the tangent scale if the figures on the latter are rearranged so that the zero is at the division at which the needle points in its normal position.

By thus changing the zero of the instrument the range of movement can be considerably increased; thus if $\beta°$ be the angle which the needle normally makes with the coil, and if $\alpha°$ be the angle to which the needle has been deflected on the other side of the coil, then *f* being the deflective force, we have

$$f = f_1 \frac{\sin (\alpha° + \beta°)}{\cos \alpha°},$$

when f_1 is a constant. But if the needle were parallel to the coils, then

$$f = f_1 \tan \alpha_1$$

therefore $$f_1 \frac{\sin (\alpha° + \beta°)}{\cos \alpha°} = f_1 \tan \alpha°_1$$

Now if we have $\beta° = 60°$, and if the current be sufficient to turn the needle through 2 $\beta°$ or 120°—that is, if we have $\alpha° = 60°$, then

$$\frac{\sin 120°}{\cos 60°} = \tan \alpha°_1$$

but $\sin 120° = \sin (180° - 60°) = \sin 60°$; therefore,

$$\frac{\sin 60°}{\cos 60°} = \tan \alpha°_1 = \frac{\sin \alpha°_1}{\cos \alpha°_1}$$

or, $$\alpha_1 = 60°$$

that is to say, the angle through which the needle would have been turned when the zero was 60° to one side of zero would be twice what it would be if it had been deflected from the ordinary zero. The ratio of these angles, however, decreases in value, and at a certain point becomes equal to 1; that is to say, the angular deflection from the new zero is the same as it is from the old zero.

Let $$\frac{\sin (\alpha° + \beta°)}{\cos \alpha°} = \tan \alpha°$$

therefore $$\frac{\sin (\alpha° + \beta°)}{\cos \alpha°} = \frac{\sin \alpha°}{\cos \alpha°},$$

or $$\sin (\alpha° + \beta°) = \sin \alpha°.$$

Digitized by Google

If the angle α° is negative—that is to say, if the angular deflection from the new zero is less than the angle β°—then we have

$$\sin(\beta^\circ - \alpha^\circ) = \sin \alpha^\circ,$$

or

$$\beta - \alpha^\circ = \alpha^\circ;$$

that is

$$\beta^\circ = 2\alpha^\circ,$$

or

$$\alpha^\circ = \frac{\beta^\circ}{2};$$

that is to say, whatever be the angle β° (the angular distance of the new from the old zero), then a current sufficient to move the needle a distance of $\frac{\beta^\circ}{2}$ from the old zero would move the needle the same distance from the new zero. *If the deflection from the old zero be less than* $\frac{\beta^\circ}{2}$, *then the deflection from the new zero will be less still*, so that there is no advantage in the use of the new zero unless the deflections exceed $\frac{\beta^\circ}{2}$.

If the angle β° be made greater than 60°, then the possible angular movement of the needle becomes still further increased; but inasmuch as any increase in the length of the tangent scale brings the division at the ends of the scale proportionally closer together and more difficult to read from, there would be no practical advantage in making the angle larger. A marked advantage, under certain conditions, is found when the new zero, has such a value that the deflection from a given current causes the needle to turn up to the ordinary zero—that is to say, to the position where the needle becomes parallel to the coil; in this case the instrument becomes highly sensitive, and any increase in the strength of the current produces a very considerable change in the deflection.

Thus, supposing the new zero to be, as before, 60°, then if after the needle had been deflected to the old zero the current which had caused this deflection had increased 10 per cent., then the deflection, α°, beyond the ordinary zero would be such that

$$\tan \alpha^\circ + \tan 60^\circ = \tan 60^\circ \times \frac{110}{100},$$

or

$$\tan \alpha^\circ = \tan 60^\circ \left(\frac{110}{100} - 1\right) = 1{\cdot}7320508 \times \frac{10}{100}$$

$$= {\cdot}17320508 = \tan 9^\circ 50'.$$

If, however, the deflection had been from the old zero in the first instance, then this deflection γ° would have been such that

$$\frac{\sin(0^\circ + 60^\circ)}{\cos 0^\circ} = \tan \gamma^\circ,$$

or

$$\sin 60^\circ = \tan \gamma^\circ;$$

therefore

$${\cdot}8660254 = \tan \gamma^\circ{}_1$$

or

$$\gamma^\circ = 40^\circ 54'.$$

If the current under these conditions were increased 10 per cent., then the increased deflection, γ°, would be such that

$$\tan \gamma^\circ{}_1 = {\cdot}8660254 \times \frac{110}{100} = {\cdot}95262794 = \tan 43^\circ 37',$$

which is an increase of

$$43^\circ 37' - 40^\circ 54' = 2^\circ 33'$$

as against 9° 50′ when the deflection was taken from the new zero, an increased sensitiveness of over 4 : 1 in favour of the new zero.

If the angle β had been 85°, then an increase of 10 per cent. would move the needle as much as 48° 45′ beyond the ordinary zero. It might then seem that the greater β° is made the better; but there is a practical limit to this increase, for the larger we make β the more does the deflective action of the coil tend to act in a direction parallel but opposite to the earth's magnetism, the consequence being that the resultant of the two forces is a comparatively small quantity, and the friction of the pivot, &c., prevents the needle from settling down to the true angle representing the force of the current. Under such conditions very large errors in the readings may result. Were it not for this fact the instrument would increase in actual sensitiveness up to that point at which $\beta' = 90^\circ$, at which point the needle would not move unless acted upon by a current exceeding in deflective force the intensity of the earth's magnetism; when the current exceeded this value the needle would swing completely round through an angle of 180°.

A NEW FORM OF STANDARD SINE GALVANOMETER.*

BY J. T. BOTTOMLEY.

Mr. Gray proposes to use a coil of uniform wire laid into the thread of a screw cut with all possible accuracy on the surface of a cylinder. The absolute force at the centre of such a coil is calculated by a well known formula. In the centre of the tube is hung a short magnetic needle with mirror attached. A short scale or mark at one end of the tube is received by means of a telescope at the other end of the tube, and the whole tube is turned round on a central transverse axis till maximum deflection of the magnet is obtained and the instrument is used as a sine galvanometer.

ABSTRACT OF THE REPORT OF THE COMMITTEE ON ELECTRICAL STANDARDS.*

Eighteen stantard coils have been tested during the year and certificates of their value issued. The attention of the secretary was called to the fact that the paraffin in some of the coils showed a trace of green colouration round the edges. This has been shown to arise from the action from a small amount of acid left in the paraffin on the copper of the case and connecting rods, and the committee are considering how to deal with the difficulty. At the present the insulation resistance of the coils is extremely high, amounting to as much as 8,000 megohms. The committee wish to express their sense of the great desirability of establishing a national standardising laboratory for educational instruments on a permanent basis, and their readiness to co-operate in their endeavour to secure the same. The committee apply for reappointment, and for a grant of £50.

UNDERGROUND TELEPHONIC CABLES IN THE STATES.

At the recent Telephone Convention at St. Louis Mr. C. N. Fay read a long paper on this subject, and quoted statistics which had been furnished him by various companies in different parts of the country. The information obtained related to induction, insulation, capacity and resistance of the underground cables, and, though sometimes interesting, was, as a rule, far too fragmentary, uncertain, and conflicting to furnish any really valuable data. In general, it appears that upon short lengths and with high insulation resistance the experience of underground conductors has been fairly satisfactory, especially in those cases where some form of anti-inductive shield has been employed. In one form of cable so furnished it is stated that, although the insulation resistance is no more than 0·2 megohm per mile, yet absolutely no "cross-talk" is perceptible. The general tendency, however, in America—and one which is undoubtedly wisely directed—is towards the employment of heavier lines and higher insulation. The following passages detailing the experience of the author himself are sufficiently important to be reproduced at length. For experimental purposes Mr. Fay was able to connect together several lines which gave him a circuit "consisting of nearly three miles in cables, of which about a mile was the Waring cable underground, another mile Patterson cable overhead, and another mile Patterson cable underground. Testing these conductors by themselves last January, without connection with aërial wires at either end, we found but litle cross-talk in the new underground work, but a great deal in the old aërial cables. This fall, testing again, we find considerable cross-talk in all of those cables; we find that the insulation runs down rapidly, and is very difficult to keep up; that

* Paper read before the British Association at Birmingham.

Digitized by Google

most of this failure is in the terminals; that as the insulation runs down the cross-talk increases; that in comparison with the old overhead systems the cross-talk is probably two or three times as great. As regards insulation the cable portion of our wires is much more highly insulated than the old aërial wires, especially as we used to run them upon porcelain knobs. We find that the paraffin cables absorb moisture at the terminals, and that it is very difficult to keep up the insulation on that account. It is true, however, that insulation of three or four hundred megohms, such as we have had at the beginning on most of our cables, might be called 'too fancy' for practical use. We are attempting to keep up an insulation on our cable work that we do not follow out throughout the switch-board, office wires, &c.

"The general result of our cable work is unsatisfactory by reason of cross-talk and indistinctness of transmission. We have spent a great deal of time and money measuring up lines, cutting out bad points and rebuilding and putting everything in shape. One of our best inspectors thinks that the indistinctness of transmission is due very largely to poor contacts in the switch-board, caused either by iron plugs which rust, or by phosphor-bronze on other contact points, which tarnish. This theory has been broached but lately, and we are now at work upon it; but I fear that the increasing use of cables is destroying the satisfactory character of telephone transmission. We expect this year to put down two miles and a half of Brooks oil cable throughout the central district, connecting our whole system together. When this is completed, a few months' use will show whether my fears are well founded; but I have serious doubts whether we can, after this year, continue further our underground extensions.

"An interesting fact is that the Brooklyn cable, a mile long, fifty wires, No. 16 gauge, shows no cross-talk. The insulation of this cable is but 27 megohms, but its resistance is also very low, 13 ohms to the mile."

Following this a paper was read by Mr. Sargent on the underground work in Brooklyn. We gave some account of the Brooklyn experiments not long since. Our readers will, perhaps, remember that creosoted wood has been adopted for the conduits, and that no attempt is made to render them watertight. This arrangement continues to give satisfaction, and the first half-mile has now been in use for nearly two years. The lead casing of the cables is, however, in many cases excessively corroded, but the valuable though accidental observation of the fact that a small admixture of tin with the lead effectually prevents the corrosive action seems now to be fully established.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION OF THE UNITED STATES.

(Continued from page 414.)

The discussion which followed the reading of the paper on electro-motors (which we reproduced last week) can scarcely be said to have elucidated any points of real interest, whether of a technical or a practical character. Most of the speakers testified to the great interest which is being taken in the subject both by the electric lighting companies and by the public at large. Little or nothing was said as to self-regulation or as to the efficiency of the various types in use. Some conversation took place upon the subject of "whether arc light or incandescent light circuits are most suitable for running motors." One gentleman, who seemed to have some experience with motors run on arc circuits, or, as we should say, series-wound, wanted to know whether he could not make use of the same machines on an incandescent circuit. Up to the present time the series-wound motor has received by far the greatest amount of attention. This was to be expected, not only because arc light circuits are far more numerous in the States than circuits of constant E.M.F., but also because the problem of the series-wound motor is by far the more simple of the two. Mr. Baxter explained at some length, but in very simple language, the difficulties which would arise if a motor running in multiple arc received the full E.M.F. of the circuit while the armature remained at rest. Several members mentioned that they were using shunt-wound motors with success, but in no case did they give any further details of importance.

The following paper on wiring buildings led to a discussion of greater practical value:—

Some Features of Incandescent Lighting and Wiring.

BY MR. T. C. MARTIN.

In bringing to your attention a few remarks on incandescent lighting and wiring, it will be of interest to note that at the first meeting of the Association the first subject on the programme was "incandescent lighting." It seems to me wise that the subject should have been given such prominence. The arc light is to many of us a main object of concern, as it is a main source of income; but, after all, as Dr. Otto A. Moses pointed out so forcibly at our New York meeting last September, the arc lighting field, when wholly covered, is but 5 per cent. of the possible area over which electric current can be utilised for illuminating purposes, in cities and towns, to replace gas, oil, and candles. We are told by some that even in its own special and peculiar sphere of occupation—that of street lighting—the arc lamp is to give way before large incandescent lamps disposed, as are the gas jets, on short, ordinary posts. That may be, though I hardly expect to witness a complete change yet awhile. I know of few more cheerful or beautiful sights than the tower, like a "radiant sister of the day," as Shelley phrased it, holding aloft through storm and calm its torch of living fire; or the long lines of steadfast white stars that now begirdle and illumine nightly the finest thoroughfares of our most progressive cities. Those lights have come to stay, little as the Hickenloopers may be willing to admit it.

Meantime, the incandescent light is rapidly gaining ground, leaving its more robust brother outside, for the present, as a most unquestionable cock of the sidewalk. At the Baltimore meeting last February, Mr. De Camp summed up the situation in regard to indoor lighting in half a dozen highly significant words. He said: "The incandescent light is popular. It is growing in popularity. It is most popular among the business people." That being the case, there has been a general desire on the part of arc lighting companies to meet the demand that comes to them for both forms of the light. To the public, the electric light still means either arc or incandescent, indifferently, to be ordered at the same station, just as one would order butter and cheese at the same store counter. One effort to meet the new requirement has been made in the supply of incandescent lights on arc circuits, run from distributing boxes; and while that method is characterised by many practical men as a craze, and by others is regarded as still in the stages of experiment more or less advanced, it has the recommendation of filling a gap. Some companies are trying the system with success, while others, with deeper purses or fortified by the courage of their convictions, have put in already separate plant for incandescent lighting, and are running independent circuits for it. At the beginning of the present year, about sixty arc companies were operating incandescent lights as a regular and large part of their business, and from what I can learn, the number has doubled since then. Altogether, the late remarkable development of the incandescent field is, I venture to say, well worthy the consideration of the Association in its assemblage to-day. The chief elements of operation are now well ascertained and determined. We have dynamos of high efficiency giving us currents of constant potential, we have lamps steadily gaining in life and candle-power, and through the meetings of the Association we are quickly learning the best methods of station equipment and management. But, so far, little has been said in public or in print about wiring, in connection with which many important "details of refinement" have still to be settled. My own interest in the matter has been aroused by an inspection of some of the work done in New York, especially that of Mr. Augustus Noll, of the firm of Noll Brothers, who have put in probably more than 50,000 lights for the Edison Company, the confidence of which they deservedly enjoy. From the fact that the Edison Company has lately abolished its wiring department and turned over the work to this firm, I cannot but infer that the methods adopted have been such as to reflect great credit on the Edison system wherever thus installed. A glance at those methods, then, will perhaps be beneficial and suggestive.

Mr. Noll is an enthusiastic advocate of the "distribution" system in wiring as compared with the "circulation" system, and I am free to own that the little study I have been able to give the subject almost persuades me, too, to be a "distributionist." A definition of the two systems, or rather a statement as to their differences, may be attempted here. "Circulation," regarded broadly, consists, for instance, in a large building, in running the main wire clear through from the dynamo to the last floor, and at each floor taking off a feeder by which in turn the lamps there are supplied. Now, according to Mr. Noll, a system of this nature is very difficult to manipulate. You have naturally a large loss between the first lamp and the last, and the only way to get equal candle-power on each floor is to put in lamps of lower voltage the further they are removed. But the lower the voltage of the lamps, the less economical does the system become; the heat units on the line are increased, warming up the conductors undesirably, and as some of the lamps nearest the machine will be run above their candle-power, there will be abnormal breakage. Moreover, if the building have great depth, the lamp furthest from the main on the same floors will show a drop in candle-power as compared with the lamp on that floor nearest the main. Besides, in testing for grounds and leakages, much cutting and time are required to locate the trouble, especially where, as I have known to be the case in some large installations, as many as fifty or sixty lights have been placed under the control of a single switch.

Digitized by Google

Turning to the "distribution" system, as recommended so enthusiastically and employed so skilfully by Mr. Noll, it would appear that a plant, no matter how large, can be wired in such wise that the loss or drop between the top floor and the basement will be as inconsiderable as only one or two volts. The idea is to wire to centres, or distributing points midway in the installation, thus equalising the pressure on all parts of the conductors, and making it possible to use the same volt lamp in the plebeian dive, the luxurious parlour, and the journalistic garret on the the seventh floor. The wires are so arranged, too, that any portion of the system may be individually disconnected and tested, and hence the cutting of wires and damage of floors and ceilings can be avoided or minimised where the wires are concealed from sight. When the building is very large, it is advisable to run two or more main feeders, as by using only one the distance from the distributing centre will be great enough to increase the drop on the line. For other reasons, too, it is always preferable to have more than one main feeder. Should any mishap occur with dynamo or engine, you can throw off one section of the building or throw in another dynamo, or where both machines supply together, leave one with the lightened load. A further advantage of frequent distributing points is, that all safety devices, such as cut-outs, switches, &c., are located on each floor in one known place or more, easy of access to those in charge; whereas in ordinary "circulation" they are placed in all parts of the building indiscriminately. To give two examples of Mr. Noll's methods: I found that in the new Astor Building, in Wall-street, a structure of great depth, he has three main circuits on each floor, with the switches and safety catches in groups of five in definite locations within the hallway panelling. Hence he could test our trouble down to any group of five, and then go without the least delay to the box revealing the actual fault. In the Central Park Plaza Hotel, where more than 3,000 lights are being installed, Mr. Noll has five main feeders connecting with five switches and boxes on each floor. The boxes are placed in the hallways just at the top of the wainscoting, and, while in nobody's way, can be got at immediately. It is evident that by locating all the control devices in lock boxes in the hallways, in hotels or apartment houses, you do not inconvenience any occupant of a room. If trouble arises, you go direct to the box concerned and test from that point. The matter of covering up wires is another point on which the Association might well utter an official opinion. In the new buildings on which he is at work, Mr. Noll has all his wires out of sight, in the walls, under the plaster and the woodwork. The effect is admirable. Yet it was but the other day that the president of a parent company in the incandescent field expressed to me his decided preference for wires in sight, that being in accord with modern architectural and engineering practice as far as he was acquainted with it. He liked mouldings; while another active worker in incandescent lighting told me not long ago that the sight of a moulding on a wall for wires was abhorrent to his ideas of beauty and seemliness. Perhaps uniformity in this respect will not be reached until, as will soon be the case, all buildings are wired from the start. Then they will be, I think, in the walls and under the floors, as are the gas pipes to-day. There are some places, however, where wires are necessarily strung in full view, such as breweries, dye-houses, stables, and like establishments, in which the air is very damp or is laden with acid vapors. I notice that Mr. Noll makes a practice in such cases of using good insulated wire suspended as much as possible, using a minimum quantity of insulators or fastenings. This should be, as perhaps it has already become, a generally adopted method.

And now, fittingly, one or two words as to the underwriters' rules and regulations. In New York it is required that wires should have 2½in. space between them, or not less than half-an-inch of some solid non-conductor, such as dry wood. When the work is finished, the company or contractor notifies the board, and an inspection is made. Now the work may be seemingly good, but should that dry wood become wet, a not unlikely contingency, any defect or shortcoming in the work would soon manifest itself unpleasantly. Again, in a new building, where wires are laid under the floors or imbedded in plaster, the contractor can in reality use any material he pleases and run the wires as his fancy or convenience dictates, for when the inspection occurs, after the work is finished, the underwriters' man has to depend rather on the evidence of his ears than of his eyes. The wires being concealed, the inspector can only know of their position and condition by some intuitive process. To step in at so late a stage is rather superfluous.

Moreover, there is a want of uniformity in system. In New York the underwriters depend for safety on the distance apart of the conductors, while in Chicago, I am informed, they depend chiefly on testing the resistance of insulation, which, not unlike the little girl of history, may be "very, very good" at one time, but decidedly "bad" and "horrid" at another. In New England, as I understand, samples of wire are given to lighting companies and wiring contractors, accompanied by rules as to which should be used and as to the nature of the workmanship. In that section more has been done, I believe, than anywhere else to secure good, honest work. Still, in a comparatively new industry there will be frequent opportunities of evasion. It is suggested by Mr. Noll, in reply to my queries on this point, that in all large cities and manufacturing centres an intelligent, trustworthy inspector be appointed, having the necessary qualifications to judge of proper mechanical and electrical construction. Then, when a building is to be wired, notification of the fact should be sent in, with samples of the wires to be used. At the time fixed for starting, the inspector should be in attendance to look over the building and offer suggestions, and from that time the work should have his supervision so that he can satisfy himself as to the standard quality of material and work. On completion, the inspector could at once issue his permit. I am not greatly in favour of inquisitorial methods of keeping mankind straight, but it is not impossible that a plan of this character would do much to raise the quality of the work, secure satisfactory operation of plant, and give greater stability to the whole business. Or, as an alternative, the step might be taken under the auspices of this association, of examining and certifying or licensing those who do the actual wiring. This is the practice with steam engineers and plumbers, yielding excellent results, and it might go far toward securing the users of electric light against inferior and dangerous work. Nothing is good enough until it is as good as it can be.

In the course of the discussion which followed, Mr. CHENEY said that his company had not found much advantage in running incandescent lamps on arc circuits. He thought it to be a dangerous practice to run wires under floors, &c., and made a strong plea for the use of mouldings.

Mr. RIDLON said that it was thought by their insurance people that an air space with the wires in sight was far better and safer than any moulding whatever. If they were to have a moulding they should have one that was fire-proof and proof against dampness between the moulding and the wall.

Mr. RHODES said that at Niagara Falls they were using water power, and had a good many Swan lamps running very satisfactorily from their Brush arc circuits. These incandescent lights were used in connection with a Brush box, both 38 and 92 volts. Some of them were located several miles away from the station, some of them over in Canada. They crossed the river twice with their wires, but not under water. "We do not use barrels for the protection of our wires either, but they cross on one bridge and come back on the other. One of our circuits is 12 miles long. We find no difficulty whatever in using these lamps at that distance from the dynamo. But I have come to learn more about wiring. Our wiring has been done by men who have grown up in the business with us, and the only lessons they have had have been lessons of experience." In reply to questions, Mr. Rhodes continued:—"We are running in the usual way, seven 38 or sixteen 92 volt lamps from these distributing boxes. I am sorry to say we have not had any way yet of keeping a record of the life of the lamps thus run in hours. We run our lamps either for all-night business or for half-night business, and those who run for part of the night are permitted to burn their lamps until 10 o'clock in some cases; those lamps burn all the way up till 10, 11, 12, and 1 o'clock. With a number of boxes, I suppose the average burning will be from one hour before sunset until 10 or 11 o'clock at night. We keep account of our breakage, not by hours but by the month. We find that for the last three months our breakage has been three lamps per month to each set of seven. For some reason or other not quite clear to us, the breakage is becoming less and less. Whether the manufacturers are making the lamps better, or whether we are learning to run the dynamo more steadily, and to keep our current more regular, I am not prepared to say; but certainly we are gaining in that respect. Thus the breakage will now be about two per month to each set of seven, which would be twenty-four in a year. Any one can figure out the expense of that, and will find that it is not a remarkably serious item of expense, as this is practically almost the entire expense of running. How this would be varied by running by steam I am not prepared to say, but I believe that as we run by water-power our current is much more regular than it can be made by the best steam engines; and, I believe, that in that respect we have an advantage over steam engines. Another point is, our expense is so very little on other items that we consider this breakage to be our principal item of expense. Our entire cost for horse-power is $15 per horse-power per year, including the rent of the building and the installation of the wheel. We do not own the wheel, but rent power. As the power required for seven 38-volt lamps is considerably less than a horse-power, the power expense is very small indeed. The expense also of the men who take care of these lamps is very small indeed, because it is delegated to the lamp trimmers and occupies very little of their time. The success with us is so great that it is at least satisfactory. The lights are satisfactory to our customers, and the prices are as satisfactory to us as to them." The 16 candle-power lights easily take the place of a 5ft. gas burner. They are run on the same circuit as the arc lamps; but we have been advised that if we put our entire number of incandescent lamps in groups, on a circuit by themselves, the breakage will be still less. But we cannot do that without doubly covering our entire district, and we prefer to continue doing as we are, with a single system of wiring covering our entire territory, sandwiching in among our arcs the incandescents, just as they happen to come.

Mr. DE CAMP inquired as to price compared with that obtained for the arc lamp displaced by the group.

Mr. RHODES: We charge in all cases $1 per month for each incandescent lamp. We get $7 for each set of seven. Where we put in the sixteen we make $1 reduction, leaving the charge $15 for the sixteen lamps, a slight inducement to the customer to take the additional number. We add 50 per cent. to that for lamps that burn all night. For arc lights we receive $8 per month single lamps, and $10 double lamps. In some cases we find that we have been obliged to substitute the incandescent lamps for the arc, whether we wanted to do it or not, and I believe that has been found to be the experience of others, as already stated. There is a call for incandescent lamps, no matter how well the arcs burn—and ours burn as well as anybody's. Nearly all the customers who occupy small stores, as is the case in small towns, and to a great extent in large towns, prefer the incandescent lamps to the best possible arc lamp in existence. We find that there is a call for these incandescent lamps from those who have been using arc lamps. We find that there is not a very great difference between the profit of one and the other, and we try to balance one against the other at those prices which I have named. We are very much pleased to substitute the incandescent lamps for the arc. We try to fix our prices so that it will be as satisfactory to ourselves in one case as in the other, and then we let the customer make his own selection.

(To be continued.)

PHOSPHOR-BRONZE *VERSUS* IRON WIRE.

At a recent meeting of the Société Belge des Electriciens, M. Bède, having enumerated the well-known advantages of phosphor-bronze for telegraphic and telephonic purposes, inquired why it was that the material had not been more widely employed in Belgium, especially in view of the fact of the introduction of the Van Rysselberghe system, for which a non-magnetic line was very desirable. In replying to these questions at a subsequent meeting, M. Banneux stated that the question of employing either bronze or copper wires for telegraphic purposes occupied the attention of the Belgian Government as long ago as the summer of 1883. In the course of this and the following year 440 kilometres of bronze and 150 kilometres of hard drawn copper were erected. The advantages of these wires when working with currents of brief duration and the increased conductibility and high tensile strength were fully recognised, but the question came to be one of cost. In the first place, the lifetime of an iron wire 4mm. diameter is known to extend over an average period of at least 25 years; but the life-time of the non-magnetic wires is still an unknown quantity. While this is the case it is impossible to arrive at any definite conclusion as to the relative cost of the two materials. At the same time the cost of a phosphor-bronze wire of 1·4mm. is 50 per cent. higher than that of an iron wire of 4mm., which represents the same conductivity. A phosphor-bronze wire of the most recent manufacture will have a conductivity equal to 33 per cent. of that of pure copper, with a tenacity of about 48 tons per square inch. Whenever it becomes a question of erecting an entirely new line of posts, whether for telegraphic or for telephonic purposes, there can be no hesitation in adopting either bronze or copper wires, for then the additional cost of the lines is fully balanced by the diminution in the number of posts required, and the saving not only of material but in the cost of transport and of labour. In the meantime, taking into consideration the difference in the cost, the superiority of the bronze wire was not of so overwhelming a character as to justify the entire replacement of the iron wires at present in use. It may be added that hard drawn copper wire is now obtainable having a tensile strength of 19 tons to the square inch, and owing to the great depreciation in the value of this metal its price compares favourably with iron wire of the same conductivity. The specific resistance is usually about 96 per cent. of that of pure copper.

CHEMISTRY AS A SCIENCE.

(Continued from page 416.)

But if the evidence in favour of Prout's hypothesis in its original guise is deemed insufficient, may not Mr. Clarke's suggestion of half multiples place it upon an entirely new basis? Suppose that the unit of the scale, the body whose atomic weight, if multiplied by a series of whole numbers, gives the atomic weights of the remaining elements, is not hydrogen, but some element of still lower atomic weight? We are here at once reminded of helium—an element purely hypothetical as far as our earth is concerned, but supposed by many authorities, on the faith of spectroscopic observations, to exist in the sun and in other stellar bodies. Most solar eruptions present merely the characteristic lines of hydrogen, C, F, and H, and along with them one particular line which at first was classed in the sodium group, but which is a little more refrangible, and is designated by the symbol D_3. According to Mr. Norman Lockyer and the late Father Secchi, this ray undergoes modifications not comparable to those affecting other rays of the chromosphere. In the corresponding region of the spectrum no dark ray has been observed. That the accompanying lines, C, F, and H, pertain to hydrogen is evident; and as D_3 has never been obtained in any other spectrum, it is supposed to belong to a body foreign to our Earth, though existing in abundance in the chromosphere of the sun. To this hypothetical body the name helium is assigned.

In an able memoir on this subject, read before the Academy of Brussels, the Abbé E. Spée shows that, if helium exists, it enjoys two very remarkable properties. Its spectrum consists of a single ray, and its vapour possesses no absorbent power. The simple single ray, though I believe unexampled, is by no means an impossible phenomenon, and indicates a remarkable simplicity of molecular constitution. The non-absorbent property of its vapour seems to be a serious objection to a general physical law. Professor Tyndall has demonstrated that the absorptive power increases with the complexity of molecular structure, and hence he draws the conclusion that the simpler the molecule the feebler the absorption. This conclusion the Abbé Spée regards as perfectly legitimate; but it neither explains nor even necessitates the absence of *all* absorptive power.

Granting that helium exists, all analogy points to its atomic weight being below that of hydrogen. Here, then, we may have the very element, with atomic weight half that of hydrogen, required by Mr. Clarke as the basis of Prout's law.

But a more important piece of evidence for the compound nature of the chemical elements has yet to be considered. Many chemists must have been struck with certain peculiarities in the occurrence of the elements in the Earth's crust; it is a stale remark that we do not find them evenly distributed throughout the globe. Nor are they associated in accordance with their specific gravities; the lighter elements placed on or near the surface, and the heavier ones following serially deeper and deeper. Neither can we trace any distinct relation between local climate and mineral distribution. And by no means can we say that elements are always or chiefly associated in nature in the order of their so-called chemical affinities; those which have a strong tendency to form with each other definite chemical combinations being found together, whilst those which have little or no such tendency exist apart. We certainly find calcium as carbonate and sulphate, sodium as chloride, silver and lead as sulphides; but why do we find certain groups of elements with little affinity for each other yet existing in juxtaposition or commixture? The members of some of these groups are far from plentiful, not generally or widely diffused, and certainly they are not easy to separate.

As instances of such grouping we may mention—

1. Nickel and cobalt, of which it may be said that had their compounds been colourless they would have been long regarded as identical, and possibly even yet would not have been separated.

2. The two groups of platinum metals.

3. The so-called "rare earths," occurring in gadolinite, samarskite, &c., and evidently becoming more numerous the more closely they are examined.

Certain questions here suggest themselves:—Is the series of these elements like a staircase or like an inclined plane? Will they the more closely they are scrutinised, be found to fade away the more gradually the one into the other? Further, will a mixture hitherto held to be simple, like (*e.g.*) didymium, be capable of being split up in one direction only, or in several? I have been led to ask this last question because I have separated from didymium bodies which seem to agree neither with the praseodymium and neodymium of Dr. Auer von Welsbach, nor with the components detected by M. de Boisbaudran and M. Demarçay.

Why, then, are these respective elements so closely associated? What agency has brought them together?

An eminent physicist evades the difficulty by suggesting that their joint occurrence is simply an instance of the working of the familiar principle "Birds of a feather flock together." In their chemical and physical attributes these rare earths are so closely similar that they may be regarded as substantially identical in all the circumstances of solution and precipitation to which they may have been exposed during geological ages.

But do we, in point of fact, recognise any such agency at work in nature? Is there any power which regularly and systematically sorts out the different kinds of matter from promiscuous heaps, conveying like to like and separating unlike from unlike? I must confess that I fail to trace any such distributive agency, nor, indeed, do I feel able to form any distinct conception of its nature.

I must here remark that coral worms in some cases do effect a separation of certain kinds of matter. Thus a *Gorgonia* of the species *Melithœa*, and *Mussa sinuosa*, undoubtedly eliminate from sea-water not merely lime, but even yttria; and other recent corals, *Pocillopora damicornis*, and a *Symphyllia* close to the yttria-secreting *Mussa*, separate samaria from sea-water. Sea-weeds and aquatic mollusks contain a larger proportion of iodine and bromine than the waters which they inhabit, and may thus be said to separate out these elements from the chlorine with which they are mingled.

But if we examine these cases of elimination we see that they are limited in their scope. They extend only to substances existing in solution, of which there is a fresh supply always at hand, and which are capable of entering into the animal or vegetable economy. Again, the elimination of iodine and bromine, effected as just described, is of a very imperfect character, and when such water plants and animals die and decay, their constituents will be again distributed in the water.

We cannot well consider that nickel and cobalt have been deposited in admixture by organic agency, nor yet the groups iridium, osmium, and platinum—ruthenium, rhodium, and palladium.

Since the earthy metals to which I have referred—such as yttrium, samarium, holmium, erbium, thulium, ytterbium, &c.—are very rare, the probability of their ever having been brought together in some few uncommon minerals discovered only in a few localities must be regarded as trifling indeed, if we suppose that these metals had at any time been widely diffused in a state of great dilution with other matter. The features which we have just recognised in these earths seem to point to their formation severally from some common material placed in conditions in each case nearly identical. The case is strengthened by a consideration of the other groups of elements, also similar in properties, having little affinity for each other and occurring in admixture; either all or at least some of the elements concerned being, moreover, decidedly rare. Thus, we have nickel and cobalt not plentiful or widely distributed; cobalt, perhaps, never found absolutely free from nickel, and *vice versâ*. We have also the two platinum groups, where very similar features prevail.

A weighty argument in favour of the compound nature of the elements is that drawn from a consideration of the compound radicals, or, as they might be called, pseudo elements. Their similarity with the accepted elements is perfectly familiar to all chemists. If, for example, we suppose that in some age or in some country men of science were cognisant of the existence and of the behaviour of cyanogen, but had not succeeded in resolving it into its constituents, nothing, surely, would prevent their

Digitized by Google

viewing it as an element, and assigning it a place with the halogens. It may fairly be held that if a body which we know to be compound can be found playing the part of an element, this fact lends a certain plausibility to the supposition that the elements also are not absolutely simple. This line of thought, or at least one closely approximating to it, was worked out by Dr. Carnelley in a paper read before this Association at its last meeting. From a comparison of the physical properties of inorganic with those of organic compounds, Dr. Carnelley concludes that "*the elements, as a whole, are analogous to the hydrocarbon radicles.*" This conclusion, if true, he adds, should lead to the further inference that the so-called elements are not truly elementary, being made up of at least two absolute elements, named provisionally A and B. Hence, he argues, it should be possible to build up a series of compounds of these two primary elements which would correspond to what we now call elements. Such an arrangement, to be admissible, would have to fulfil certain conditions:—The secondary elements thus generated from A and B must exhibit the phenomena of periodicity, and the series would have to form octaves; the entire system is bound to display some feature corresponding to the "odd and even series" of Mendeleeff's classification; the atomic weights must increase across the system from the first to the seventh group: that is, from the positive to the negative end of each series; the atomicity would have to increase from the first to the middle group, and then either increase or decrease to the seventh group; some feature should appear corresponding to the eighth group; and, lastly, the atomic weights in such a system ought to agree with the atomic weights as experimentally determined.

This last condition Dr. Carnelley rightly regards as the most crucial, and he finds his arrangement gives atomic weights which in a majority of instances coincide approximately with the actual atomic weights. Thus out of a total of sixty-one elements whose atomic weights have been determined with at least approximate accuracy, and whose places in the periodic system are not disputed, twenty-seven agree almost exactly with the actual numbers, whilst 19 others are not more than one unit astray.

For a detailed consideration of the conclusions which follow from Dr. Carnelley's views I must refer to his paper as read at our last meeting. Two points bear more especially upon the subject now under consideration—that is, if this speculation on the genesis of the elements is well founded. First, the existence of elements of identical atomic weights, isomeric with each other, would be possible; as such Dr. Carnelley mentions respectively nickel and cobalt (now found to have slightly different atomic weights), rhodium and ruthenium, osmium and iridium, and the metals of some of the rare earths. Secondly, in Dr. Carnelley's scheme all the chemical elements save hydrogen are supposed to be composed of two simpler elements, A = 12 and B = −2. Of these he regards A as a tetrad identical with carbon, and B as a monad of negative weight—perhaps the ethereal fluid of space.

Dr. Carnelley's three primary elements, therefore, are carbon, hydrogen, and the ether.

Starting from the supposition that pristine matter was once in an intensely heated condition, and that it has reached its present state by a process of free cooling, Dr. E. J. Mills suggests that the elements as we now have them are the result of successive polymerisations. Dr. Mills reminds us that chemical substances in the process of cooling naturally increase in density, and, if such increase be measured as a function of time or of temperature, we sometimes observe that there are critical points corresponding to the formation of new and well-defined substances. In this manner ordinary phosphorus is converted into the red variety, I is transformed into I_2, S_2 becomes S_6, and NO_2 N_2O_4. Among organic bodies styrol, in like manner, according to Dr. Mills, is converted into metastyrol, aldehyd into paraldehyd, the cynates into cyanurates, and turpentine into metaterebenthene. At the critical points above referred to heat is liberated in especial abundance, and the bodies thus formed are known as polymers. If we could gradually cool down substances through a vast range of temperature, we should then probably discover a much greater number of such critical points, or points of multiple proportion, than we have been able to discover experimentally.

The heat given out in the act of polymerisation naturally reverses to some extent the polymerisation itself, and so causes a partial return to the previous condition of things. This forward and backward movement, several times repeated, constitutes "periodicity." Dr. Mills regards variable stars as instances, now in evidence, of the genesis of elementary bodies.

From a study of the classification of the elements, Dr. Mills is of opinion that the only known polymers of the primitive matter are arsenic, antimony, and perhaps erbium and osmium; whilst zirconium, ruthenium, samarium, and platinum approximate to the positions of other polymers. Hence, from this genetic view, these elements may be described as products of successive polymerisations.

I must now call attention to a method of illustrating the periodic law, proposed by my friend Prof. Emerson Reynolds, of the University of Dublin, which will here assist us. Prof. Reynolds points out that in each period the general properties of the elements vary from one to another with approximate regularity until we reach the seventh member, which is in more or less striking contrast with the first element of the same period, as well as with the first of the next. Thus chlorine, the seventh member of Mendeleeff's third period, contrasts sharply both with sodium, the first member of the same series, and with potassium, the first member of the next series; whilst, on the other hand, sodium and potassium are closely analogous. The six elements whose atomic weights intervene between sodium and potassium vary in properties, step by step, until chlorine, the contrast to sodium, is reached. But from chlorine to potassium, the analogue of sodium, there is a change in properties *per saltum*. Further, such alternations of gradual and abrupt transitions are observed as the atomic weights increase. If we thus recognise a contrast in properties—more or less decided—between the first and the last members of each series, we can scarcely help admitting the existence of a point of mean variation within each system. In general, the *fourth* element of each series possesses the properties we might expect a transition-element to exhibit. If we examine a particular period—for instance, that one whose meso-element is silicon, we note:—*First*, that the three elements of lower atomic weight than silicon, viz., sodium, magnesium, and aluminium, are distinctly *electro-positive* in character, while those of higher atomic weight, viz., phosphorus, sulphur, and chlorine, are as distinctly *electro-negative*. Throughout the best known periods this remarkable subdivision is observable, although, as might be anticipated, the differences become less strongly marked as the atomic weights increase. *Secondly*, that the members above and below the meso-element fall into pairs of elements which, while exhibiting certain analogies, are generally in more or less direct chemical contrast. Thus, in the silicon period we have—

	Si^{iv}	
	+ Al$'''$	P$'''$ −
	+ Mg$''$	S$''$ −
	+ Na$'$	Cl$'$ −

This division also happens, in many cases, to coincide with some characteristic valence of the contrasted elements. It is noteworthy, however, that the members on the electro-negative side exhibit the most marked tendency to variation in atom-fixing power, so that valence alone is an untrustworthy guide to the probable position of an element in a period.

Thus, for the purpose of graphic translation Prof. Reynolds considers that the fourth member of a period—silicon, for example—may be placed at the apex of a symmetrical curve, which shall represent, for that particular period, the direction in which the properties of the series of elements vary with rising atomic weights.

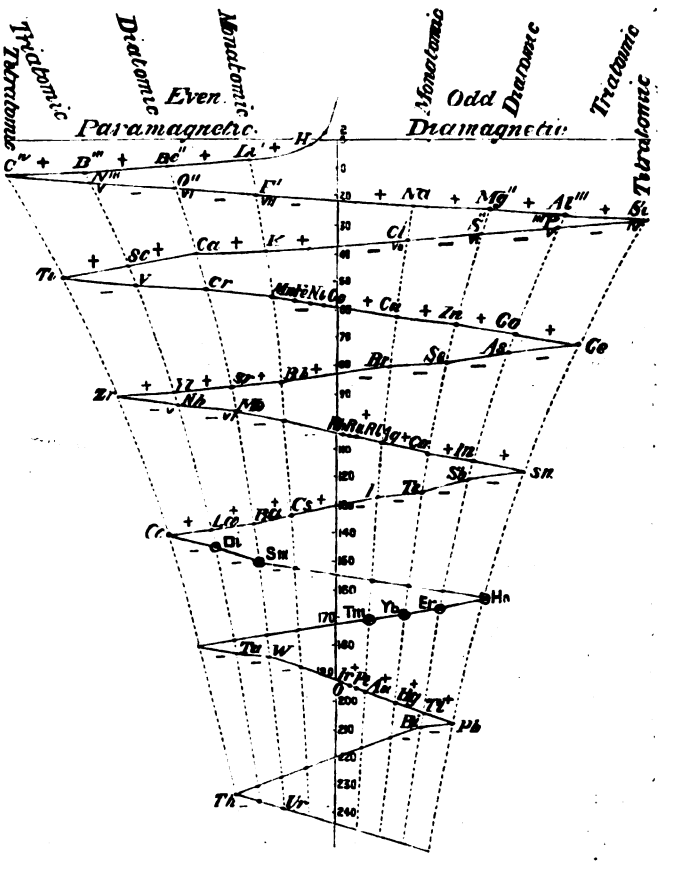

FIG. 1.

In the drawing before you (Fig. 1) I have modified Prof. Reynolds's diagram in one or two points. I have turned it the reverse way, as it is more convenient to start from the top and proceed downwards. I have represented the pendulous swing as gradually declining in amplitude according to a mathematical law, and I have introduced another half-swing of the pendulum between cerium and lead, which not only renders the oscillations more symmetrical, but brings gold, mercury, thallium, lead, and bismuth on the side where they are in complete harmony with members of foregoings groups, instead of being out of harmony with them. This modification has another advantage, inasmuch as it leaves many gaps to be hereafter filled in with new elements just when the development of research is beginning to demand room for such expansion.

I do not, however, wish to infer that the gaps in Mendeleeff's table, and in this graphic representation of it, necessarily mean that there are elements actually existing to fill up the gaps; these gaps may only mean that at the birth of the elements there was an easy potentiality of the formation of an element which would fit into the place.

Following the curve from hydrogen downwards we find that the elements forming Mendeleeff's eighth group are to be found near three of

Digitized by Google

the ten nodal points. These bodies are "interperiodic," both because their atomic weights exclude them from the small periods into which the other elements fall, and because their chemical relations with certain members of the adjacent periods show that they are probably interperiodic in the sense of being transitional.

This eighth group is divided into the three triplets—iron, nickel, and cobalt; rhodium, ruthenium, and palladium; iridium, osmium, and platinum. The members of each triplet have often been regarded as modifications of one single form of matter.

Notice how accurately the series of like bodies fit into this scheme. Beginning at the top, run the eye down analogous positions in each oscillation, taking either the electro-positive or electro-negative swings:—

N	Be	Li	Na	Mg	Al	Si	P	S	Cl	C
V	Ca	K	Cu	Zn	Ga	Ge	As	Se	Br	Ti
Nb	Sr	Rb	Ag	Cd	In	Sn	Sb	Te	I	Zr
—	Ba	Cs	—	—	—	—	—	—	—	—
Ta			Au	Hg	Tl	Pb	Bi			

Notice, also, how orderly the metals discovered by spectrum analysis fit in their places—gallium, indium, and thallium.

The symmetry of nearly all this series proclaims at once that we are working in the right direction. We can also learn much from the anomalies here visible. Look at the places marked with a circle; didymium, samarium, holmium, erbium, ytterbium, and thulium. Didymium cannot follow in order after the triad nitrogen, vanadium, columbium; nor erbium follow phosphorus, arsenic, antimony; nor thulium follow chlorine, bromine, iodine; nor ytterbium follow potassium, rubidium, cæsium. The inference to be drawn is that these bodies are out of place, owing to their atomic weights not having been correctly determined—an inference which is strengthened by the knowledge that the elementary character of some of these bodies is more than doubtful, whilst the chemical attributes of most of them are unknown.

The more I study the arrangement of this zigzag curve the more I am convinced that he who grasps the key will be permitted to unlock some of the deepest mysteries of creation. Let us imagine if it is possible to get a glimpse of a few of the secrets here hidden. Let us picture the very beginnings of time, before geological ages, before the earth was thrown off from the central nucleus of molten fluid, before even the sun himself had consolidated from the original *protyle*.* Let us still imagine that at this primal stage all was in an ultragaseous state, at a temperature inconceivably hotter† than anything now existing in the visible universe; so high, indeed, that the chemical atoms could not yet have been formed, being still far above their dissociation point. In so far as *protyle* is capable of radiating or reflecting light, this vast sea of incandescent mist, to an astronomer in a distant star, might have appeared as a nebula, showing in the spectroscope a few isolated lines, forecasts of hydrogen, carbon, and nitrogen spectra.

But in course of time some process akin to cooling, probably internal, reduces the temperature of the cosmic *protyle* to a point at which the first step in granulation takes place; matter as we know it comes into existence, and atoms are formed. As soon as an atom is formed out of *protyle* it is a store of energy, potential (from its tendency to coalesce with other atoms by gravitation or chemically) and kinetic (from its internal motions). To obtain this energy the neighbouring *protyle* must be refrigerated by it,‡ and thereby the subsequent formation of other atoms will be accelerated. But with atomic matter the various forms of energy which require matter to render them evident begin to act; and amongst others, that form of energy which has for one of its factors what we now call *atomic weight*. Let us assume that the elementary *protyle* contains within itself the potentiality of every possible combining proportion or atomic weight. Let it be granted that the whole of our known elements were not at this epoch simultaneously created. The easiest formed element, the one most nearly allied to the *protyle* in simplicity is first born. Hydrogen—or shall we say helium?—of all the known elements the one of simplest structure and lowest atomic weight, is the first to come into being. For some time hydrogen would be the only form of matter (as we now know it) in existence, and between hydrogen and the next formed element there would be a considerable gap in time, during the latter part of which the element next in order of simplicity would be slowly approaching its birth-point; pending this period we may suppose that the evolutionary process which soon was to determine the birth of a new element would also determine its atomic weight, its affinities, and it chemical position.

In the original genesis the longer the time occupied in that portion of the cooling down during which the hardening of the *protyle* into atoms took place, the more sharply defined would be the resulting elements; and, on the other hand, with more irregularity in the original cooling, we should have a nearer approach to the state of the elemental family such as we know it at present.

In this way it is conceivable that the succession of events which gave us such groups as platinum, osmium, and iridium—palladium, ruthenium, and rhodium—nickel and cobalt, if the operation of genesis had been greatly more prolonged, iron, would have resulted in the birth of only one element of these groups. It is also probable that by a much more rapid rate of cooling, elements would originate even more closely related than are nickel and cobalt, and thus we should have formed the nearly allied elements of the serium, yttrium, and similar groups; in fact the minerals of the class of samarskite and gadolinite may be regarded as the cosmical lumber-room where the elements in a state of arrested development—the unconnected missing links of inorganic Darwinism—are finally aggregated.

(To be continued.)

* We require a word, analogous to protoplasm, to express the idea of the original primal matter existing before the evolution of the chemical elements. The word I have ventured to use for this purpose is compounded of πρό (*earlier than*) and ὕλη (*the stuff of which things are made*. The word is scarcely a new coinage, for 600 years ago Roger Bacon wrote in his *De Arte Chymiæ*, "The elements are made out of ὕλη, and every element is converted into the nature of another element."

† I am constrained to use the words expressive of high temperature; but I confess I am unable clearly to associate with *protyle* the idea of hot or cold. *Temperature*, *radiation*, and *free cooling* seem to require the periodic motions that take place in the chemical atoms; and the introduction of centres of periodic motion into protyle would constitute its being so far changed into chemical atoms.

‡ I am indebted to my friend G. Johnstone Stoney, F.R.S., for the idea here put forward, as well as for other valuable suggestions and criticisms on some of the theoretical questions here treated of.

THE BRITISH ASSOCIATION MEETING.

PRESIDENTIAL ADDRESS.

(Concluded from page 417.)

I have elsewhere endeavoured to show, on the evidence found in Canada, that the occurrence of marine shells, land plants, and insects in the glacial deposits of that country indicates not so much the effect of general interglacial periods as the local existence of conditions like those of Grinnelland and Greenland, in proximity to each other at one and the same period, and depending on the relative levels of land and the distribution of ocean currents and ice-drift.*

I am old enough to remember the sensation caused by the delightful revelations of Edward Forbes respecting the zones of animal life in the sea, and the vast insight which they gave into the significance of the work on minute organisms previously done by Ehrenberg, Lonsdale, and Williamson, and into the meaning of fossil remains. A little later the soundings for the Atlantic cable revealed the chalky foraminiferal ooze of the abyssal ocean; still more recently the wealth of facts disclosed by the "Challenger" voyage, which naturalists have not yet had time to digest, have opened up to us new worlds of deep sea life.

The bed of the deep Atlantic is covered for the most part by a mud or ooze largely made up of the *débris* of foraminifera and other minute organisms mixed with fine clay. In the North Atlantic the Norwegian naturalists call this the Biloculina mud. Further south the "Challenger" naturalists speak of it as Globigerina ooze. In point of fact it contains different species of foraminiferal shells, Globigerina and Orbulina being in some localities dominant, and in others other species, and these changes are more apparent in the shallower portions of the ocean.

It is also to be observed that there are means for disseminating coarse material over the ocean-bed. There are in the line of the Arctic current on the American coast great sand-banks, and off the coast of Norway sand constitutes a considerable part of the bottom material. Soundings and dredgings off Great Britain, and also off the American coast, have shown that fragments of stone referable to Arctic lands are abundantly strewn over the bottom along certain lines, and the Antarctic continent, otherwise almost unknown, makes its presence felt to the dredge by the abundant masses of crystalline rock drifted far from it to the north. These are not altogether new discoveries. I had inferred many years ago, from stones taken up by the hooks of fishermen on the banks of Newfoundland, that rocky material from the north is dropped on these banks by the heavy ice which drifts over them every spring, that these stones are glaciated, and that after they fall to the bottom sand is drfted over them with sufficient velocity to polish the stones and to erode the shelly coverings of Arctic animals attached to them.† If then the Atlantic basin were upheaved into land we should see beds of sand, gravel, and boulders with clay flats and layers of marl and limestone. According to the "Challenger" Reports, in the Antarctic seas S. of 64deg. there is blue mud with fragments of rock in depths of 1,200 to 2,000 fathoms. The stones, some of them glaciated, were granite, diorite, amphibolite, mica schist, gneiss, and quartzite. This deposit ceases and gives place to Globigerina ooze and red clay at 46deg. to 47deg. S., but even further north there is sometimes as much as 49 per cent. of crystalline sand. In the Labrador current a block of syenite weighing 490lbs. was taken up from 1,340 fathoms, and in the Arctic current 100 miles from land was a stony deposit, some stones being glaciated. Among these were smoky quartz, quartzite, limestone, dolomite, mica schist, and serpentine; also particles of monoclinic and triclinic felspar, hornblende, augite, magnetite, mica, and glauconite, the latter no doubt formed in the sea-bottom, the others drifted from Eozoic and Palæozoic formations to the north.‡

A remarkable fact in this connection is that the great depths of the sea are as impassable to the majority of marine animals as the land itself. According to Murray, while twelve of the "Challenger's" dredgings taken in depths greater than 2,000 fathoms gave 92 species, mostly new to science, a similar number of dredgings in shallower water near the land gave no less than 1,000 species. Hence arises another apparent paradox relating to the distribution of organic beings. While at first sight it might seem that the chances of wide distribution are exceptionally great for marine species, this is not so. Except in the case of those which enjoy a period of free locomotion when young, or are floating and pelagic, the deep ocean sets bounds to their migrations. On the other hand the spores of crytogamic plants may be carried for vast distances by the wind, and the growth of volcanic islands may effect connections which, though only temporary, may afford opportunity for land animals and plants to pass over.

With reference to the transmission of living beings across the Atlantic,

* "Notes on Post-Pliocene of Canada," 1872. One well-marked interval only has been established in the glacial deposits of Canada.

† "Notes on Post-Pliocene of Canada," 1872.

‡ General Report, "Challenger" Expedition

Digitized by Google

we have before us the remarkable fact that from the Cambrian age onwards there were on the two sides of the ocean many species of invertebrate animals which were either identical or so closely allied as to be possibly varietal forms.* In like manner the early plants of the Upper Silurian, Devonian, and Carboniferous present many identical species; but this identity becomes less marked in the vegetation of the more modern times.

In so far as plants are concerned, it is to be observed that the early forests were largely composed of cryptogamous plants, and the spores of these in modern times have proved capable of transmission for great distances. In considering this we cannot fail to conclude that the union of simple cryptogamous fructification with arboreal stems of high complexity, so well illustrated by Dr. Williamson, had a direct relation to the necessity for a rapid and wide distribution of these ancient trees. It seems also certain that some spores, as, for example, those of the Rhizocarps,† a type of vegetation abundant in the Palæozoic, and certain kinds of seeds, as those named *Ethcotesta* and *Pachytheca*, were fitted for flotation. Farther, the periods of Arctic warmth permitted the passage around the northern belt of many temperate species of plants, just as now happens with the Arctic flora; and when these were dispersed by colder periods they marched southward along both sides of the sea on the mountain chains.

The same remark applies to northern forms of marine invertebrates, which are much more widely distributed in longitude than those further south. The late Mr. Gwyn Jeffreys, in one of his latest communications to this Association, stated that 54 per cent. of the shallow water mollusks of New England and Canada are also European, and of the deep sea forms 30 out of 35, these last of course enjoying greater facilities for migration than those which have to travel slowly along the shallows of the coasts in order to cross the ocean and settle themselves on both sides. Many of these animals, like the common mussel and sand clam, are old settlers which came over in the Pleistocene period, or even earlier. Others, like the common periwinkle, seem to have been slowly extending themselves in modern times, perhaps even by the agency of man. The older immigrants may possibly have taken advantage of lines of coast now submerged, or of warm periods, when they could creep around by the Arctic shores. Mr. Herbert Carpenter and other naturalists employed on the "Challenger" collections have made similar statements respecting other marine invertebrates, as, for instance, the Echinoderms, of which the deep-sea crinoids present many common species, and my own collections prove that many of the shallow-water forms are common. Dall and Whiteaves‡ have shown that some mollusks and Echinoderms are common even to the Atlantic and Pacific coasts of North America; a remarkable fact, testifying at once to the fixity of these species and to the manner in which they have been able to take advantage of geographical changes. Some of the species of whelks common to the Gulf of St. Lawrence and the Pacific are animals which have no special locomotive powers even when young, but they are northern forms not proceeding far south, so that they may have passed through the Arctic seas. In this connection it is well to remark that many species of animals have powers of locomotion in youth which they lose when adult, and that others may have special means of transit. I once found at Gaspé a specimen of the Pacific species of Coronula, or whale-barnacle, the *C. reginæ* of Darwin, attached to a whale taken in the Gulf of St. Lawrence, and which had probably succeeded in making that passage around the north of America which so many navigators have essayed in vain.

It is to be remarked here that while many plants and marine invertebrates are common to the two sides of the Atlantic, it is different with land animals, and especially vertebrates. I do not know that any fossil insects or land snails or millipedes of Europe and America are specifically identical, and of the numerous species of batrachians of the Carboniferous and reptiles of the Mesozoic all seem to be distinct on the two sides. The same appears to be the case with the Tertiary mammals, until in the later stages of that great period we find such genera as the horse, the camel, and the elephant appearing on the two sides of the Atlantic; but even then the species seem different, except in the case of a few northern forms.

Some of the longer-lived mollusks of the Atlantic furnish suggestions which remarkably illustrate the biological aspect of these questions. Our familiar friend, the oyster, is one of these. The first known oysters appear in the Carboniferous in Belgium and in the United States of America. In the Carboniferous and Permian they are few and small, and they do not culminate till the Cretaceous, in which there are no less than ninety-one so-called species in America alone; but some of the largest known species are found in the Eocene. The oyster, though an inhabitant of shallow water, and very limitedly locomotive when young, has survived all the changes since the Carboniferous age, and has spread itself over the whole northern hemisphere.§

I have collected fossil oysters in the Cretaceous clays of the coulées of Western Canada, in the Lias shales of England, in the Eocene and Cretaceous beds of the Alps, of Egypt, of the Red Sea Coast, of Judea, and the heights of Lebanon. Everywhere and in all formations they present forms which are so variable and yet so similar that one might suppose all the so-called species to be mere varieties. Did the oyster originate separately on the two sides of the Atlantic, or did it cross over so promptly that its appearance seems to be identical on the two sides? Are all the oysters of a common ancestry, or did the causes, whatever they were, which introduced the oyster in the Carboniferous act over again at later periods? Who can tell? This is one of the cases where causation and development—the two scientific factors which constitute the basis of what is vaguely called evolution—cannot easily be isolated. I would recommend to those biologists who discuss these questions to addict themselves to the oyster. This familiar mollusk has successfully pursued its course and has overcome all its enemies, from the flat-toothed selachians of the carboniferous to the oyster-dredgers of the present day, has varied almost indefinitely, and yet has continued to be an oyster, unless indeed it may at certain portions of its career have temporarily assumed the disguise of a Gryphæa or an Exogyra. The history of such an animal deserves to be traced with care, and much curious information respecting it will be found in the report which I have cited.

But in these respects the oyster is merely an example of many forms. Similar considerations apply to all those Pliocene and Pleistocene mollusks which are found in the raised sea-bottoms of Norway and Scotland, on the top of Moel Tryfaen in Wales, and at similar great heights on the hills of America, many of which can be traced back to early Tertiary times, and can be found to have extended themselves over all the seas of the northern hemisphere. They apply in like manner to the ferns, the conifers, and the angiosperms, many of which we can now follow without even specific change to the Eocene and Cretaceous. They all show that the forms of living things are more stable than the lands and seas in which they live. If we were to adopt some of the modern ideas of evolution we might cut the Gordian knot by supposing that, as like causes can produce like effects, these types of life have originated more than once in geological time, and need not be genetically connected with each other. But while evolutionists repudiate such an application of their doctrine, however natural and rational, it would seem that nature still more strongly repudiates it, and will not allow us to assume more than one origin for one species. Thus the great question of geographical distribution remains in all its force, and, by still another of our geological paradoxes, mountains become ephemeral things in comparison with the delicate herbage which covers them, and seas are in their present extent but of yesterday when compared with the minute and feeble organisms that creep on their sands or swim in their waters.

The question remains, Has the Atlantic achieved its destiny and finished its course, or are there other changes in store for it in the future? The earth's crust is now thicker and stronger than ever before, and its great ribs of crushed and folded rock are more firm and rigid than in any previous period. The stupendous volcanic phenomena manifested in Mesozoic and early Tertiary times along the borders of the Atlantic have apparently died out. These facts are in so far guarantees of permanence. On the other hand, it is known that movements of elevation along with local depression are in progress in the Arctic regions, and a great weight of new sediment is being deposited along the borders of the Atlantic, especially on its western side, and this is not improbably connected with the earthquake shocks and slight movements of depression which have occurred in North America. It is possible that these slow and secular movements may go on uninterruptedly until considerable changes are produced; but it is quite as likely that they may be retarded or reversed.

It is possible, on the other hand, that after the long period of quiescence which has elapsed there may be a new settlement of the ocean-bed, accompanied with foldings of the crust, especially on the western side of the Atlantic, and possibly with renewed volcanic activity on its eastern margin. In either case a long time relatively to our limited human chronology may intervene before the occurrence of any marked change. On the whole the experience of the past would lead us to expect movements and eruptive discharges in the Pacific rather than in the Atlantic area. It is therefore not unlikely that the Atlantic may remain undisturbed, unless secondarily and indirectly, until after the Pacific area shall have attained to a greater degree of quiescence than at present. But this subject is one too much involved in uncertainty to warrant us in following it farther.

In the meantime the Atlantic is to us a practically permanent ocean, varying only in its tides, its currents, and its winds, which science has already reduced to definite laws, so that we can use if we cannot regulate them. It is ours to take advantage of this precious time of quietude, and to extend the blessings of science and of our Christian civilisation from shore to shore until there shall be no more sea, not in the sense of that final drying-up of old ocean to which some physicists look forward, but in the higher sense of its ceasing to be the emblem of unrest and disturbance, and the cause of isolation.

I must now close this address with a short statement of the general objects which I have had in view in directing your attention to the geological development of the Atlantic. We cannot, I think, consider the topics to which I have referred without perceiving that the history of ocean and continent is an example of progressive design, quite as much as that of living beings. Nor can we fail to see that, while in some important directions we have penetrated the great secret of Nature, in reference to the general plan and structure of the earth and its waters, and the changes through which they have passed, we have still very much to learn, and perhaps quite as much to unlearn, and that the future holds out to us and to our successors higher, grander, and clearer conceptions than those to which we have yet attained. The vastness and the might of ocean and the manner in which it cherishes the feeblest and most fragile beings, alike speak to us of Him who holds it in the hollow of His hand, and gave to it of old its boundaries and its laws; but its teaching ascends to a higher tone when we consider its origin and history, and the manner in which it has been made to build up continents and mountain chains, and at the same time to nourish and sustain the teaming life of sea and land.

COMPANIES' MEETINGS.

Direct Spanish Telegraph Company (Limited).

The twenty-sixth ordinary general meeting of this Company was held at Winchester House, Old Broad-street, on Thursday, under the presidency of Sir James Anderson.

The MANAGER (Mr. C. Gerhardi) read the notice calling the meeting.

The CHAIRMAN then said: I have very little to say, and I need say as little as possible, as we have far more important business to go to. At the last meeting I held out to the shareholders the necessity of lifting our cable, and seeing what could be done with it, and whether we should have to abandon it altogether. We have picked it up, and it is now being overhauled, with a view of getting for it what we can. It is not very easy to sell an old cable, but I do not think it will cost the Company anything, at all events for picking it up. You already know that it was too bad to repair or to make anything like a good cable of it for relaying. The only other remarks I have to make as to our ordinary report is that our expenditure is £189 less than last year, and after three months' trial with the reduced tariff we are only £56 worse than before, compared with any other three months. I will make no other remark on this report at present, but will forthwith move, "That the report and accounts now presented be received and adopted."

Mr. EDMUND ETLINGER seconded the motion.

Mr. A. BAKER asked the cost of picking up the cable, and by whom it was done.

The CHAIRMAN said that the work was done by the Eastern Telegraph Company at cost price, and the cost would be nearly £7,000.

Mr. BAKER said it was not shown in the report.

The CHAIRMAN replied that it was not all in this half year's accounts, and that it would have to come before the shareholders again. They had not yet been offered anything like the amount he had stated for it; but he was trying to bring about an arrangement by which they would receive more. In further reply to Mr. C. H. Cochrane, the Chairman said the original cost of the Bilbao cable, including its removal to Santander and re-establishing it at Bilbao, was £126,000, with stores and other things. It would be remembered that this amount was paid when cables were dearer, when concessions cost something, and promoters required to be paid also.

Mr. BAKER said that the capital of the 10 per cent. preference shareholders was raised exclusively for the Marseilles-Barcelona cable, irrespective of the first venture from England to Spain.

The CHAIRMAN replied that it was for effecting this purchase and "other purposes" of the Company. He then read the resolution passed referring to the issue of the preference shares.

Mr. COCHRANE inquired whether he understood from the Chairman that the whole of the old cable had been picked up.

The CHAIRMAN: No, all that could be picked up—about 150 miles.

Mr. COCHRANE: The cable for which that money appears in our accounts is lost.

The CHAIRMAN: Entirely lost.

Mr. BANNATYNE said he objected to the following passage in the report "They" (meaning the Directors), "enclose a special report on the financial steps which are requisite to be taken in consequence of the loss of this cable as an asset." He did not agree with that paragraph because, in his opinion, the proposals were not requisite, and he was prepared at the extraordinary meeting to maintain that view.

The CHAIRMAN said that to meet this objection they would insert the words "they deem" in place of the word "are" in the passage quoted.

Mr. BANNATYNE said that with that alteration he would agree to the motion.

The CHAIRMAN, in answer to Mr. COCHRANE, said that the cost of sending out the proxies was £3, and that if the shareholders objected to pay it the Directors would do so.

The motion, as altered, was then agreed to.

An extraordinary general meeting was afterwards held.

The CHAIRMAN said that he expected the proposal for reducing the capital to be severely criticised, because he himself had been against it very much at starting. He had thought that they might find some plan of inducing the preference shareholders, by giving them a little more than the ordinary shareholders, to accept the proposal more readily, and as the preference shareholders were always nearest a dividend, he thought they ought to be mollified by something of the kind. They had, however, been told, and they found plenty of reasons for seeing its force, that in winding up, for example, if they were compelled to wind up, the ordinary shareholders, who held two-thirds of the whole of the capital, would get two-thirds whatever the result might be in disposing of the property, and the preference shareholders only one-third. Again, the preference shares had only a preference upon the revenue or dividend. They had no preference upon anything else, and it was perfectly obvious to every one that without the votes of the ordinary shareholders they could no more make an adjustment of the capital than they could without the votes of the preference shareholders. Both sides had their rights, and must be reasoned with, and he hoped they would see the matter from the Directors' point of view. If they had given the preference shareholders something more, they had plenty of reasons for knowing that the ordinary shareholders would not have voted and would not vote for the adjustment of the capital. His own notion was that if they could have given the preference shareholders £6, the scheme would have been easier to carry than the present one, and that view he would argue as long as he had a leg to stand upon. There were, however, large and important holders of ordinary shares who said that they would not assent to that, and he understood from their legal adviser, who had taken advice, that they would have infinitely more difficulty in doing anything of that kind than was proposed in the plan before them. After all sorts of considerations and taking advice from all useful sources, they came to the conclusion that there was nothing better to advise the shareholders to accept than the plan submitted by the Directors. There had been an argument advanced by some shareholders in letters to the Directors (they had only had four letters) that if they had reduced the dividend upon the preference shares, and given, for instance, 7 per cent. instead of 10 per cent., the proposal would have been more equitable; but it was illogical, and it would not be so easy to put through the Court. Indeed it was not even legal, and they were advised they could not carry it. But it was an idea which he also had held. The object of the Directors, of course, was that they should be able to ride a living horse instead of whipping a dead one for ten years—that they should make the undertaking a living concern, and if they went on prosperously that would advance their shares in the market, make the investment a sound one, and they would have their capital represented by assets with a reserve fund at the back of it. The Company, in his opinion, when Mr. Bannatyne was chairman, had been worked upon the plan of hoping and believing that the traffic would grow, and thus enable the Directors to lay by a good reserve fund. But the traffic had not grown, and the average of the few best selected years gave only £13,000. They had taken the average of the last three years, and two were of the better kind and one not so good, giving £12,700 odd of net revenue, as was shown in the Directors' special report. One gentleman had written them asking why they wanted to lay another cable. They did not want to do so, but they desired to have the money in hand to lay another cable if it was necessary to do so. They had estimated the life of the Barcelona cable at 25 years, and of the Bilbao cable at 20 years. Twelve years of the former and 17 of the latter had yet to run, and as nothing had been laid by to reserve hitherto, these calculations upon the life of the cables required £5,000 a year. He was satisfied that no one with any sense of responsibility, and the requisite knowledge for judging of the life of a cable, would say that the Directors had not done the best thing possible for the shareholders in taking these two terms of life. They had lost the original Bilbao cable. Fortunately for the Company the Eastern Company had two ships on their way from the Mediterranean. The Direct Spanish Company was not charged one shilling for bringing those ships to the ground where they had to work, and the two ships went to work in the most economical way possible, and brought home all the cable they could lift. Some part of the cable was brought home. That which had been put in of recent years was very good. The rest was being overhauled, and the whole expense of picking it up would be just over £7,000, perhaps not so much.

Mr. BAKER: Who made the cable?

The CHAIRMAN: The Silvertown Company. It was not the kind of cable they would lay in that depth of water. He blamed no one; but as he had said, the cable was lost, and the capital was gone. They had had one letter telling them that the Company was to be sacrificed to the Eastern Company, but he was quite sure that the gentleman—the writer—would not have said so if he had had sufficient knowledge to guide his judgment. As far as his opinion went, the Direct Spanish Company must have been in liquidation but for the joint-purse arrangement of the Eastern Company, which Mr. Gerhardi and himself made some years ago, and subsequent to that all the disaster of the broken cable had come upon them. That would have necessitated liquidation, or, if the concern had had to be set on its legs, it must have been at a dearer price than the Directors now proposed to pay by wiping off some of the capital. With that proposal carried he believed it would become a sound paying concern. They would thus lay by a reserve fund, and be able to reissue their debentures cheaper; but he reminded them that the scheme submitted by the Directors did not provide for any amortisation of debentures. They must trust to the growth of traffic to get funds for that purpose. The Directors had received proxies representing 800 votes. He concluded by moving the following resolution:—

"That in consequence of the abandonment of the Company's original cable, the capital of the Company be reduced from £190,000 (at present represented by 6,000 preference shares of £10 each, all issued and fully paid-up, and 13,000 ordinary shares of £10 each, whereof 12,931 are issued and have £9 per share paid up, and 69 are unissued) to £95,000, and that such reduction be effected by writing off £5 per share from the amount credited as paid up on each issued share, and £5 per share from the nominal amount of each unissued share, the amount so written off the issued shares being capital not represented by available assets."

Mr. ETLINGER seconded the motion.

The CHAIRMAN added that when he joined the Company he found the idea pretty generally prevailing that the assets would not fully represent the capital of the Company. He was, however, rather of a sanguine disposition himself, and Mr. Bannatyne would bear him out when he said that he at that time took a cheerful view of matters.

Mr. COCHRANE thought that the seven days' notice was very short for placing such a matter before the shareholders. He also inquired whether, by the conditions under which the preference capital was raised, they could force the preference shareholders to assent to the plan proposed.

The SOLICITOR, in reply, stated that seven days' notice was sufficient for any meeting held by the Company. As to the second question, the act under which they were proceeding was passed only ten years ago. It was not very clear what precise power there was in any individual case to object to the steps taken. He might say that the Directors anticipated that the question might be raised, and they would not be sorry if that were done, as it would make them perfectly clear, and save them from any anxiety in the future. Meanwhile, the first thing was to pass the resolutions at the two meetings—the present one and the one which would be called later—to con-

Digitized by Google

firm what was done now. Then they would have to go to the Court for a resolution to reduce the capital. At that stage some shareholder might think it worth while to raise the question whether shareholders dissenting from the proposal could be bound by it. The resolutions would have to be passed now by a majority of three-fourths of those present in person or by proxy.

Mr. BANNATYNE said he was utterly unable to agree with the proposal. He held 100 ordinary and 100 preference shares, so that it would make no difference to him from that standpoint whether the motion was carried or not. He opposed the proposal because he considered it unjust, inequitable, and illegal. He should certainly not abandon any of his rights to a dividend of 10 per cent. upon his £10 preference shares. He could only be compelled to give way by the Company going into liquidation, and he would run the risk of that. He should take all legal means to defend his rights if necessary. He felt deeply for the ordinary shareholders; but the case of the preference shareholders was also a hard one. At the time the preference capital was raised it was of essential importance for the Company to have it, and it had to be all paid up at once. The subscribers thought they would get their dividends regularly, and they never imagined either that debenture holders would come in before them. He admitted that if they went into liquidation the preference shareholders would only get a *pro rata* distribution of the assets; but while they presented such a report as that which was submitted on the present occasion, they would not get from any Court power to go into liquidation. In regard to the prospects of the Company the Directors in their calculations were, he thought, very much on the safe side.

Mr. DYETT: Quite right; that is as it should be.

Mr. BANNATYNE: I admit that, but I am more sanguine.

Mr. LOW: You always were sanguine; and then the capital was lost.

The CHAIRMAN, in reply, stated that Mr. Bannatyne was for many years chairman of the Company, when the Directors issued 10 per cent. capital upon their poor little Company without telling the shareholders that there was the risk of the cables breaking, and that there was the certainty of the cables deteriorating; and no reserve was laid by at all. It was all stuff and nonsense for Mr. Bannatyne to talk about his conscientious objections to the proposal now made, and his pity for the shareholders. The proprietors' interests were not looked after at the time, no reserve fund being provided; and any man understanding anything about a cable knew that it was no property without a reserve fund at the back of it. In all that Mr. Bannatyne had said he had lost sight of the fact that half of the capital was lost, and that was the position that the "poor shareholders" were in. His own wish was to show them how they might get something, and how the concern might be made a living one.

Mr. BANNATYNE said that the Directors in his time did make some provision for a reserve, but it would be supposed from what the Chairman had said that they put by nothing.

The CHAIRMAN: When I joined the Board there was not £1,000 of reserve fund.

Mr. LOW: After being established twelve years.

Mr. BAKER said he considered the proposal so far as regarded the preference shareholders was most inequitable. The preference capital was raised for a specific purpose, which was now going on; and yet it was to be reduced equally with that of the shareholders. If the £1 a share liability on the ordinary shares was called up, and the £10,000 reserve fund was added there would be £23,000, and another £50,000 would lay a new cable.

The CHAIRMAN: Why lay another cable?

Mr. BAKER: To replace the one lost. He went on to argue that if that course was adopted, the position of the preference shareholders would be much better than under the scheme now proposed, the effect of which, he maintained, was to unduly depreciate the value of the preference shares, and, similarly, to raise the value of the ordinary shares.

Mr. LOW said he would assent to no arrangement other than that proposed by the Directors.

Other SHAREHOLDERS having spoken,

The CHAIRMAN, in reply, said the position of all concerned would be improved if they could put the Company in a dividend-paying position. Mr. Baker had more experience than himself of the Stock Exchange value of a thing, but for his own part he imagined that a £5 preference share, carrying a dividend of 10 per cent. would be worth more than £5 in the market; and, moreover, with the Directors' proposal carried, the preference shareholders would get £2 10s. per share at once for their arrears. The case of the position of the Anglo-American Company was different. The preference shares of that company were of a different kind to the preference shares of this Company. Adding together the £13,000 uncalled liability on the ordinary shares and the £10,000 of reserve fund, they were still a long way off the £60,000 which would be at least necessary to lay another cable. The longer, however, that they could keep their sovereigns at the bank the better. Reference had been made to the Directors only giving seven days to the shareholders to consider the matter, but that was long enough to read their proposals. The Directors, however, had been closely considering the subject for the last year or eighteen months.

Mr. ETLINGER said he had been a Director of the Company for twelve years, and he considered that the proposal now before the shareholders was the best in their interests.

The motion was then put and declared carried by 17 to 5.

The CHAIRMAN said he hoped yet to be able to "talk over" Mr. Bannatyne and Mr. Baker too.

The following resolution was then passed:—"That the Directors may make such regulations as they think fit for exchanging the certificates of shares for certificates in conformity with the foregoing resolution."

A vote of thanks to the Chairman and Directors brought the meeting to a close.

Maxim-Weston Electric Company (Limited).

An extraordinary general meeting of the shareholders of this Company was held on Monday, at the Cannon-street Hotel, under the presidency of Mr. H. Watt, M.P., for the passing of a resolution authorising the Directors to issue up to 100,000 shares, at not less than the par value of 5s. each, as, when, and how they might think fit.

The SECRETARY (Mr. Buchanan Cox) read the notice convening the meeting.

The CHAIRMAN reminded them that the last time he addressed them was in February, and in the ordinary course of events they would not have met again until next year. The exigencies of the Company, however, had rendered necessary the present meeting; but to explain fully the cause of the meeting it was necessary to refer to the events of three years ago. The then Board were authorised to issue up to 500,000 shares, but at a meeting held a year afterwards, from the suggestion of a shareholder of the Company, a moral pledge was given that they would not issue beyond 250,000 shares without the consent of the shareholders. It was owing to that pledge that they met now. There was nothing of a legal character about the pledge referred to, but the present Board were most reluctant to take any steps whatever which might, in the opinion of the shareholders, be calculated to be detrimental to the interests of the Company without taking them first into their confidence. The present number of the shareholders was 2,000, compared with 900 when the present Board took office—a sign which he always thought healthy. Many of them might not be conversant with the early history of the Company, and a short retrospect would therefore be beneficial. As some of the shareholders of the Company still possessed shares in the name of the Electric Light and Power Generator Company he might observe that that was the original name of the Company, which was established to work certain patents, but upon the purchase of the Maxim-Weston patents the title of the Company was altered as at present. When the present Board took office the capital of the Company was, if he remembered rightly, 172,500 shares of £1 each. But the capital existed only on paper. The amount paid for patents, &c., was about £130,000, but as to a portion of the purchase he thoroughly endorsed the action of the old Board in adding to the patents account the sum of about £60,000 for the purchase of the Maxim-Weston patents; in fact, but for those patents the Company would long ago have ceased to exist. The whole of the capital was virtually gone when the present Board took office, and they had to devise the best means they could to raise working capital to carry on the business. The expenditure of the Company, according to the balance-sheet of 1883, under the old *régime* was £16,000 to £17,000 per annum, and the revenue when he joined the Board was only about a fourth of the expenditure. The new Board had had a somewhat arduous experience, but he would pass over that with the remark that they had so far succeeded, and that the Company was now in a better position than it had ever been. He might say that the shareholders had such confidence in the old Board that when an issue of 77,500 shares was attempted they would take up only 2,000, though the price of issue was 5s. The present Board had to face the situation and find capital, which they did, with the result that at the end of that year the surplus was something in excess of £2,000. Having referred to the formation of the Lancashire Maxim-Weston Company, he reminded them that at the last meeting he told them that the factory accommodation which they then had, owing to the growth of their business, was entirely inadequate for the purposes of manufacture. He was happy to say that they had found premises at Dalston containing a superficial area four times in excess of that of the old factory, for which they paid only about 25 per cent more rent. They were now adding to their plant, with the view of manufacturing their heavier class of dynamos and plant. One essential necessity for manufacturing that plant was that Government contracts would only be given out to British companies manufacturing their plant here, so that there might be no necessity for going to America in the event of repairs being necessary. They would be in a position in a month or so to turn out any amount of plant up to an installation of 1,000 lights without having recourse to America at all. With regard to incandescent lamps, he said that it cost the old Board about 17s. 6d. to manufacture one, but under the present Board that price had been reduced to something like 3s. Unfortunately, however, the lamps did not possess the durability of American made lamps. He might say *en passant* that when the late Board purchased the Maxim-Weston patents they made a very good condition in insisting that the Company should have all improvements for five years in those patents without paying anything for them. It was unfortunate, however, that one point was overlooked—that they did not stipulate that the plant obtained from America should be purchased at 5 or 10 per cent. over the cost of manufacture; but they had now obtained from the American company a concession of something like 30 per cent. off what they charged for dynamos and lamps, as compared with what was paid before; and he calculated that by manufacturing their dynamos, &c.—in fact everything but incandescent lamps—they would effect a further saving of 25 or 30 per cent. If so, they would be able to compete with the very lowest prices in the market. Though the business done this year in volume—in weight of plant—had exceeded by nearly 50 per cent. what they did in the previous year, the value obtained had not been in the same ratio as before, although the amount had been larger. They were still subjected to what he would call competition of an unfair character—that was to say, competition on the part of persons or firms supplying plant at an absolute loss. He knew of one case recently where a contract had been made which must cause a loss of about 40 per cent. upon the price at which the plant could be laid down. This Company had undertaken nothing of that sort. He thought the amount of business they had done had been fairly satisfactory; but in these days of depressed trade they would agree with him as to the advisability of

Digitized by Google

their being in a position to purchase their plant at the lowest possible price. They were constantly experimenting and trying to put themselves in a position to meet the requirements of their customers. The result of their experiments with their dynamo had been that, from the improvements they had effected, they were now able to produce with one dynamo 72 lamps, whereas before they could only produce 30 of the large—the old Maxim-Weston—lamps. The consequence was that they could produce plant to meet the lowest price of any opponent in the trade, provided that that opponent was securing for his manufacture a price which would leave him any margin at all. Alluding to the litigation in which the Edison and Swan Company had been engaged, owing to infringements of their patents, he said he was happy to state that the American Company had fought the Edison Company over their own lamp, and beaten them. Since then a new lamp had come into the market—the Weston wavy filament—which he claimed to be the most economical. He estimated that ten lamps would cost something like 1¼d. an hour, all plant and wear and tear included. He agreed that the Edison and Swan Company were right in defending their patents, considering the price which they, like this Company, had paid for them; but he thought they would have acted judiciously had they consulted with the Brush Company and this Company before engaging in the litigation referred to, so that the advisability of taking combined action might have been considered. He believed, had such combined action been taken they would have been successful against all comers, and that the large price which they had paid for their patents would not have been money thrown away. As it was, the competition of persons who had paid nothing for their patents subjected those companies who had paid heavily for theirs to a great disadvantage. In common with others they had received from the Edison and Swan Company a notice as to expecting a royalty, but he had no hesitation in expressing his belief that the patent which the Edison and Swan Company were now proceeding upon was the Sawyer and Mann, and in the litigation in America to which he had alluded, those interested in the Weston patent had maintained its position. That being the case, he entirely failed to see how the Edison and Swan Company could possibly have any action against this Company. No action had been taken against them by the Edison and Swan Company, and he thought that if it came to fighting, the Maxim-Weston Company would have the best of it. The Post Office installation had been going on very satisfactorily, with the exception that it was so huddled that the heat of the engine house was so great as to render the running unsatisfactory. As to their plant, different officials of the Post Office had intimated that nothing could be better. Since then he had secured several orders from the Government, and he was now in negotiation with a view of selling a considerable amount of plant as soon as they were able to send it out. The last important installation which they fitted up was at the Palace Hotel, Southport. Since that he was happy to say they had secured five contracts, and if they went on to the end of the year as they were going on securing work—and their present surplus was in excess of that at the corresponding period of the previous year—the capital which the proposed issue of new shares would produce would be absolutely required. He did not say that it would be necessary to issue the whole 100,000 shares at once, and they had no wish to issue one more share than was absolutely necessary. They had always worked on a very small capital. By the report of another company he saw that they had received no less than £120,000 in calls in one year. But the chairman of that company had expressed his opinion that the whole stock of the company was worth about £70,000, or £50,000 less than the calls of that one year had produced. The Maxim-Weston Company did not hold one penny in stock which was not saleable, and they were constantly economising in every possible form. If they could not work the Company so as to be of benefit to the shareholders he would no longer have anything to do with it. They had some very good contracts in hand, and there were some very large ones in negotiation, but they were not at present in a position to close a contract for £10,000. They had now a very large stock of plant—sufficient to despatch an installation of 1,000 lights within 48 hours; but they had only at the bank some £3,000 or £4,000, and in the event of their obtaining a Government contract for £5,000 that money would not be paid to them for probably nine months afterwards. He concluded by moving the resolution.

Mr. BROWN having seconded the motion, a discussion followed, principally with regard to the terms on which the new shares should be issued, it being contended by several speakers that it was only right that existing shareholders should have the first option of taking the new issue, and that the general public ought not to have them unless at a premium.

The CHAIRMAN pointed out that the resolution said that the new shares were to be issued at not less than the par value.

A SHAREHOLDER urged that the question of issuing further shares should be postponed until the next general meeting.

Another SHAREHOLDER thought that the issue might be limited for the present to 50,000 shares.

Mr. JACKSON argued in favour of the shareholders foregoing their dividends for a time so as to give the Company the working capital required, as constant issues of new shares depressed the market value of the existing shares. He thought an assurance ought to be given by the Directors that none of the fresh money to be obtained by the issue of shares should be used in litigation.

The CHAIRMAN, at the close of the discussion, in reply to questions, said he was informed that the original Edison patent expired in 1884, and therefore, as he had said already, he thought that the Edison and Swan Company must be going on the Sawyer and Mann patent. If so the parties in America who were interested in that patent contested every stage of the Weston lamp and failed. He sympathised with those shareholders who, like himself, had paid a heavy premium for their shares. He held more than 1,000 shares, which had cost him £1. 15s. each. He thought that the suggestion which had been made by more than one speaker was equitable, namely, that the shareholders should have the first opportunity of subscribing for the new shares. With reference to the remark about foregoing the dividend, the Board were in the hands of the shareholders. As he stated at the last meeting, however, there were a great many poor shareholders in the Company to whom a few pounds even were of value. If they did not approve of the issue of further capital it would naturally circumscribe the business of the Company. As to the amount of their working capital, he could not say exactly what it represented, not having taken stock since last January. Excluding outstanding debts, which probably amounted to £10,000, and taking the plant of the Company and the cash at the bankers, he should say that the available working capital was £25,000. That appeared a large sum, but they must take into account the fact that with every installation a third to a half consisted of plant to be bought, such as engines, cable, shafting, &c. That was the difficulty. He did not think they owed £300. If they only consented to an issue of 50,000 shares now the Board would have to come before the shareholders again, and however reasonable the ground was upon which Directors asked shareholders for capital, the tendency of a further issue, as had been stated, was to reduce the market value of the existing issue. It had been said that £100,000 had been lost by them. He was sorry to say that in his opinion that sum was much under what was actually lost. The present Board had had nothing to do with that loss. His views in regard to the enormous sums which were paid for their patents was that while the price might not have been in excess of their value in 1883, in the altered condition of circumstances in 1886 the value was absurd, and there was no reason why this Company should have continued to be saddled with a large amount of dead capital. The present Board came in as large shareholders to serve the interests of the proprietors generally, and he ventured to say that if the Company had been wound up in place of being carried on by the present Board they would not have got 6d. a share. With regard to litigation, his idea was that in the event of litigation being necessary the American Company would take the matter up. The last communication which he had received from the secretary of the Edison and Swan Company, however, was of the most friendly character, and from that he did not think they contemplated interfering with the Maxim-Weston Company.

The proposal that no capital should be issued until the annual meeting in January was then put and lost, and a similar result attended the motion to the effect that only 50,000 shares should be issued. Subsequently the original motion for the issue of 100,000 shares was carried almost unanimously, it being understood that the shareholders would have the first option of taking up the new issue *pro rata*, according to their holdings.

The proceedings then terminated.

NOTES.

THE WEST INDIAN LINES.—The cable between St. Vincent and Barbadoes is interrupted.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 1st inst. amounted to £4,375.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ended Sept. 30th were £3,585.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of September amounted to £40,778, against £47,849 in the corresponding period of last year.

ELECTRIC LIGHT AT THE VATICAN.—We learn that Messrs. Siemens and Halske have received instructions to light the Vatican by electricity. The work is to be conpleted by the end of the year.

HALIFAX.—The Halifax Industrial Society have decided to light up their extensive premises by arc and incandescent lamps, and have entrusted the work to Messrs. Blakey, Emmott, and Co.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of September amounted to £1,751, against £1,793 in the corresponding period of last year.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of September amounted to £30,107, and to £41,845 in the corresponding period of 1885.

THUNDERSTORMS.—Heavy thunderstorms are reported this week from various parts of the country. In the Isle of Wight, the north of England, and the Glasgow and Edinburgh districts the storms have been of exceptional severity.

SIGNALLING ON MEN-OF-WAR.—A committee has been ordered to assemble at Portsmouth to consider the whole subject of mechanical, electrical, and voice communication between the decks and engine rooms of men-of-war.

NUREMBERG.—It is stated that the electric lighting of the Nuremberg theatre, which has been in hand for a considerable time, will not be completed for some weeks yet, "owing to the fact that the gas engine supplied was not nearly powerful enough."

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 1st inst. were £3,555, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST AFRICAN CABLES.—The cable steamer "Dacia" arrived at the moorings off the Silvertown works on Sunday, the 3rd inst., after successfully completing her portion of the work in connection with the laying of the West African Company's cables.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for September were £25,600, and the receipts for the period from 1st January to 30th September, £195,560; for the corresponding months in 1885 and 1884, £217,240 and £208,680 respectively.

TELEPHONIC COMMUNICATION BETWEEN PARIS AND BRUSSELS.—M. Granet, the French Minister of Posts and Telegraphs, is now in Brussels in order to discuss with the Belgian Government the terms of the proposed arrangements for connecting Paris and Brussels by telephone.

ANOTHER FORGED TELEGRAM.—At the Mansion House last week Henry Burnell was fined £5 for sending a fictitious telegram to a Mrs. Cooke to the effect that her husband had severely injured his hands.—In the Hammersmith case reported last week the offending woman has been fined £3.

TELEPHONY IN GERMANY. — The trunk line between Stuttgart and Heilbrow has proved to be a commercial success; the average daily number of communications now amounts to sixty. Lines have now been completed between Stuttgart, Ulm, and Friedrichsafen—a total distance of 200 kilometres.

THE TELEGRAPH CLERKS.—The Postmaster-General has replied to the telegraph clerks of the London Central Telegraph Office, in answer to their petition for a better scale of pay. He sees no reason for disturbing the classification of 1881, by which the staff of the central station received considerable benefit.

THE TELEPHONE IN BELGIUM.—The system of "delivering" telegrams by telephone (if the Hibernicism be permissible), which is being tentatively introduced in this country, has in Belgium become very widely employed. In that country, in the month of July last, no less than 31,812 telegrams were telephoned to their destination.

A CHURCH LIGHTED BY ELECTRICITY.—The church of St. Anne, Chasetown, near Walsall, which was built by the munificence of the late Mr. J. R. M'Clean, M.P., together with the National Schools, is now supplied with the electric light from the Cannock Chase Colliery Works, where an electric lighting plant has for some time been in use.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of Sept. was 2,675, estimated to produce £2,250, against 2,583 messages, producing £2,160 in the corresponding month of last year. The traffic receipts for the month of June, estimated at £2,775, realised £2,767.

AN ELECTRICAL BALLOON.—The French Government have not yet given up the hope of finding a really successful method of steering balloons. At Meudon a very large balloon is now in course of construction; it is to be steered by means of a continuously-rotating sail-rudder, driven by an electro-motor, for which a primary battery will supply current.

THE SPRAGUE ELECTRIC RAILWAY SYSTEM.—Pressure upon our space this week compels us to hold over an important and interesting account of the Sprague Electric Railway system, which, it seems probable, will before long be definitely adopted for the New York elevated railways. We hope next week to be able to publish full details of the system.

BOOK RECEIVED.—From Messrs. Cassell and Company we have received a copy of "Electricity in the Service of Man, a popular and practical treatise on the application of Electricity This work is translated from the German of Dr. Alfred Urbanitzky, and edited with additions by Dr. R. Wormell M.A. The introduction is written by Prof. John Perry, F.R.S

SECONDARY GENERATORS POPULARLY EXPLAINED.—One of the Brussels daily papers thus expounds the theory of the action of transformers:—"They attract to themselves electric molecules which have been endowed with an alternating motion with high tension in the central cable, and they transform the said molecules into a small current of great quantity, but of less tension."

PROPOSED CENTRAL LIGHTING STATION AT TRENTE.—The Municipal Council at Trente has unanimously decided to introduce electric lighting, and has applied to the Government for the necessary authorisation. The River Fersina will furnish 600 available horse-power, and the engineer of the town estimates that the total cost of an installation upon this scale will not exceed £18,000.

Digitized by Google

ELECTRIC LIGHTING IN BELGIUM.—The surface works of the Noël-Sart Colliery, at Gily, are now lit with four arc and 120 incandescent lamps. The current is supplied by two Crompton dynamos. At Antwerp Messrs. Beuckelair's large biscuit factory has recently been supplied with 18 arc and 400 incandescent lamps. The arc lamps are of low candle-power, and are worked upon the same circuit as the incandescents.

PROPOSED ELECTRIC RAILWAY AT LITTLEHAMPTON.—From a local journal we gather that at the next meeting of the Littlehampton Local Board plans for a proposed electric tramway are to be laid before the Board. The account from which we quote states that "Mr. Gantham, C.E., has prepared the plans, and Mr. Volk, proprietor of the electric tramway at Brighton, will, it is hoped, construct, stock, maintain, and work the electric railway."

FLUORESCENCE OF MANGANESE.—M. Lecoq de Boisbaudran has communicated to the Paris Academy of Sciences some interesting experiments on the "Fluorescence of the Compounds of Manganese subjected to Electric Effluvium in Vacuum." The fluorescence of some of the compounds of manganese is an extremely sensitive reaction, and the author of the paper considers that the method may be employed for the detection of minute quantities of the metal.

THE TELEPHONE IN SPAIN.—Six years ago the inhabitants of Bilbao applied to the Spanish Government for permission to supply themselves with a telephone exchange. The subject having now received due consideration, the necessary permission has just been granted. We learn that it is proposed to fit up a telephone for the use of any one of good position who asks for it free of all charge for one year, with the option at the end of that period of continuing it at a fixed tariff.

REGULATION OF DYNAMOS.—A recent American dynamo is regulated by the movement of the commutator. The commutator bars are set at a small angle with the axle of the machine, and thus if the commutator be moved longitudinally upon the axle the brushes slide from one bar to the next. It is not difficult to form an opinion as to the probable value of this device. The same object might evidently be obtained by sliding the brushes longitudinally instead of the commutators.

KING'S COLLEGE, LONDON.—Prof. W. Grylls Adams, F.R.S., will deliver a course of lectures on electricity and magnetism, and their applications to electric lighting, transmission of power, &c., at King's College, during the academical year 1886-7. A course of practical work in electrical testing and measurement, with especial reference to electrical engineering, will also be carried on under his direction in the Wheatstone laboratory. In the Wheatstone laboratory there are also special courses of practical work for students preparing for the science examinations of the University of London.

ANOTHER BRITISH EARTHQUAKE.—Information has been received at Lerwick stating that two shocks of earthquake had been experienced at Baltasnd Unst, Shetland, on Monday night. The first shock was felt at eleven, the other two hours later. Several people were roused from sleep by houses trembling and china rattling. Both shocks last several seconds; but no damage occurred to property. Baltasnd is situated in the Shetland Islands, and is the most northerly of Her Majesty's dominions. Twenty years ago an earthquake was experienced at the Flugga Lighthouse, Unst.

ELECTRIC LIGHT IN TEXTILE FACTORIES.—A prize of the value of £25 is offered by the *Deutsche Wollen-Gewerbe* (a journal devoted to the textile industry), for the best paper on the employment of the electric light in various textile works. The paper must deal in detail with the different systems of electric lighting, with the prime movers, and must also contain comparisons between oil, paraffin, gas, and electric light, with regard to first cost, working expenses, danger from fire, hygienic considerations, and the influence on the sight of the operatives. The papers must be written in German.

THE TIVOLI INSTALLATION.—This installation has now been brought into successful operation. It consists at present of about 200 Cruto lamps, each of 50 candle-power, 80 lamps of 16 candle-power (presumably Edison) which are used for lighting the public offices, and six Siemens arc lamps of 200 candles. Transformers upon the Gaulard-Gibbs system are employed, and the primary circuit extends over a length of 30 kilometres. The motive power for the alternating machine is derived from two turbines on the Tiber. This little town, which is not far from Rome, was previously lit by oil lamps.

POLICE TELEGRAPHS.—The commission of inquiry appointed after the riots in the West End which occurred in February last has just presented its report. Among other things they recommend that the system of police telegraphs which connects the principal stations in different parts of the metropolis should be largely extended, so as in effect to enable each police station to communicate with all others in the same district. They also recommend that every police officer be empowered upon due occasion to send an "urgency" telegram from any postal telegraph office, and that such telegrams shall have priority of transmission.

THE PARIS G.P.O.—Much disappointment is expressed that it should have been definitely decided not to light by electricity the new building for the Paris General Post Office. The architect has explained at some length his reasons for prefering gas, but they will scarcely convince any one not previously of the same opinion. M. Gaudet's idea that it is easier to "distribute" gas than electricity, of course, arises simply from want of information. His further argument that the methods of producing electric light continue to undergo unlimited improvement week by week is, we fear, equally fallacious. Considering that motive power is to be provided for other purposes, we certainly agree with the French journals that a mistake has been made in this matter.

ELECTRIC LIGHTING IN MINES.—Speaking at the recent meeting of the Montana Company, Mr. John Bayliss, in the course of his address to the shareholders, after his visit to the company's mines in America, said, referring to the introduction of the electric light, that the total cost of the installation had been 3,665 dollars, and that the cost per month for working, including maintenance and interest on the capital, was 250 dollars. The old system of lighting cost 500 dollars per month, so there had been a saving on this item of 3,000 dollars a year on an expenditure of 3,665 dollars. Beyond that there was the untold saving arising from their comparative immunity from fire by the electric light, compared with their position under the old system of oil and candles. It was intended to extend the installation to the new 60 stamp mill, but the cost would not exceed 1,200 dollars.

ELECTRIC LIGHTING IN GERMANY.—A company calling itself the North German Electrical Works has just completed its first central station in Hanover. Electricity is supplied to customers who undertake to subscribe for three years, payment being by meter at the following rates:—·42 pence per lamp hour for a 10-candle lamp, and ·5 pence per lamp hour for a 16-candle lamp. It is proposed to light the river docks at Frankfort with four arc and 280 glow lamps. The first cost is estimated at £2,200, and the working expenses at £160 per

Digitized by Google

annum. Since the beginning of the autumn season, with the 1st of September, the town theatre in Cologne has been lighted by electricity. This installation was planned and carried out in the short space of eight weeks, and has worked from the first without a hitch. It has been undertaken by the Gas and Waterworks Company of Cologne, and the same company is now preparing plans for a central station in Cologne.

"SQUAWKERS" FOR EXPERIMENTS IN STATICAL ELECTRICITY.—It is possible that some of our readers may not be familiar (by name at least) with the instrument of torture known in the States by the onomatopoetic and euphonious name of "squawker." They are, however, exceptionally fortunate if at some period of their existence they have not been exposed to its distressing effects upon the auricular nerves. A squawker is a small india-rubber bag, which, being inflated by the the lungs of a small boy, emits a dismal and discordant shriek while the air issues through a wooden pipe. The *Scientific American* recommends the employment of this apparatus in place of the traditional pith ball for illustrating the phenomena of statical electricity. If two or three such balls be inflated they can readily be electrified by stroking with a cat-skin, and may then be floated in the air. A number of interesting and instructive experiments with this apparatus will readily suggest themselves.

THE CONSTITUTIONAL CLUB.—The new and palatial building of this club were opened on Monday last. The architect for the work is Mr. R. W. Edis, F.S.A., and the façade forms one of the most striking features of Northumberland Avenue. A unique arrangement has been adopted in the artificial lighting. Incandescent electric lights are fixed in the ceilings, and so arranged as to harmonise with the treatment of the decorations. In the day time the means of artificial lighting are effectively concealed; while at night the uniform glow, distributed from the ceilings throughout the whole area of the rooms, forms the nearest possible approach to daylight. The electric machinery is erected in the basement of the building, both the engines and the dynamos being in duplicate. The idea of lighting the building in this manner originated with the architect, and has been efficiently and completely carried out by Messrs. B. Verity and Sons, of Covent Garden, who have also just lighted the Junior Carlton Club.

THE EXHIBITION AT THE PALAIS DE L'INDUSTRIE.—The following is a list of the more important electrical novelties which are to be seen at the Exhibition of Arts and Sciences at present being held in Paris:—New dynamos by Scrive-Hermite and one by Mondos; a machine exhibited by the Société Centrale d'Electricité, and an alternating current machine by M. Goulard; primary battery designed for electric lighting by M.M. Goodwin, Buchin, and Tricoche, and one by M. Lagarde; secondary batteries by Julien (designed for electric traction) and by M. Reynier; a secondary generator by M. L. Clerc; a coulomb-meter and watt-recorder by M. Jacquemier; an alternating current recorder by M. Cauderay; incandescent lamps by M. Lodyguine and by M. Werndl; arc lamps by M. Clostermann and by M. Pieper; electric tramway on the Julienne system; a long distance telephone transmitter by M. Ader; and a model of a species of telpherage system by M. Radiquet. We hope shortly to give detailed accounts of such of these exhibits as seem likely to become of any practical importance.

ELECTRIC LIGHTING AT LISKEARD.—The *Western Morning News* of the 4th inst. contains the following:—"Liskeard was on Saturday evening illuminated by the electric light for the first time. Eight arc lamps of 1,200 candle-power each were used in an area comprising the Parade, Pike-street, Market-street, Fore-street, Bay Tree-hill, and Barras-street. The experiment was most successfully conducted under the superintendence of Mr. Wharton, of the firm of Laing, Wharton, and Co., assisted by Mr. Perrott. The light was most brilliant and steady throughout. The streets were crowded with sightseers, all of whom were loud in their praise of the arrangements, and many expressed the hope that the light might become a permanent institution. This evening some of the shopkeepers will have their establishments lit by electricity, and it is intended that lights shall be generally distributed in the various shops during the next three weeks. On Thursday Mr. Wharton will deliver in the Guildhall a lecture on electric lighting. The Mayor will preside. The hall will be suitably lit for the occasion. On Friday week the parish church will be illuminated for the harvest festival service."

SELF-INDUCTION IN VOLTMETER COILS.—In reply to a correspondent, M. Hospitalier gives the following experiment, to illustrate the effects of self-induction in the coils of a voltameter:—Place in circuit an incandescent lamp, an electro-dynamometer, a resistance without self-induction, and an alternating current machine, and connect the voltmeter in parallel with the lamp. By adjusting the speed of the machine and the value of the resistance, bring the lamp to its normal luminosity; note the readings of the dynamometer and the voltmeter. Now increase the speed of the machine, and by adjusting the resistance again reduce the lamp to normal incandescence. The dynamometer reading will be the same as before, but the voltmeter reading will be smaller. The greater the increase in the velocity, the greater will be the difference between the two readings of the voltmeter. Are we to imagine that the number of watts consumed in the lamp is different in the two cases? Certainly not. We are simply to conclude that a voltmeter containing a coil inductively-wound, especially if there be also a soft iron core, is utterly useless for measuring alternating currents.

USE OF THE MICROPHONE FOR DETECTING LEAKAGE.—The microphone has several times rendered important service in the United States in the detection of the exact locality of a leak in an underground water main. Experiments have recently been carried out in Germany by some of the water companies, with the result that the instrument has been definitely adopted for the purpose as a part of the regular equipment of the companies. The apparatus consists of a microphone of any ordinary construction, a dry battery, and a telephone. It is used principally for the detection of badly-fitting water cocks. When the microphone is placed upon the cock it is stated that a leak of only one or two drops per second causes sufficient vibration of the metal to give perfectly distinct indication in the telephone. We are pleased to hear that experiments have proved the method to be successful in practice. We should almost have been inclined to fear that at any rate in large cities, where so many "earth" connections are made with gas and water mains, a telephone in the immediate neighbourhood might frequently be influenced by direct induction from currents in the mains themselves.

GLASGOW COLLEGE OF SCIENCE AND ART.—We observe from the syllabus of the Glasgow College of Science and Art that the winter session commences this week. Both day and evening lectures are given in magnetism and electricity, and electrical engineering; and an important step has been taken in the establishment this session of an honours practical class for electrical testing and research, under the direction of Principal Jamieson and his assistants. This class has been started with the view of enabling young electrical engineers

Digitized by Google

to become familiar with the scientific apparatus and tests so very necessary in connection with their profession. The Glasgow College has had a remarkably successful career. At the last May examinations of the City and Guilds of London Institute one of the students gained the first place in honours, with £5 and silver medal, in telegraphy, while another took the second place in the ordinary stage, and a third the second place in the same stage in electric lighting and transmission of power. The science and art passes, combined with the six Whitworth scholarships, seem to have been largest from this than from any other technical institution in the kingdom. The John Pender gold medal has been carried off by John Macfee, jun., superintendent of the Paisley Telephone Branch of the National Telephone Company's Scotch system.

THE CANADIAN PACIFIC TELEGRAPH SYSTEM.—The *Electrical World* says:—The opening of the Canadian Pacific Railway's telegraph took place September 13, with a through line from Montreal to the Pacific coast, and with a maze of branch lines, giving connection with all centres of trade and population in Canada. On commencing operations the company will have four direct wires between Montreal and Winnipeg, two of which will be used for the movements of trains and other railroad matter. This will leave two wires for commercial business. The wire used in this gigantic circuit is No. 6, and is of a grade particularly designed for long circuits. It was imported from Germany, where it was manufactured under the specifications adopted by the company as a standard. Before the wires of the company were completed right through to Winnipeg the opinion was expressed that, despite any precautions which could be taken, it would be impossible to operate this circuit of 1,422 miles without the use of at least four repeaters. But, as a matter of fact, only one repeater will be required, and even this will be dispensed with in clear, dry weather, such as generally prevails during the winter. The company makes connections at Richford, Vt., and Morristown, N.Y., with the Postal Telegraph Company of the United States.

PROJECTED ELECTRIC RAILWAY IN BUDA-PESTH.—A correspent of *Industries*, writing from Vienna, says:—Within the last few years the town of Buda-Pesth has developed at a very fast rate, and the present means of communication are beginning to be inadequate. An electric railway has been proposed, which is intended to connect the central parts of the town with steam tramways in the suburbs. The project is for a double line, about three miles long, part of which will be laid along the lower embankment of the Danube, on an iron viaduct. The existing traffic and the view to the river will not be impeded, there being a clear headway of 12ft. 6in. between the ground and the under side of the girders on which the viaduct is supported. That portion of the line which crosses the Franz Josefs-square will be underground, the head of rails in the tunnel being 13ft. below the pavement. Since at so small a depth there would be no room for masonry arches, it is proposed to form the ceiling of the tunnel of iron girders, which will rest on the side walls, and be supported in the middle by a row of columns placed between the two lines of rails. The maximum gradient is 21·7 per thousand, and the sharpest curve will have a radius of 150ft.; each car will have its own electromotor, and the rails are to be used for the out and home circuit. The current will be supplied by fixed engines and dynamos.

SOME NEW LECTURE EXPERIMENTS.—Under the title of "New lecture experiments upon the transportation of electric energy," *l'Electricien* describes several interesting and instructive experiments with induction coils. To illustrate some of the effects of self-induction the following arrangement is suggested. A battery which is capable of supplying a sufficient number of watts to light up a small incandescent lamp, but which at the same time has not sufficient E.M.F. to do so under ordinary circumstances, is joined up with the primary of an induction coil, the latter being provided with the usual vibrating break. The lamp is connected as a shunt across the terminals of the coil, the secondary circuit in this case remaining unclosed. As soon as the current is switched on, the "extra current," due to the self-induction of the coil, will light up the lamp. To make this experiment successful, the total volt-amperes in the primary circuit must clearly, however, be considerably in excess of that required by the lamp, and the condenser should also be disconnected. The action of transformers and the phenomenon of mutual induction may be conveniently illustrated by means of two similar Rhumkorff coils. The secondary circuits having been connected together, a battery is placed in circuit with the primary of the first coil, and the vibrator of the second is screwed down. The current generated in the primary of the latter coil then illustrates the action of the secondary circuit of a transformer.

CITY AND GUILDS OF LONDON TECHNICAL COLLEGE, FINSBURY.—The Old Students' Association of this college held its first annual dinner on Friday last at the Duval Restaurant, Strand. A distinguished company, numbering over sixty, of members and friends interested in the welfare of this young and flourishing association, was present, under the chairmanship of its first president, Mr. H. Newman Lawrence, and included Prof. S. P. Thompson, D.Sc., Principal of the College, Prof. J. Perry, F.R.S., Prof. Meldola, F.R.S., Prof. W. E. Ayrton, F.R.S., and Prof. H. Armstrong, F.R.S., of the Central Institution; Mrs. Ayrton, the Rev. T. J. Lawrence, M.A., L.L.M., Camb. University Extension Lecturer, Mrs. Mercer, and others. The after dinner proceedings were most enthusiastic, the toasts of the "Technical College," proposed by the chairman, and responded to by the Principal, and the "Old Students' Association," proposed by Dr. Thompson, and responded to by the President and the president-elect (Mr. A. Chatterton, B. Sc.), were especially well received. It is needless to say that with the gentlemen named above present many excellent speeches were made, and a most enjoyable evening spent. It was announced that the silver medal of the association for the best paper read at the discussion meetings has been awarded to Mr. A. W. Slater, for his paper on "Torpedoes." Such a cordial and enthusiastic gathering of professors and students, past and present, speaks well for the internal working of the educational system, inaugurated and so well maintained by the City Fathers, and we heartily wish the Old Students' Association continued and increased success.

HAVANAH-KEY WEST CABLES.—The Silvertown Company has received a telegram from Mr. Theophilus Smith, engineer-in-charge of the cable steamer "International," announcing the completion, on the 4th inst., of the repairs to the duplicate cable between Havanah and Key West. These repairs give the International Ocean Telegraph Company, of New York, a practically new cable from end to end, as the part untouched by the "International" was laid during repairs carried out within the last two or three years. The type of cable employed is specially protected to withstand the corrosive action of the bottom on the sheathing, this action having been very noticeable in the cable hitherto laid in this locality. Although more than ordinary care has been exercised in the relaying, it is impossible to free this cable from the danger of damage from the hot pitch springs met with on the north coast of Cuba, in depths ranging up to 800 and 900 fathoms. The operations completed were of no ordinary character, as a large

Digitized by Google

portion of the work was carried out in the axis of the Gulf, where, dependent on the winds to a great extent, the current varies from half a knot from the eastward to over five knots from the westward, the normal direction of the flow. Mr. Theophilus Smith has had the advantage, during the operations, of the local knowledge of Mr. M. L. Hellings, who is cable manager of the International Ocean Telegraph Company, and who has either superintended or has been present at every repair to this company's cables during the last twelve or fourteen years. Mr. March Webb and Capt. Wilson-Barker, R.N.R., were respectively chief electrician and commander on board the "International."

AN ELECTRIC LOG.—Some few weeks ago, in the columns of a recently established contemporary journal, we noticed an account of a newly invented ship's log, in which electricity played the part of a recording agent. The device was ingenious, but as it did not appear to have been carried into practice we did not consider the paragraph worth reproducing. We have since learnt that the same, or a very similar device was actually employed, as long ago as 1882, on board some of the ships of the Compagnie des Messageries Maritimes. This earlier electric log was the joint invention of two officers of the company, Captains Fleurias and Bretel. It consisted of a screw, having several blades, which, when thrown into the water and dragged behind the ship, revolved in an open framework. An insulated wire was connected with this frame in such a way that at every revolution of the screw contact was made with the extremity of the wire, and a circuit was thus closed through the water to the ship. The circuit was completed on board by means of a battery and a telephone. Knowing the number of revolutions of the screw corresponding to any required distance traversed, it was easy to obtain the rate of sailing by listening at the telephone, and counting the number of contacts made during one minute. This arrangement seems to have been quite successful in action, although we do not know whether it is still in use. The more recent invention referred to above differs only in respect to the manner in which the number of revolutions of the screw is ascertained, and in this respect it is certainly an improvement. The telephone is replaced by an electro-magnetic speed counter, which receives a step-by-step movement every time the circuit is closed. We see no reason why these devices should not be perfectly successful and reliable in operation, and they might well supersede the primitive method of counting the time-honoured "knots" as the line slips through the seaman's hands.

THE BRUSH MOTOR.—The Brush Electric Company are now manufacturing at their Cleveland works an electro-motor which is electrically the counterpart of the well-known Brush dynamo. The regulation is effected mechanically by a somewhat novel method, which is described as follows:—A centrifugal governor is provided, consisting of a metallic shell securely bolted to the armature shaft. To the inner periphery of the shell are pivoted on opposite sides of its centre two governor arms, the inner and free ends of which are connected to the opposite arms by spiral springs. On each of the arms are placed adjustable weights. To the arms near their free ends are pivoted links, the opposite ends of which are connected to the commutators; the latter are set loosely on the armature shaft. As the governor shell rotates with the armature shaft, carrying with it the parts described, the weights will at a certain speed be moved by centrifugal action towards the periphery of the shell, and through the medium of the connecting links will impart a rotary adjustment to the commutator, varying its position in the armature shaft. When the motor is at rest, the spiral springs will retain the weights in close proximity to the shaft and the commutator, at the extreme limits of its rotary adjustment in one direction, and the brushes will bear on the maximum points of the commutator. When current is switched into the motor, rotary motion is imparted to the armature and its shaft, the speed of which gradually increases until it has attained its normal velocity, when the governor weights will begin to recede from each other, and rotate the commutator on the shaft carrying its maximum point away from the contact of the brushes. This action decreases the effect of the current until a point is reached where this effect is balanced by the load on the motor, and the speed remains constant. On the other hand, should the speed of the motor be retarded by an increase of current or an increase of load, the governor weights will be drawn towards each other by the spiral springs, and thereby rotate the commutators in the opposite direction, the effect of which is to move the maximum points nearer to the brushes, and thereby increase the speed. The direct connection of the governor with the commutator would seem to ensure prompt adjustment of the latter without loss of motion, and at a minimum expense of power.

ELECTRIC LIGHTING IN LEEDS.—The *Leeds Mercury* of the 30th ult. contains the following:—"This system of lighting is being rapidly pushed forward in Leeds, and apparently with good results. The new building of Messrs. Goodall, Backhouse, and Co., White Horse-street, Boar-lane, has been furnished with the electric incandescent lamps, as also have several parts of the old building. The installation consists of one of Crompton's compound self-regulating dynamos, and some 300 16 candle-power Edison-Swan incandescent lamps of 110 volts each. The dynamo is a very powerful and substantial-looking machine; and the field-magnets are made of the best soft wrought iron, planed all over, and polished bright. It is driven from a countershaft by a pair of engines with cylinders 14in. diameter, 28in. stroke, capable of working up to 100 horse-power. The machine is run at a speed of 525 revolutions per minute. In arranging the power it was at first thought that accumulators would be absolutely necessary, on account of some 80 to 90 lights being occasionally required after the main engine stopped. This difficulty, however, Mr. Wilson Hartnell surmounted by putting down an auxiliary engine, and this at about one-fifth the expense. The latter is one of Turner's 4 horse-power (nominal) vertical engines, fitted with Hartnell's patent governor. It is arranged to drive on to the same countershaft as the main engine, and a fast and loose pulley are provided for each. It can be started before the main engine stops to maintain a continuous light. In the main driving belt provision has been made for transmitting upwards of 300 horse-power. The main switch-board (Hartnell's patent) is fixed near the dynamo. They are double-pole switches with quick action, and the making or breaking of the contact is done instantaneously on both the positive and negative wires at the same time. Double-pole cut-outs are also provided, as well as a small fusible cut-out to each lamp in the branch leads and at the main junctions. In the offices the lamps are suspended by silk flexible cords from ceiling plates, corresponding with the ornamental ceiling. Each lamp is fitted with suitable shades, and the whole has a very pleasing appearance. The electrical work has been carried out by Mr. Wilson Hartnell, consulting engineer, Leeds; and we are informed that the work has given satisfaction to all concerned." We recently had the pleasure of looking over this installation, and fully endorse the above commendation. All details, both as to design and execution, have been thoroughly well worked out. It may be added that the engines are by Messrs. Mann and Co., of the Elland-road Works, Leeds.

INSTALLATION AT WENTWORTH CASTLE.

The owners of valuable pictures, and rare books, as well as the owners of expensive furniture and elegant fittings, and those who live in houses highly decorated, have each and all a distaste for gas. Many refuse to use it, and have hitherto trusted to candles or oil for artificial light. The cry of the age is for more light – more light physically as well as mentally. Nature never intended that man should emulate the cat, and try to gradually evolve a different type of eye. Yet this seems to be the usual plan. Darkness made visible is applicable to the state of many a dining and drawing room. Surely numbers of eyesights suffer from the stupidity that prefers three or thirteen candles to four or forty, or too little light instead of sufficient. If work is necessary after the sun is down, that work be it reading, sewing, drawing, or factory work, should be performed in as good a light as can be obtained. It may be said that gas will give all that the electric light will give, but this we firmly and emphatically deny. The adoption of the electric light at Wentworth Castle and similar places will assist to dispel the illusion. Gas at its best is a bad medium for lighting, and can hardly be said to be comparable to the incandescent electric light.

Fig. 1.—Wentworth Castle.

Wentworth Castle (Fig. 1), near Barnsley, the seat of Thomas C. F. Vernon Wentworth, Esq., has recently been lighted throughout by the electric incandescent light, by Mr. Wilson Hartnell, M.I.M.E., of Leeds.

The electric light installation consists generally of the engines and boilers, dynamos, and everything complete. The whole installation consists of over 500 lights, with provision for 600. As an example of the application of the electric light to a large mansion we think it sufficiently interesting to give a description in detail.

Commencing with the machinery, there are a pair of 12 horse-power Cornish boilers, by Marshall and Sons, of steel, of most modern construction, all the holes being drilled, the flues strengthened by Adams's seams throughout, and suitable in every way for a working pressure of 80lbs. The boilers are 14ft. 9in. long, 5ft. 3in. diameter, with a 2ft. 10in. flue. All the rivet holes in the boilers were drilled by special machinery, and the boilers tested by hydraulic pressure to 160lbs. per square inch. They are provided with a full set of steam and furnace fittings and mountings. For supplying the boilers with water a No. 5 Giffard injector and a No. 0 Blake boiler feeder are used, each with suitable connections, and either of these is capable of feeding both boilers if required. Figs. 2 and 3 show a plan and an elevation of the dynamos and engine.

A large tank has been specially provided for the water supply. The chimney is of wrought iron, placed near the trees, so as to be as little prominent as possible. It rises without stays from a stone basement, to which it is secured by bolts of some 13ft. in length.

The engines are horizontal (Fig. 4), with cylinders 10½in. diameter, 16in. stroke, fitted with Hartnell's patent automatic expansion governor. The speed is 140 revolutions per minute, at which they will indicate 35 horse-power, each cutting off at about one-third the stroke. The engines drive a steel countershaft,

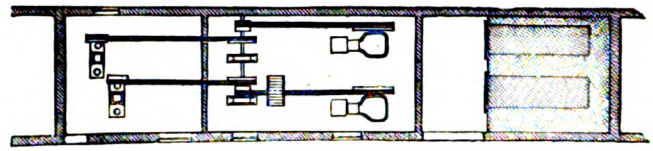

Fig. 2.—Plan.

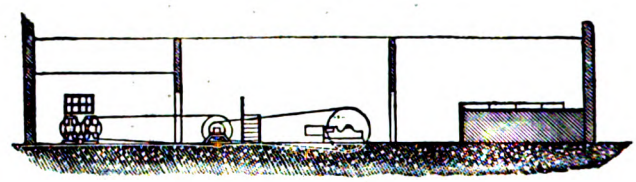

Fig. 3.—Elevation.

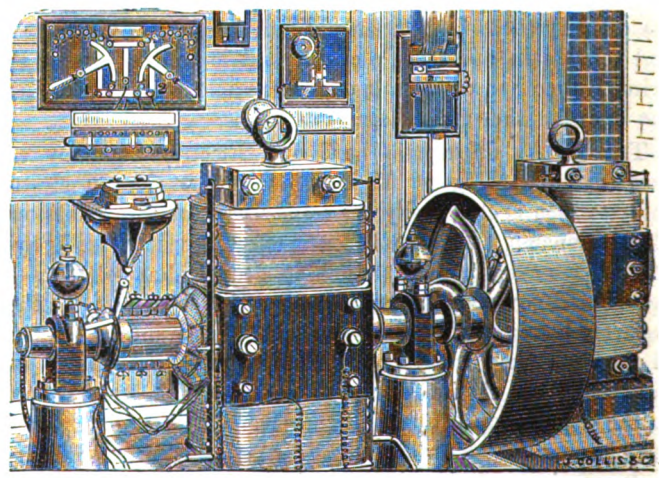
running in phosphor-bronze bearings, the latter carrying four pairs of fast and loose pulleys, two pairs of which are for the dynamos and two pairs for the engines. The object of this arrangement is that either or both engines can drive either or both dynamos, and either can be stopped or started independently of the other. We may remark that the engines and dynamos are in duplicate, each set being capable of working about 300 lights. The whole of the machinery is fixed on heavy stone foundations. The dynamos are two 15-unit Crompton compound-wound machines of the slow-speed type. There is a novelty in the winding and the coupling of these machines. The compound winding is such that the E.M.F. with a constant speed rises with the current to allow for the resistance of the main leads, the total rise with the maximum 320 amperes being from 110 to 134 volts, so as to maintain a constant E.M.F. at the castle. This includes an allowance due to the estimated reduction in the speed of the engine with a heavy load. A special method of coupling the dynamos had to be adopted owing to this variation of the E.M.F. (which shall hereafter be described), so that one dynamo could be started or stopped whilst the other was at work without affecting the E.M.F.



Dynamo Room—Wentworth Castle Installation.

The dynamo main switch-board consists of a black enamelled slate, carrying one of Hartnell's patent compound switches (Fig. 5) for each dynamo. Each switch has eight contact terminals, six of which make or break contact in stopping or starting the dynamo. The advantages of these compound switches over a large number of independent switches are that by one switch all the shunts or circuits necessary to be made or broken in

Digitized by Google

starting or stopping a dynamo are effected by one movement in the proper manner and in their right order. No mistake being possible, no skilled manipulation is required. By a further movement of either of these switches the current of

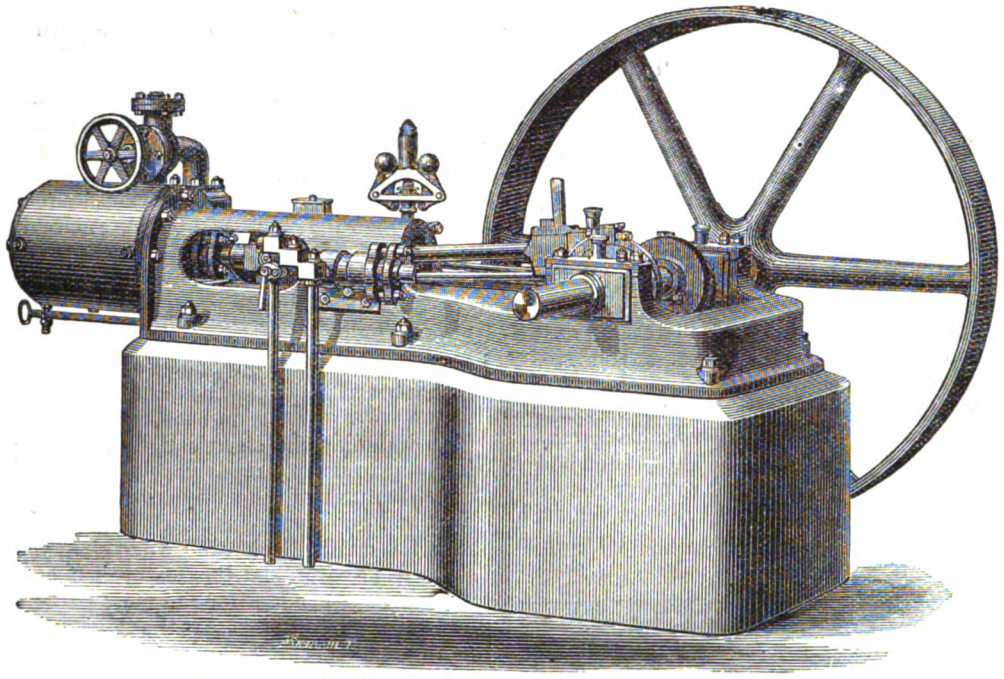


FIG. 4.—Marshall's Engine, Wentworth Castle Installation.

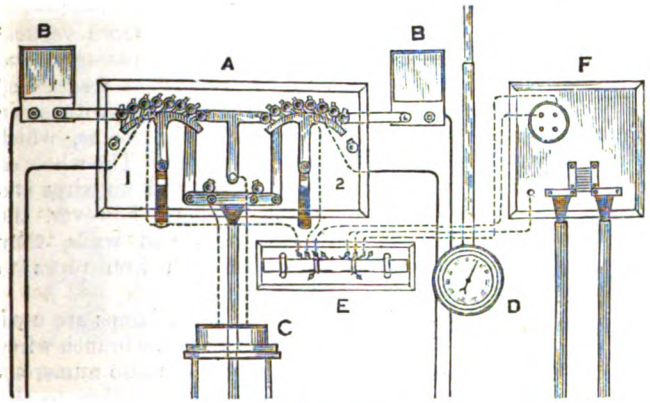

FIG. 5.

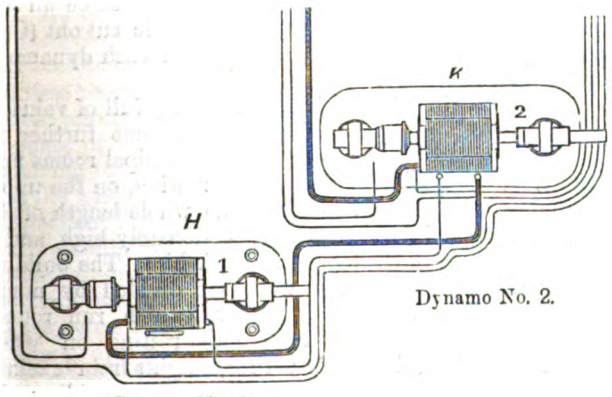

Dynamo No. 1.

In this figure A represents the compound switch, C the Crompton-Kapp current motor, D the Cardew voltmeter. E is the voltmeter switch-board, and deserves some explanation. It consists of a positive and negative brush, which by means of a slide can be connected to either of four pairs of positive and negative brushes. Thus the E.M.F. can be measured at either dynamo, at the Castle distributing board (by means of a pair of wires laid with the main cables), and at the local circuit. F is the negative board; it carries a fusible cut-out on the negative cable. G (Fig. 5A) is the E.M.F. regulating switch; its use is to maintain a constant E.M.F. at the Castle, notwithstanding any disturbance due to the lights on the branch cable leading to the stables, &c., and other purposes. The variations due to the Castle itself are provided for in the compound winding. This regulating switch-board carries two resistances, one for each dynamo, through which the current round the dynamo shunt travels. By means of a slide and two brushes, and 32 small terminals to each resistance, the resistances may be cut out 1-3rd at a time. H and K show a plane view of No. 1 and No. 2 dynamos, with a diagrammatic representation of the connection. It must be remembered that these dynamos are not compounded to give a uniform E.M.F. irrespective of the current. On the contrary, the E.M.F. varies with the current, and is constant 300 yards away at the Castle. Thus the ordinary methods of coupling dynamos in parallel would fail in this case. The return wire passes first to dynamo No. 2. The return current traverses No. 2 (in four parallels) and then passes to No. 1 dynamo, which it similarly traverses, and is there at liberty to return to the negative brushes of either or both dynamos. The details of these connections can be readily thought

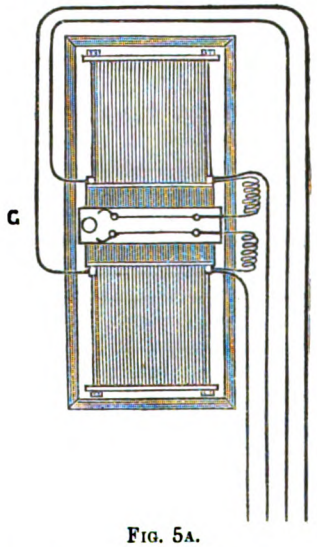

FIG. 5A.

out, but would be tedious to minutely describe. The shunt wires, as before stated, start at the 5th brushes of the switch, and thence pass to their respective resistance coils in the regulator G, and then return to the positive ends of their own dynamo coils. Thus each dynamo is similarly excited, whatever be the E.M.F. or the current in the main cables. It may be noticed in passing that the same result might have been produced by the return current being equally divided before passing to the coupled negative brushes. In either case the series coil of the dynamos must be large enough to carry twice the current it is intended to produce. In like manner, if three dynamos with a rising E.M.F. had to be coupled, the series wires must carry three times the current generated by each dynamo, and so on.

Digitized by Google

either dynamo can be separately measured. There is also a small switch-board connected with the voltmeter for measuring the E.M.F. of either dynamo, the E.M.F. at the castle, and the E.M.F. of the lamps in the immediate neighbourhood. A branch is taken off from the main cable underground for supplying the outbuildings. This branch necessitates making a further adjustment of the E.M.F. at the dynamo to keep it constant in the castle. This is effected by a variable resistance in the shunt coil of each dynamo, which can be simultaneously adjusted by a small switch-board, having 36 terminals to each resistance, so that the same adjustments serve for either or both dynamos. This resistance will be automatically worked by Hartnell's patent electrical governor. It will be noticed that this governor has only to correct small differences of E.M.F., due to several disturbing causes, the adjustment for the most part being effected by the compound winding and Hartnell's automatic expansion governor on the engine.

Fig. 6 shows the compound switch-board. The main switch-board A carries two quadrant switches, No. 1 and No. 2. The diagram shows each switch turned fully. Above each quadrant are eight copper brushes, seven of which rest on the quadrants. The brushes are carried on suitable terminals, with connections behind the switch-board. The switch-boards are all of black enamelled slate. The eighth or outer terminals are connected with dynamos No. 1 and No. 2 respectively. The fifth terminals are connected to the positive ends of the shunt

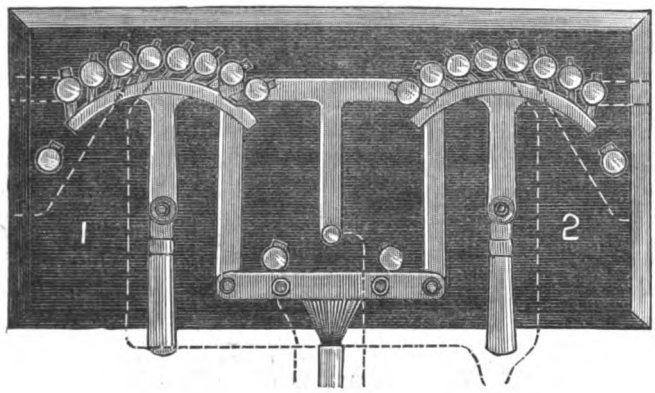

Fig. 6.

wires of their own dynamos. The second terminals are connected to the positive main cable. The first terminals are connected to a T piece, and are used for shunting the current through the current meter by an outer movement of either quadrant, which brings the first brush into contact, and at the same time moves a recess in the quadrant under the 2nd brush, thus breaking the direct connection with the main positive cable. The intermediate terminals are coupled to each other through resistance frames, the object of these being, that if the switch be turned off with the full load on, no risk of damage is incurred by the dynamos. On turning off the switch, when the quadrant leaves the 8th brush the current is shunted through about 2-3rd ohm; on leaving the 7th brush the current is shunted through an additional 2 ohms; on leaving the 6th brush the main current, now reduced, say, to 30 amperes, is broken. When the quadrant leaves the 5th brush the dynamo shunt current is shunted through 30 ohms; and on leaving the 4th brush it is shunted through an additional 30 ohms; and on leaving the 3rd brush the dynamo shunt current is broken. To start the first or either dynamo, its switch must be placed in the upright position shown, thus connecting its shunt wire with its positive pole. The second dynamo started becomes fully excited when its quadrant switch has reached the 5th brush, which connects its shunt to the already positively excited cable.

The main cables to the castle switch-board are composed of 19 strands of No. 10 wire of Callender's most highly insulated cable, and is laid on bituminised wooden supports in a wooden trough filled in with bitumen, the whole being buried in the ground, the cable from switch-board to switch-board being 295 yards (*i.e.*, 590 yards in all). A pair of small wires are laid with the main cable, in order to measure the E.M.F. at the castle, in the dynamo house, and actuate the electrical governor.

The castle is a quadrangular building (see Fig. 1) with a central court; the east and south faces are each about 160ft. long, the western and northern being shorter.

The main leads from the switch-board are as follows:—

			Lamps.
East wing.....	1	North Grand Hall, &c....	73
,, ,,	2	South ditto, &c.	35
Ditto upper floors...	3	North Picture Gallery, &c.	53
,, ,,	4	South ditto, &c.	54
South wing	5	South circuit.....	63
West wing	6	West circuit	49
North wing	7	North circuit.....	73
			400

The distributing switch-board contains seven switches, with provision for eight, on a cast-iron base; there is also a negative switch-board of enamelled slate for the purpose of isolating the negative wires or measuring the current on either circuit.

In designing the electric light fittings great care was taken not only to make them suitable to the architectural or decorative features of the various rooms, but also to make them as light and unobtrusive as possible. The glow lamp, only weighing a few ounces, looks well when simply pendant from its own conducting wires, and this feature has been retained in all the upper rooms, pendant for the most part from light brackets on the walls. In several cases the brackets are floral designs, of light, simple character and graceful form, and free from superfluities, but of the best workmanship, by Messrs. Faraday and Son.

The general distribution of the wires is as follows:—The leads go direct from the switch-board to one or more vertical wires in each wing, with branches through the passages, and branches again into the various rooms, somewhat resembling what may be called the tree system, there being switches in each passage, as well as sundry switches in the rooms, which are with few exceptions, of the Lundberg type. The whole of the wires are laid in grooved woodwork, and no wires laid between the floors, or out of sight. Where, however, the mains necessarily pass through the floors and walls, they are wrapped with asbestos, passed through iron pipes to prevent injury from rats or other cause.

The vitrite holders and Edison-Swan collar lamps are used throughout. Fusible cut-outs are provided for the branch wires to every lamp (with few exceptions). There are also numerous cut-outs to the various main branches. In addition to the cut-outs on the distributing switch-board, the mains are protected by a fusible cut-out on the negative cable in the dynamo house, and there also by a magnetic cut out (Cunnyngham's patent) on the positive leads from each dynamo to the dynamo switch-board.

Wentworth Castle being a place of interest, full of valuable paintings and other objects of attraction, some further detailed description of the lighting of the principal rooms may be interesting. Commencing with the east wing, on the upper floor is the picture gallery, extending the whole length of the wing, 176ft. long and 24ft. broad, proportionately high, and is considered to be one of the largest in Yorkshire. The building being of a classical style, the walls are divided by numerous pilasters supporting the architraves which run round, and there are arches near each end resting on white marble. This is lighted entirely with side lights from brackets of light and special design, in appearance resembling the stalks of flowers rising from a group of leaves and drooping over. Leaves of chased brass are placed at intervals on the stem, which terminates in a globular frosted glow lamp specially made for this installation. The effect is heightened by mirrors placed between the pilasters, the lights on either side of these bending gracefully forward so as to be reflected. There are 107 lamps in this room; the appearance of the lights hanging from their graceful stems, either singly, double, or in groups like bunches of fruit, is exceedingly pleasing, if not unique. The pictures are well lighted, and the whole is seen to great advantage. Omitting the remainder of

Digitized by Google

the upper rooms, we descend the grand staircase, which is lighted by a 7-lamp electrolier (Fig. 8), and enter the Strafford Room, which is lighted by 8 side lights. The walls of this room are lined with valuable pictures, as, indeed, are all the rooms on the ground floor of the east and south wings. Next follows the dining room, lighted by 12 side lights and also by a pendant electrolier for dining table, &c., containing three groups of lamps under three dome shades, which are capable of sliding backwards and forwards (Fig. 9). The apparatus may be described as consisting of spring brushes travelling in + and − rectangular channels, and connecting with a centre by cone bearings so as to allow of a rocking action in the electrolier when being drawn in one direction or the other. The weight of the electroliers is carried by insulated pullies on an independent travelling line. This makes a most effective and brilliant way of lighting a dining room table. Following on is the grand hall, decorated in white and gold, lighted by 16 side lights. These are for the most part placed in front of mirrors, and on light descending stems proceeding from lions' heads, in keeping with the other decorations. It may be here remarked that the whole of the east wall of this story is decorated with mirrors, which have lights on each side of them. The lower floors of the eastern wing consist of several libraries and sitting rooms, which are lighted with side lights on brackets of varied designs.

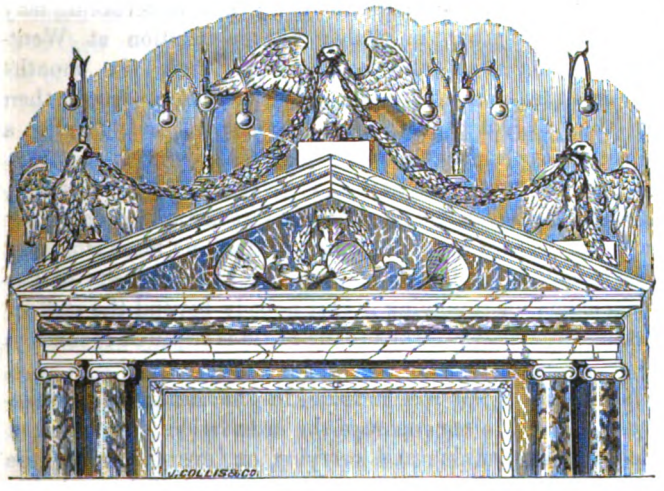

FIG. 7.—Lighting over Mantelpiece in Gallery.

The upper rooms, known as the Swan, Roman, Canopy, and Ark, are lined with tapestry, doors included, which is said to be unsurpassed. These are all lighted by side pendants of various colours, suspended from brackets above the tapestry.

These rooms being also furnished as sitting rooms, there are double jointed brackets on either side of the fireplace for convenience of reading, as there are also in many other rooms. Referring to the other parts of the house it may be remarked that the whole is well lighted, the kitchen, for example, having six pendant lights.

An outside cable is run to the conservatory, which is lighted up for reading and writing, and for lunching, the effect of the light amongst the ferns and flowers, orange trees, and foliage being charming.

There are sundry outside lamps for lighting up the approaches. The outside premises consist of steward's house, stables and coach houses, cow houses, farmyard; also the laundry, dairy, &c., with other appurtenances. To light these a branch cable of Callender's make joins the main cable at about 200 yards from the dynamo station. This leads to a central switch-board, which is of slate—Hartnell's patent—which switches off both the positive and negative wires, with fusible cut-outs on the main leads and on the positive and negative of each circuit. These premises are lighted for the most part by simple pendants, which call for no special remark excepting that the work is thoroughly done, no part being left unlighted. There are 97 lights on this circuit. There are besides 15 lights in the premises adjacent to the dynamo.

The greatest care has been taken not only in the general plan of this arrangement, but in all the details, from the boilers to the lamps, to make it as perfect as possible in every respect, everything being of the best quality. In addition to the special arrangement for the simplification of the switches complete instructions, mounted and framed, are placed near each switch-board; in short, the utmost pains are taken to make the whole most simple and intelligible. The installation has now

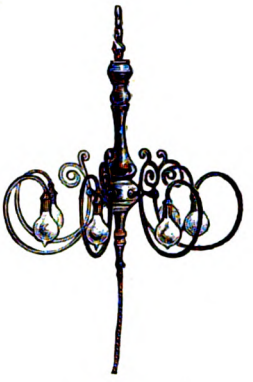

FIG. 8.

run for over nine months without a hitch of any kind, and that, too, without the supervision of any electrician or anybody beyond those already employed on the estate. These facts are of the greatest importance, proving that the electric light can be so arranged as to be perfectly trustworthy, easily and inexpensively managed, and to give no trouble whatever. Its advantages as compared with the paraffin lamps, candles, and lanterns previously used are immense, and with such an example of beauty, brilliance, and elegance it is to be expected that ere long we shall see many of the large and historical mansions similarly lighted, and in this way the owners will secure for themselves the greatest comfort, convenience, and pleasure,

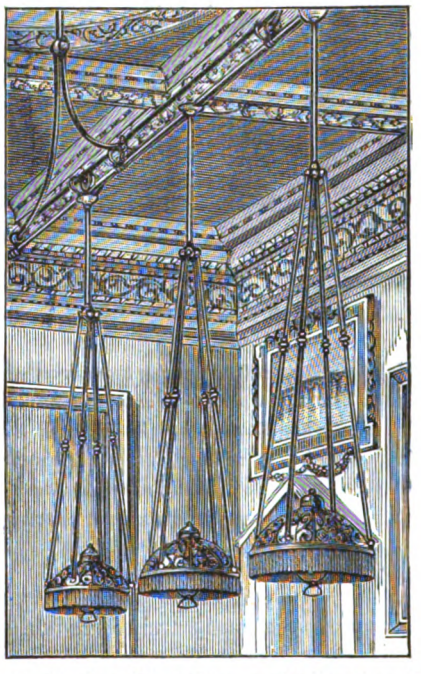

FIG. 9.—Pendant Electrolier over Dining Room Table.

whilst adding to their historic treasures that which is one of the greatest triumphs of the present century.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the half month ended the 30th September are £1,678, as compared with £1,862 in the corresponding period of 1885. The June receipts, estimated at £5,322, realised £5,333

ANSWER TO CORRESPONDENT.

X + Y.—*We do not know of any book containing the description you require. A number of illustrations, with descriptions of Wheatstone's apparatus, as shown at the Crystal Palace Exhibition, will be found in* THE ELECTRICIAN, *Vol. IX. Descriptions will be found in the text books of Preece and Sivewright, and of Culley, both published by Longmans and Co.*

TELEGRAPHIC FRAUDS.

Under this heading we last week published a paragraph with reference to accusations seriously reflecting on the local officials of the Western Union Telegraph Company. Our authority was the (American) *Electrical World*, which again had the statement from an American contemporary. We omitted to give our authority for this piece of gossip, a circumstance rendered the more unfortunate by the accidental insertion of the word "cable" in our description of the "lines." The representative of the Western Union Company on this side of the water—the lessees of the American Cable Company—positively assures us there is no foundation for the statement; and, of course, there never was any as against the "Cable" Company. We gladly accept this assurance, and hasten to express our sincere regret at having inadvertently given pain and annoyance by publishing the paragraph in that misleading form. The wording complained of was, in fact, due to a mere blunder, the writer of the abstract failing to observe that "local officers" might be construed as referring to any person or persons in this country. We give prominence to this explanation, in order that no effort on our part may be spared to correct the erroneous impression which is said to have arisen from our note.

ISOLATED INSTALLATIONS.

We notified in these columns last week that our present issue would contain some fuller information respecting an experiment on a large scale and of considerable importance as touching the question of indoor and domestic lighting by means of electricity. A special agent of *The Electrician* has personally visited the place where this experiment has been carried out, and we are now able to publish a descriptive account of what he saw, illustrated by drawings taken on the spot. We call it an experiment, because in the present state of electric lighting development every new undertaking may be so regarded; but in reality the installation at Wentworth Castle was completed more than six months ago, and has been in constant operation from then until now. Our agent went to inspect not merely a completed work, but a work which had stood the test of a trial as severe as any it is ever likely to be put to, and which has given the most perfect satisfaction to everybody concerned. There has been, we are assured, no hitch whatever in the supply of the light; and such is the simplicity of the arrangements for supplying it that nobody beyond the staff of assistants ordinarily attached to the castle is required to manage or superintend the working.

The reason for this will be found in the admirable arrangements described in our report of the installation. No care had been spared in planning and carrying out every detail of the scheme, with a view, not only to its security and efficiency, but to its being rendered virtually independent of any special technical supervision. The elaborate precautions which have been taken in every direction against accidents of all kinds may appear at first sight, when read in the detailed account furnished by our correspondent, suggestive of constantly recurring danger. But a similar suggestion would arise were we nowadays to describe all the needful devices with which long usage has familiarised us in the case of gas. In describing the particular safeguards adopted at the seat of THOMAS C. F. VERNON WENTWORTH, Esq., our object is to supply information for the guidance of contractors elsewhere; and this we do the more confidently because the results of a good six months' trial justify its being adduced as a pattern of efficiency. Nobody can seriously allege that gas is either safe or sure; but experience has gone a very long way to make it both. Similarly we are aiming at making electricity not less harmless and trustworthy, and it must be confessed that the progress already made is highly encouraging. Indeed, with Wentworth Castle before us lighted throughout from stables to picture galleries, and from kitchen to banquet hall, we feel tempted to say that the plant and appliances are now in such a perfected state that domestic lighting by electricity is certainly as safe as by gas, and in similar situations—that is to say, isolated from any great centre of supply—is almost, if not quite, as sure.

Apart, however, from the purely technical features of this installation, there are points of interest about it which have an

Digitized by Google

important bearing on the future of domestic lighting. Its perfect success at Wentworth Castle will be an example soon followed by the owners of other country seats for which England is so justly famous. At very many of these places, as at Wentworth, there are collections of pictures and works of art of priceless value, which it is the honourable obligation of the proprietor to preserve unimpaired. To efficiently light such establishments with oil or candles has been found both difficult and dangerous; and to the manufacture of gas on the premises—which is at best a costly and cumbersome business—there is the still graver objection that its consumption means injury and often complete destruction of the finer specimens of decorative and pictorial art. Add to this the vitiated atmosphere inseparable from the use of gaslight—a fact of which the upper classes are latterly showing their appreciation by reverting to the use of candles or oil—and we have a condition of things highly favourable to the electric light, the manufacture of which is easy and cheap, and its consumption wholesome and cleanly.

As a proof of the acknowledged unfitness of gas for purposes of this kind, we have only to mention the fact that Wentworth Castle is situated within a few hundred yards of coal mines on the estate; and is therefore within reach of coals at their very cheapest. Were cost a sole object, coal gas would of course be employed here, if anywhere; but except as fuel for the engines, the price of coal does not enter the question; and we suspect that this is the case generally elsewhere. The electric light is a luxury, but when it is charged with being an expensive luxury we reply that so, too, was gas in its earlier days, and is so still for the many who can only afford mineral oil. Even in situations where the cost of production is far greater than at Wentworth, the electric light will gladly be paid for as a desirable luxury. It is far less expensive than candles, and involves less trouble than either candles or oil lamps; and, what is of equal moment, it is more ornamental than either, and not so liable to accident. The beauty of the lighting at Wentworth Castle is a matter of general observation, adding as it does to the splendour of the rooms by night, and appropriately displaying those objects of art which previously had been lost to sight with the closing of the day.

One other point worth special notice has been established by this installation, namely, the peculiar mobility of the new light. The lights can be shifted about from place to place, accumulated at particular points when required, or distributed over larger areas at pleasure. Nothing like this can be said for gas lighting on a similar scale. A gas pipe is an unpliable thing, and the gasfitter an uncongenial adjunct to one's establishment. The electric wire is perfectly tractable in comparison, and its fittings are incomparably more accommodating. An example of what we mean may be seen over the table in the dining room of Wentworth Castle, where by a simple mechanical contrivance the positions of the electroliers are expanded so as to suit any length the table underneath may be required to assume. To complete the convenience, switches at suitable points facilitate the instantaneous lighting of a number of lamps in any given direction, and, what is of almost equal convenience, their immediate extinction. Some 400 or 600 lamps are in this way under the perfect control of unskilled attendants, who if they follow their instructions can make no mistakes, and who can do very little mischief even if they are careless. The installation is, on the whole, of so excellent and comprehensive a character that it affords examples of almost every kind of domestic electric lighting, and we heartily commend it to the attention of our readers.

CORRESPONDENCE.

THE ELECTRIC LIGHT AND EYESIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the article on this subject in to day's *Electrician*, based on the paper read by Mr. Oakley before the Sanitary Congress at York last week, you remark that he attributes the prevalence of shortsightedness among the rising generation to "increased pressure of schooling, to the excessive use of the eyes for near objects, and to close application with strong mental effort in early life."

This doubtless is true, but it is not the whole truth, inasmuch as it is the *circumstances* under which the said schooling is conducted, rather than the schooling itself, which tend to produce this shortsightedness. That I am correct will, I am sure, be admitted by any one who will read Prof. Fuchs' Prize Essay on "The Causes and Prevention of Blindness," a translation of which, by Dr. Dudgeon, of London, was published last year by Boillière, Lindall, and Cox. In this book all the causes which lead to blindness and short sight are thoroughly investigated, and the means necessary for their prevention examined.

At page 37, Prof. Fuchs says, with regard to *illumination*, "In his first investigations in 1865 Cohn paid particular attention to this factor. Twenty elementary schools examined by him, in which the requirements of the education were pretty much alike, and therefore admitting of a comparison, showed a variation in the number of myopes of from 1·8 per cent. to 15 per cent., dependent on the illumination of the school rooms." Here, then, is shortsightedness directly attributed to defective illumination. After pointing out the requirements for affording a sufficiency of good daylight, he attends to artificial illumination. He says:—

"For larger schools with evening instruction, especially for drawing lessons, electric light is advisable. The first employment of this, as far as I am aware, was made in the middle and technical schools of Liége, which were opened in October, 1883. Three rooms for drawing classes were lighted by electricity; each room, 13⅓ yards wide and twice that length, was lighted by two electric sun lights. These were fixed at the lower end of iron rods, which hung halfway down into the room. Underneath each sunlight there is a concave mirror, one side of which shades the light from view, while the other throws the light on the white-washed ceiling. From this it is reflected throughout the room. Thus, the light comes from above and falls in pretty equal degree upon all the desks, whilst the sources of the light themselves are invisible. The light is quite sufficient, but not at all dazzling."

He here refers the reader to p. 192, where the conditions of an artificial light are examined in relation to the health of the eyes. He shows that to be wholesome a light should be bright, that it should not be dazzling, that the flame should not flicker, that a light having a minimum of yellowish tinge is that which is best endured, that an artificial light is injurious in proportion to the degree of heat which it produces, and he also dwells upon the atmospheric deterioration caused by petroleum, gas, and colza oil, adding, "the electric light causes no pollution of the air." He sums up the result of his facts as follows:—"From a hygienic standpoint the electric light must be regarded as the best, provided a proper construction of the apparatus shall secure the necessary steadiness of the light, and that when the intensity of the light is great its source shall be concealed from the eye.

"By the electric light the air is neither polluted nor heated. The illumination is so excellent that the acuteness of vision is increased by ⅕ to ½ compared to gas. The acuteness of vision for colours is doubled or quadrupled (Cohn). Where the electric light has been employed on an extensive scale no complaints have been made of straining of the eyes (Javal, Poucet du Cluny, Cohn). I can corroborate this for the Liége Schools."

If it was once fully and generally understood that from the standpoint of health, and especially from that of the health of the eye, and the preservation of sight, how greatly superior the electric light is to every other form of artificial illumination, it surely would not be so very long, after all, before "the electric light will help the ordinary scholar with his books."

EFFICIENCY TESTS OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to your remarks on my letter in last week's issue, I would beg to say that I indicated *two* methods in my letter of March 15th. The one to which you allude depends upon the use of a dynamometric brake, which has the advantage of being much more accurate and easy than a transmission-dynamometer test. As for the other, it must be admitted that mechanical and other friction is independent of the current strength in the armature; but this need to be admitted only for similar working circumstances, the motor being used only as a motor, and the generator only as a generator.

This being admitted, it is clear that the difference in electric work supplied to the motor in two tests (of course, the loss in heating the wires of the motor being taken in account) will be equal to the difference of the mechanical work delivered by the motor.

Thus, the mechanical work consumed under given circumstances by a dynamo-generator may be determined by two tests, one with generator and motor coupled together, and one with the motor alone, but with the same current in the electro, and at the same speed.—Yours, &c.,

C. L. R. E. MENGES.

The Hague, Holland, October 5th, 1886.

THE PROPOSED ELECTRIC LIGHTING AT BOURNEMOUTH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your note on "The Proposed Electric Lighting at Bournemouth," in your last issue, you state that only incandescent lights upon a low tension current were used, whereas an arc lamp of 3,000 candle-power was running off the same circuit; in fact, it was the same plant which gave such satisfaction at the Inner Temple, on the occasion of the visit of the Princes Louise, on the 19th June last, and was noticed in your esteemed journal. In replying to the question of danger I volunteered to go to the engine room, and in presence of any of the audience would grasp the poles or brushes of the dynamo whilst running, as I had frequently done before. Mr. Donkin, the secretary *pro tem.*, then stated that he also had done so at my request, with the result mentioned. I then appealed to Dr. Philpots, the gentleman who took the chair on two previous occasions, and who has the only electric light installation in Bournemouth up to the present time, and he admitted that on one occasion he happened to touch his electric light leads and was completely knocked over, showing the effect of careless workmanship. The doctor is a very enterprising man, and had already incurred considerable expense in fitting up, and it was a misfortune that the original work was not efficient. I offered to make the installation so that he could use it at cost price, and have received the following letter from him:—

(Copy.)

Dear Mr. Shepherd: Thanks to your skill my installation has become a greater success than it has hitherto been. In fact, it is now perfect with one exception, I must have a larger dynamo. I have quite sufficient faith in your judgment from past experience to be guided by you in your choice of a machine. You know I want one on a good system for 100 lights. If you see one you can recommend please let me know, and we will at once see about the purchasing of it.—Yours sincerely and obliged,

Signed, E. P. Philpots, M.D.

If you will kindly insert this you will greatly oblige.—Yours, &c., JAMES SHEPHERD.

London, W.C., Oct. 6, 1886.

SILENCE IN A TELEPHONE.

When a conductor subjected to alternating currents is divided between two points into two parallel portions, and when the terminals of a telephone are connected, one to a point in one of those parallel portions and the other to a point in the other portion, silence may, under certain circumstances, exist; just as when the split conductor is subject to a uniform current, and a galvanometer is substituted for the telephone, no visible motion of the needle may take place.

In either of these cases the failure to detect an electric flow may arise from want of sufficient sensitiveness in the instrument employed, telephone or galvanometer, or to a want of sufficient sensitiveness in the organ of sense employed, ear or eye.

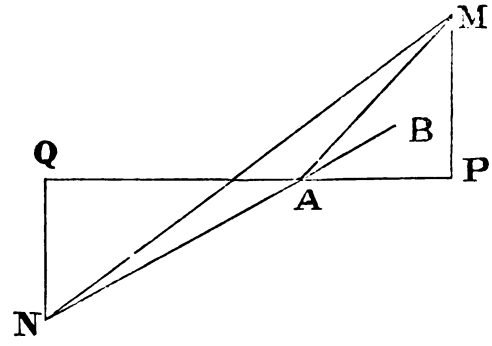
But if in either case no electric flow takes place, then there must be silence in the telephone, and no movement given to the galvanometer needle, however sensitive the instruments, and however quick the senses. Absolute silence in a telephone will therefore exist when its terminals are always kept at equal potentials.

The problem of determining the conditions of absolute silence may be complicated by the existence of coefficients of self-induction in the four portions of the divided part of the conductor, by coefficients of mutual induction, not merely between these four portions, but between them and the rest of the circuit, and by the existence of finite capacity at points of the parallel portions.

I propose merely to deal with the very limited case of the presence of self-induction in each of the four portions of the parallel parts, each section being supposed to be so situated as to suffer and offer no induction from or on any other portion of the system. This case can be easily handled by the geometrical method, and will afford a fair example of its use.

Consider, at first, one of the parallel portions into which the conductor is split, and let r_1 r_2 be the resistances of the two parts into which that portion is divided by the terminal of the telephone; and let L_1 L_2 be the coefficients of self-induction appertaining to each part.

Since there is no current through the telephone, any current through r_1 must exist also through r_2. Hence the currents in these parts must be identical in phase and value. On this account, therefore, the effective electromotive forces through the two parts must be in the same phase, and proportional to the resistances of their respective parts. If, therefore, we take a line P Q, and divide it in A, so that P A : A Q :: r_1 : r_2, P A, A Q may



be taken to represent the effective E.M.F.'s through r_1 and r_2. At the point A set off the angle P A M, so that $\tan PAM = \frac{L_1 \pi}{T r_1}$ where 2T is the period of the alternations.

And at the same point A, but on the side of P Q, remote from M, set off the angle Q A N, so that $\tan QAN = \frac{L_2 \pi}{T r_2}$.

Draw P M, Q N, perpendicular to P Q, meeting A M, A N, in M and N respectively.

Then M A represents the difference of potential of the extremities of r_1.

P M represents the E.M.F. of self-induction in r_1.

A N represents the difference of potential of the extremities of r_2.

N Q represents the E.M.F. of self-induction in r_2.

If M N be joined, M N will represent the difference of

Digitized by Google

potential of the remote extremities of the two parts, *i.e.*, the difference of potential of the points between which the circuit is divided into parallel portions.

But this difference of potential exists for the other parallel portion, the resistances of which are r_3, r_4, let us suppose. If we were to construct a similar diagram to the above for the other parallel, we should arrive at another triangle M′ A′ N′, of which we know that M′ N′ will represent the same magnitude as M N.

M′ A′ will represent in phase and magnitude the difference of potential which exists between the second terminal of the telephone, and that end of r_3 which joins on to r_1, which point differs in potential M A from the first terminal of the telephone. If, therefore, the terminals of the telephone are to be always at equal potentials, M′ A′ must be to M A as M′ N′ to M N, and the angle N M A must be equal to the angle N′ M′ A.

The same argument applies to the lines N A, N′ A′. *In fact, the triangles must be similar and the conditions of absolute silence in the telephone are expressed in the same way as the conditions of similarity in the triangles*, translating the elements of the triangles into the physical quantities they represent.

The conditions that two triangles are similar to each other are two in number.

Probably the simplest we can select in this case are—

(1). That $\frac{M A}{N A}$ shall be equal to $\frac{M' A'}{N' A'}$.

(2). That the inclination of M A to N A shall be equal to that of M′ A′ to N′ A′.

Now
$$M A^2 = (P M)^2 + (P A)^2$$
$$\frac{P M}{P A} = \frac{L_1 \pi}{T r_1}$$
$$\therefore M A^2 = P A^2 \left\{ 1 + \left(\frac{L_1 \pi}{T r_1} \right)^2 \right\}$$

Similarly
$$N A^2 = Q A^2 \left\{ 1 + \left(\frac{L_2 \pi}{T r_2} \right)^2 \right\}$$

$$\therefore \frac{M A}{N A} = \frac{r_1}{r_2} \cdot \frac{\left\{ 1 + \left(\frac{L_1 \pi}{T r_1} \right)^2 \right\}^{\frac{1}{2}}}{\left\{ 1 + \left(\frac{L_2 \pi}{T r_2} \right)^2 \right\}^{\frac{1}{2}}}, \text{ since } \frac{P A}{Q A} = \frac{r_1}{r_2}$$

Similarly
$$\frac{M' A'}{N' A'} = \frac{r_3}{r_4} \cdot \frac{\left\{ 1 + \left(\frac{L_3 \pi}{T r_3} \right)^2 \right\}^{\frac{1}{2}}}{\left\{ 1 + \left(\frac{L_4 \pi}{T r_4} \right)^2 \right\}^{\frac{1}{2}}}$$

in which L_3 L_4 are the coefficients of self-induction appertaining to r_3 r_4 respectively.

The first condition, therefore, is that

$$\frac{r_1}{r_2} \cdot \frac{\left\{ 1 + \left(\frac{L_1 \pi}{T r_1} \right)^2 \right\}^{\frac{1}{2}}}{\left\{ 1 + \left(\frac{L_2 \pi}{T r_2} \right)^2 \right\}^{\frac{1}{2}}} = \frac{r_3}{r_4} \cdot \frac{\left\{ 1 + \left(\frac{L_3 \pi}{T r_3} \right)^2 \right\}^{\frac{1}{2}}}{\left\{ 1 + \left(\frac{L_4 \pi}{T r_4} \right)^2 \right\}^{\frac{1}{2}}}$$

or

$$r_1^2 r_4^2 \left\{ 1 + \left(\frac{L_1 \pi}{T r_1} \right)^2 \right\} \left\{ 1 + \left(\frac{L_4 \pi}{T r_4} \right)^2 \right\} = r_2^2 r_3^2 \left\{ 1 + \left(\frac{L_2 \pi}{T r_2} \right)^2 \right\} \left\{ 1 + \left(\frac{L_3 \pi}{T r_3} \right)^2 \right\}. \quad (\alpha)$$

To express the second condition, produce N A towards A to B.

Then the angle B A M is the inclination between M A and A N.

$$\text{Tan B A M} = \tan \{ P A M - Q A N \}$$
$$= \frac{\tan P A M - \tan Q A N}{1 + \tan P A M \tan Q A N}$$
$$= \frac{\frac{L_1 \pi}{T r_1} - \frac{L_2 \pi}{T r_2}}{1 + \frac{L_1 L_2 \pi^2}{r_1 r_2 T^2}}.$$

The corresponding function for the other parallel is

$$\frac{\frac{L_3 \pi}{T r_3} - \frac{L_4 \pi}{T r_4}}{1 + \frac{L_3 L_4 \pi^2}{r_3 r_4 T^2}}$$

Therefore the second condition is that

$$\frac{\frac{L_1 \pi}{T r_1} - \frac{L_2 \pi}{T r_2}}{1 + \frac{L_1 L_2 \pi^2}{r_1 r_2 T^2}} = \frac{\frac{L_3 \pi}{T r_3} - \frac{L_4 \pi}{T r_4}}{1 + \frac{L_3 L_4 \pi^2}{r_3 r_4 T^2}} \quad . \quad . \quad . \quad (\beta).$$

The conditions (α) and (β) are all that are necessary for absolute silence in the telephone *under the circumstances proposed*, but among the circumstances occurs the period of the alternation, and it is quite possible to have (α) and (β) satisfied for one value of T but not for another. Thus the telephone might be silent for one tone but not for others, as tone depends upon period, and (α) and (β) are only the conditions of the silence in regard to a particular note. It remains to be seen whether it be possible to obtain silence for all notes, one independent of the value of T.

From the construction of the figure, it is clear that if T is very large M and N move to P and Q respectively, and M A becomes coincident with P A, and M N with P Q. Therefore, in order that A may divide P Q in the same ratio for both figures, it will be necessary that $r_1 : r_2 = r_3 : r_4$, or $\frac{r_1}{r_2} = \frac{r_3}{r_4}$, the usual bridge condition for no current through the galvanometer.

Now, bearing this necessary relation in mind, and noting that M P and N Q are drawn perpendicular to the same straight line P Q, so that P A : A Q :: r_1 : r_2, it will be impossible that this relation shall hold good for all straight lines drawn through A unless A lies in the straight line joining N and M.

In this case M A N becomes a straight line, making equal angles with P Q.

Hence
$$\frac{L_1 \pi}{r_1 T} = \frac{L_2 \pi}{r_2 T}$$

or
$$\frac{L_1}{L_2} = \frac{r_1}{r_2}$$

and $\frac{L_3}{L_4}$ must follow the same rule, *i.e.*,

$$\frac{L_3}{L_4} = \frac{r_3}{r_4} = \frac{r_1}{r_2} = \frac{L_1}{L_2}.$$

When these conditions are fulfilled the condition (β) is necessarily satisfied, the inclination of the lines M A, A N, being always zero. Hence these conditions are all that are needed to produce silence in the telephone for all periods of alternations harmonically executed.

SOME POINTS IN THE THEORY OF MAGNETISM.

BY FREDERIC A. B. PERRINE, D.SC.

Something over a year ago, while at Princetown College, my attention was drawn to a remarkable series of results published by Prof. John Trowbridge, in *Silliman's Journal*, where he states that when a permanent magnet is cooled to − 20° C. it loses 66 per cent. of its original magnetism. Some doubt being expressed concerning the accuracy of these results, it was determined to institute a series of experiments to test them, which was accordingly done, and resulted not only in a confirmation of his results, but also pointed out the fact that as one cooled a permanent magnet the moment at first increased to a maximum and then decreased, this maximum appearing, with the magnet used, at about − 10° C.

Somewhat similar results have been obtained by M. Favé (*Comptes Rendus* LXXXII., p. 276), but they have not been confirmed by the experiments of Gaugain, Defur, and Wiedemann. The discrepancy seems to me, however, to be explained by the fact that the temperatures used by these latter experimenters were not low enough to reach the maximum,

Digitized by Google

consequently they only observed an increase of the magnetic moment on cooling the magnet. My experiments seem to me to point to an incompleteness in the theories of magnetism cited by Wiedemann in *The Electrician* for July 9. Quoting Hughes, he says, (*a*) "Each molecule of a magnetic metal is an unalterable molecular magnet," and there is, further, (*e*) "a rigidity which retains the molecules in their positions after the cessation of the active forces." This "rigidity" is what has commonly been called "coercitive" force of the metal, and depends on the temperature of the magnet. If these two are the only active forces which govern the molecules when once directed along the axis of the bar, the only effect of changes of temperature would be the increase or decrease of the coercitive force, together with a change in the dimensions of the bar. The increase of the magnetic moment on cooling would in this case be due entirely to the increase of the coercitive force, and would rapidly approach a constant value which would never exceed the intensity of the original magnetisation; for, after the coercitive force had become sufficient to retain this amount of magnetism any further increase would be of no effect. Indeed, I cannot see how a reduction of the temperature below that of the original magnetisation would have any effect towards increasing the magnetic moment, for since permanent magnetism is but the residual effect of the magnetising force, the maximum of magnetic moment should be at the temperature where the coercitive force is equal to its value at the time of magnetisation. My experiments clearly show that not only does the magnetic moment continue increasing to a temperature much below that of the original magnetisation, but that it also reaches a maximum, and beyond that point begins to decrease again, and from Prof. Trowbridge's experiments seems to decrease very rapidly till there is a total disappearance of magnetic moment somewhere about the point of the absolute zero.

The true explanation seems to me to rest upon the movements of the molecular vortices of the body. Let us suppose that the vortex atom is impressed by a certain energy—in action analogous to electrical energy—and that the vortex filament of any magnetic body composed of these vortex atoms has a rotational motion about its axis apart from the proper motion of these fluid elements along the vortex lines. This rotation will have two effects, the one tending gyrostatically to keep the filament in a constant plane, the other tending to make the filament act as a magnetic shell by reason of the rotation of the electrical masses in it acting as a current revolving around it.

On this hypothesis the coercitive force will be due to the positions and movements of the vortices and the gyrostatic action of the vortex atoms, and will be independent of the motions or energy in the vortex atoms, while the magnetic action of any filament will depend both on the rotation of the filament about its axis and on the action of the vortex atom itself. The effect of heat on these vortices is to increase the rapidity of their motions, which will increase both their gyrostatic action and the intensity of the current about them, and in consequence their magnetic action; but, at the same time, it must be remembered that these vortices have a motion in space along their axes as well as their vortical motions, which overcomes the effect of the gyrostatic action when one raises the temperature to a high point, and hence the increase in volume and loss of rigidity of the body; at the same time, the actions of the vortical magnetic shells upon each other become very intense, and will finally render insignificant both the directive force of former magnetisations, and also, on account of the law of the inverse squares, any present magnetising force, and forming themselves into closed magnetic circuits will have no external effect. As one cools the magnet from this point the excursions of the vortices in space are lessened in amount, the gyrostatical forces are lessened, and the mutual magnetic actions of the vortices are reduced below that of the external forces upon them; hence, still turning themselves so as to embrace the greatest number of lines of force, their axes will be turned towards a position parallel to the axis of the bar, the component of the external forces diminishing continuously as they approach this position. This will cause the magnetism to approach a maximum, after which point the effect of a further decrease of the temperature will be to diminish the magnetism by diminishing the intensity of the magnetic shells.

In the case of a steel bar permanently magnetised, and brought to a stable condition by heating, or cooling, or jarring, if the heating has not been carried to the point of total loss of magnetism, cooling will, reducing the gyrostatic force of the vortices, allow the magnetic forces to direct their axes parallel to the axis of the bar; the magnetism will increase till the component of the directive force being lessened in amount by reason of the position of the vortices, the decrease in the magnetic intensity will begin to show itself, and having risen to a maximum the moment of the magnet will begin to decrease. The total loss of magnetism would occur at - 273° C., when the motions of the vortices would cease.

This hypothesis calls in a rotational motion of the vortex filaments around their axes, in addition to their regular vortical motions to explain magnetic action. This assumption seems to me to be warranted by the facts—I have lately been struck with its resemblance to Rankine's "Theory of Molecular Vortices"—while not, I think, lying open to the objections offered by Thomson to that theory.

A NEW FORM OF CURRENT WEIGHER.*

BY PROF. JAMES BLYTH.

The object of this paper is to describe a method of absolutely determining the strength of an electric current by measuring in grammes weight the electromagnetic force between two parallel circular circuits, each carrying the same current.

For convenience of calculation the circles have the same radius, and are placed with their planes horizontal.

The construction of the instrument is as follows:—A delicate chemical balance is provided, and the scale-pans replaced by two suspended coils of wire. Each of these is made of a single turn of insulated copper wire (No. 16 about) fixed in a groove round the edge of an annular disc of glass or brass of suitable diameter. The disc is made as thin and light as possible consistently with perfect rigidity. By means of two vertical pillars of brass this annulus is attached to a rigid crossbar of dry wood or vulcanite, in the middle of which is placed a hook for suspending the whole from one end of the balance beam. On each side of the hook, and equally distant from it, two slender rods of brass are screwed into the wooden bar, which support two small platinum cups for holding mercury or dilute acid. The position of these cups is so adjusted that when the whole hangs freely the cups are in line with the terminal knife-edge of the balance beam, and have their edges just slightly above its level. The free ends of the insulated wire surrounding the disc, after being firmly tied together for a considerable length and suitably bent, are soldered to the brass supports of the platinum cups, which thus serve as electrodes by means of which a current may be sent through the suspended coil. A precisely similar coil is suspended from the other end of the balance-beam.

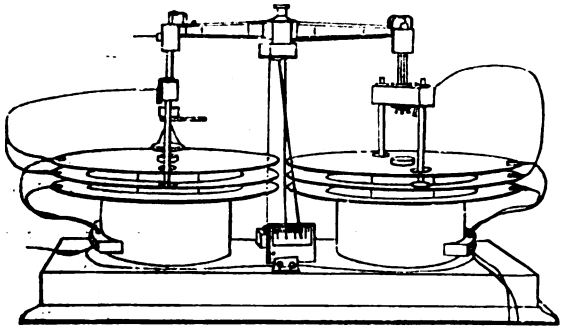
We now come to the arrangement by means of which a current is led through the suspended coils, so as to interfere as little as possible with the sensibility of the balance. This constitutes the essential peculiarity of the instrument, and is effected in the following way:—An insulated copper wire, having its ends tipped with short lengths of platinum, is run along the lower edge of the beam, and is firmly lashed to it by well rosined silk thread. The ends of this wire, bent twice at right angles, are so placed that their platinum tips dip vertically into one of each pair of the platinum cups which are attached to the vertical rods of the suspended coils. From the other cup of each pair proceed two similarly tipped copper wires, which run along the upper edge of the beam, and are also firmly tied to it. These wires, however, only proceed as far as the middle of the beam, where they are bent, first outwards, one on each side of the beam, at right angles to it, and then

* "On a New Form of Current-weigher for the Absolute Determination of the Strength of an Electric Current," being a paper read before the British Association at Birmingham.

Digitized by Google

downwards, so that the platinum tips are vertical. The latter dip into two platinum cups attached to two vertical rods, which spring from the base-board of the balance. These rods are placed at equal distances on each side of the beam, and are of such length that the platinum cups are in line with the central knife-edge of the beam, and have their edges just a little above its level. There are thus in all six cups and six dipping wires. Three of these are in line on one side of the beam, and three on the other. Also the line joining the points of each pair of dipping wires is made to coincide with the corresponding knife-edge; and, further, the edges of the cups are all in the same plane when the balance is in equilibrium.

From this it will be obvious that any motion of the beam in the act of weighing causes only a very slight motion of the platinum wires, which dip into the fluid contained in the cups. The resistance due to the viscosity of the fluid is thus very small, even in the case of mercury, and much smaller still when dilute acid is used. In point of fact, the diminution of sensibility due to this cause is less than in the case of determining the specific gravity of solids by weighing in water in the ordinary way, With clean mercury it is quite easy to weigh accurately to a milligramme.



Prof. Blyth's New Form of Current Weigher.

The fixed coils, constituting two pairs, have the same diameter as the suspended coils, and, like them, are made of single turns of insulated wire wound round the edges of circular discs of glass or brass. The discs of each pair are fixed at the requisite distance apart to a cylindrical block of wood, so as to have their planes exactly parallel and their centres in the same straight line. To ensure this they are turned up and finished on the same cylindrical block on which they are finally to rest. When in position they are so placed that, when the balance is in equilibrium, each suspended coil hangs perfectly free to move with its plane horizontal and exactly midway between a pair of fixed coils. For this purpose, as will be seen, it is necessary that two large holes be drilled in the upper disc of each pair, so as to allow the brass pillars of the corresponding annular disc to pass freely through. When the connections are made, the current is led through the entire apparatus in such a way that, while the electromagnetic force acting on the one suspended coil causes it to descend, the electromagnetic force acting upon the other causes it to ascend. The total force tending to disturb the equilibrium of the balance is thus exactly four times that due to an equal current circulating in two parallel circles of the same diameter and with their planes at the same distance apart. The current-strength is estimated from the number of grammes required to restore the balance to exact equilibrium, the weights being placed in small scale-pans attached to the movable part of the apparatus.

The electro-magnetic force between each fixed and the corresponding suspended coil is calculated from the formulæ given by Clerk Maxwell (Vol. II., p. 308), viz. :—

$$\frac{dM}{db} = -2\pi \cos\gamma \left\{ 2F_\gamma - (1+\sec^2\gamma) E_\gamma \right\}$$

where M = the potential energy between two parallel circles, each carrying unit current,

b = distance between their planes,

a = radius of each coil,

$$\sin\gamma = \frac{2a}{\sqrt{4a^2+b^2}},$$

F_γ and E_γ = first and second complete elliptic integrals to modulus $\sin\gamma$.

In one of the instruments constructed

$$a = 10\,8 \text{ inches}, \quad b = \cdot 566 \text{ inches},$$

which give

$$\gamma = 87°, \quad F_\gamma = 4{\cdot}338653976, \quad E_\gamma = 1\,005258587;$$

from which, if G denote the constant of the instrument and $g = 981$, we have

$$G = 4.\frac{dM}{db} \cdot \frac{1}{g} = \cdot 4818.$$

This gives for 1 ampere a force = ·0418 gramme weight.

Besides the one exhibited I have constructed several modifications of the instrument, only one of which, however, needs to be particularly mentioned. In it both the fixed and movable coils are replaced by flat spirals of wire, each of eleven turns. Here the practical construction is more difficult, and the calculation of the constant somewhat more laborious, unless one is content with merely integrating over the area of both the fixed and suspended spirals. This is, I think, however, hardly legitimate, at least with thickish wires, as we thereby suppose that electricity is circulating in the insulating spaces between the wires as well as in the wires themselves. To avoid this I have actually calculated the force exerted by each one of the coils of the fixed spiral upon each coil of the suspended spiral. This entails great labour, as the elliptic integrals have to be calculated for values of the modulus differing very slightly from each other. The labour, however, is worth the taking, as the attractive or repulsive force between two flat spirals is so much greater than that between two simple circles.

Discussion.

Lord Rayleigh said the diagram and description of Prof. Blyth's instrument reminded him of the work upon which he had been engaged for the past two years. The great difference between Prof. Blyth's arrangements and those he had adopted was in the use of mercury connections instead of flexible wire. Perhaps for the scale on which Prof. Blyth was working (apparently with very large currents), the mercury connections acted very well. When he was engaged in designing his experiments it so happened that he tried something, roughly, of this kind; he tried the principle of making the connection with a mercury cup, the point where the wire dipped into the mercury being in the axis of rotation. Perhaps, in consequence of imperfect arrangements, it did not result to his satisfaction, and he concluded eventually to use the flexible connection, which seemed to him really not to contain the objections which at first appeared to attach to it. Of course connection with a flexible wire could not be made without imposing a certain force upon the suspended parts. But the real question was, is that force one which can be depended upon and be eliminated from the experiments? It seemed to him it could be, because although a flexible wire undoubtedly exercised a force, still, when the suspended wires were brought into a perfectly definite position, that force must be very nearly constant, depending, of course, upon the elasticity of the material; and although it was quite true that during the passage of the electric current, and the consequent slight heating of the flexible connectors, the mechanical force exerted upon them by the suspended parts was a little different from that exerted when the apparatus was at rest, still, all those observations could be taken by reversal of the current in the fixed parts of the apparatus, reversing, of course, all the forces operated. Therefore the difference of weight required to obtain equilibrium when the current was reversed in the fixed part of the apparatus gave double attraction, independently of the different force, whether mechanical or electrical, which might be exerted by the connecting wires leading the current into the suspended parts. He must say he found no reason to disapprove of results obtained in that way, but possibly with the larger currents which Prof. Blyth wished to use there might be greater difficulty in managing leading wires of that kind. The current with which he (Lord Rayleigh) had actually worked was about from one-third to one-half of an ampere, and certainly no difficulty arose with that, nor did he think any serious difficulty would have arisen if he had wished to multiply that current a few times. He would like to know whether Prof. Blyth had translated his results into terms of the silver deposited or into the E.M.F. of some standard battery. Without that his absolute results could not be compared with those obtained by previous observers. With reference to the formula quoted from Clerk-Maxwell, it might perhaps be worth while to mention that he had calculated a table giving the quantity required from time to time by $\frac{dM}{db}$ directly, therefore not requiring a reference to the original Legendre tables; and this Prof. Blyth might find useful. As to the point raised with reference to the calculation of the perfect integration of the effect of flat spirals, of course if the two flat spirals were very close to one another it might be a little precarious to assume that the mean effect was the same as if the current were continuous over the whole area. He was not sure that the calculation Prof. Blyth had mentioned met the case much better, because such a calculation seemed to assume that the

Digitized by Google

current which, of course, was distributed throughout the section of each wire, was concentrated at its centre; and was that any better than the integration? He could not say at that moment how that might be, but it did not strike him that the objection to the one process was much less than to the other. He was very glad to see that Prof. Blyth had succeeded in designing so convenient an instrument for the absolute measurement of current. That was a very important matter, which perhaps scarcely received the full amount of attention it deserved. A very great deal of attention had been given to the determination of electrical resistance, and many skilful workers in different parts of the world had devoted themselves to the subject. To him it seemed that the measurement of current was at least as important, even if it were not more important, but for some reason or other it attracted much less attention. He hoped Prof. Blyth would continue to work upon the subject, and that he would give his results in terms of the deposition of silver or the E.M.F. of a galvanic battery.

Prof. BLYTH said he had not tested the instrument directly with regard to the deposition of silver, but had compared it with an instrument which he believed was very accurate, one of Sir William Thomson's current meters, and the result he got agreed very well with the currents as determined by that instrument. With regard to the calculation he was sorry to find on referring to Lord Rayleigh's table that it stopped at 70. If it were extended to 87 it would be a great improvement.

Mr. BOTTOMLEY said they had been working very incessantly at Glasgow on the subject of instruments of this class, and he thought they had come to a conclusion which was quite confirmed by what Lord Rayleigh had just said with regard to flexible *versus* mercury connections. They found, after a vast number of trials with all sorts of instruments, more uncertainty with the mercury connections, in consequence of the oxide which formed on the sides, than with the flexible connections, and Sir William Thomson had applied the principle of flexible connections in the form of zig-zag wire made of several, perhaps ten, small wires put together, and in these instruments they were having considerable success as against mercury cups.

Prof. ARMSTRONG said he would like to know whether any one present had made any experiments with a pretty series of flexible connections proposed by Joule. Perhaps in addition to that a series of torsional and flexible suspensions might be employed for the balance so as to avoid knife edges. But then the whole weight of the balance would have to be supported by the wires, and in that case the wires must necessarily be of great strength. These torsional and flexible connections should be so made that there should be no total torsion on the wire, the torsion on the one part compensating for the torsion on the other. He would like to extract from Lord Rayleigh, if possible, his opinion of the relative delicacy, or chances of delicacy, of this method of measuring currents and the silver voltameter method. The latter was so simple, compared with Prof. Blyth's expensive apparatus, that it was of considerable importance that people interested in physical laboratories should know whether it was worth while to get standard instruments of this kind, or whether they should content themselves with merely putting up a silver voltameter.

Prof. GEORGE FORBES would be glad if Lord Rayleigh would give his opinion also as to the Clark cell. People were abolishing every sort of standard instrument except the Clark cell, and they would all like to know what Lord Rayleigh thought was the comparative accuracy attainable with instruments of the kind just described compared with that cell also. One of the chief reasons why people had not been devoting the time and attention to current measurement that they did to resistance was owing to Lord Rayleigh himself. The general opinion was that he had taken the subject so thoroughly in hand and made it so entirely his own, that he had studied it with such very great precision in his experiments, that they might be quite contented to leave it in his hands. He specially asked the question as to the accuracy which Lord Rayleigh would expect from the system under discussion, because he could not think it was comparable in any degree in accuracy as an absolute standard with the employment of a Clark cell. He had made some experiments in the same direction himself, but he had given up altogether the idea of using the method as a standard of current, and employed such an apparatus simply as a current measurer without any magnetism in it. He was inclined to think that that was the chief use of such an apparatus. It seemed to him that there were very great difficulties in the way of making it a very exact thing. Prof. Blyth spoke of comparing his instrument with one of Sir William Thomson's accurate current meters. He did not know which instrument was spoken of, but he did not think any one of those which could have been referred to was comparable with Clark's cell for accuracy.

Lord RAYLEIGH said he did not know whether he understood clearly from Prof. Blyth whether his instrument was intended primarily for the absolute measurement of current or for continuous and daily use, for he regarded those two things as distinct. Prof. Forbes seemed to have interpreted him to mean that he used an instrument of this kind in daily use for determining currents which might occur at any moment. Clark's cell was of enormously greater value for such a purpose as that. The silver voltameter did not measure the electric current unless a certain constant were assumed. The question was whether that constant was known accurately enough. Practically, an absolute measurement of current meant the determination of the constant of the electro-chemical equivalent of silver or the E.M.F. of some galvanic cell. As regarded his own work, he endeavoured to express the results in the terms of both. If he wanted to measure a current at any moment he should use Clark's cell, and if doubtful of the result would then get it by the silver voltameter. All that came to this, that you wished to know whether what you called an ampere was an ampere. The use of the tangent galvanometer involved a knowledge of the earth's horizontal magnetic force, and that was difficult of determination. You might afterwards use your knowledge of that constant as you used your knowledge of the E.M.F. of Clark's cell. It seemed to him that the determination of the constant H was as difficult as the measurement of the current itself, if you wanted an accuracy of 1 in 1,000. If the value of H was known the comparison with the tangent galvanometer was a comparatively simple operation. If an accuracy of ½ per cent. were desired, it would be far easier to measure roughly the value of the earth's horizontal magnetism, and refer the currents to that. Even then he would prefer the silver voltameter.

Mr. R. T. GLAZEBROOK, M.A., F.R.S., said that in measuring currents with the silver voltameter it was necessary to know that the current did not vary greatly during the experiment, which must last for some time, and for that reason the method with the Clark's cell was superior for most purposes.

Lord RAYLEIGH said it was a great merit of the Clark cell, that it would measure the current at any moment. The necessity of instantaneous measurement entirely precluded the use of the voltameter for the measurement of certain currents.

Mr. BOTTOMLEY would like to know what currents Prof. Blyth intended his instrument to measure. The currents required to be measured for electric lighting purposes were very large currents in comparison with anything he supposed his instrument was intended to measure.

Prof. BLYTH said the currents he had sent through the instrument varied from one ampere to ten amperes. He had used nothing higher than from ten to fifteen amperes. The real object of his design was to try by that method to find out if the calculation he had made agreed pretty well with the currents as determined by other means. No doubt the electro-chemical equivalent of silver was so perfectly determined now that perhaps determination by a battery was as accurate a method as any. But he had thought it worth while to try the experiment to see how nearly the calculation agreed with the current as got from the instrument, and what he was especially testing was not so much mercury connections as liquid connections by means either of dilute acid or any other liquid.

AMERICAN FIRE OFFICE RULES.

The following are the rules adopted by the "Boston Tariff Association" for the running of incandescent lamps upon arc light circuits:—

Only such wire as has been approved by this "Union" shall be used in constructing lines and circuits. Wires must be run in plain sight. In damp places they must have a waterproof covering. The positive wire or wires must be kept at least three inches from the negative wire or wires in running from the distributor or regulator to the fixtures and lamps and return, except that "twin wire" may be used for a single lamp. No wires should be run through partitions, floors, or walls without being encased in a tube of hard rubber, porcelain, or if soft rubber is used it must be covered with tape. The "safety fuses" must be so proportioned that they will melt long before the wire is heated to an unsafe degree. Dust must not be allowed in the distributor-box or any of the electrical connections. The contact points should be kept clean, and care should be taken to ensure solid electrical connections at all the points of contact, and all parts must be kept free to move easily. In case any defect should arise in the distributor or regulator, or the wiring thereto, it must be arranged so as to automatically and absolutely shunt off from the arc circuit at once. In working distributors the line of circuit current must be kept at its standard amount by tests made by ampere-meter from time to time. In no case must the amount exceed the standard. Every company shall have a competent and reliable person to examine daily every distributor and regulator, or similar device, which may in the future be applied to arc circuits. The running of incandescent lights or systems on arc circuits should be avoided; but wherever this is unavoidable, a proper device or "distributor," such as may be approved by this "Union," must be provided to prevent the possibility of an excessive arc current being thrown on to any one portion of the incandescent system. Such device or "distributor" must have the approval of this "Union" before it is put in operation; it must remain open to inspection at all times, and no change be made in any part of the installation after it has been approved, without consent of this "Union." Where incandescent lights are run on arc circuits the following named practices are strictly prohibited:—Fastening or attaching electroliers or lamps to any gas fixtures which may be in electrical connection with the earth. The running of concealed wires to the electroliers or lamps under any circumstances; they must be entirely open to view. The placing of any distributor-box or regulator, electrolier, bracket, or lamp in such position that it may be connected in any way with any other wires, steam fittings, gas pipes, gas fixtures, &c., which may be electrically

Digitized by Google

connected with the earth. The placing of the distributor, electrolier, &c., in any damp location, or in any close proximity to any metal or other conductor of electricity. The building or placing of anything around the distributor or regulator so as to cut off easy access to it, or obstruct the access of air to it. All joints after leaving the distributor or regulator must be soldered, using acid as flux. Resin will not be approved under any circumstances. All new devices should be submitted to the inspector of the "Union," and must be approved by him before permission can be given for their use.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION OF THE UNITED STATES.

(Continued from page 435.)

We continue from last week the substance of the debate on Mr. Martin's paper upon "Incandescent Lighting and Wiring." Some of the ideas brought out will be found to differ very considerably from English practice :—

Mr. WEEKS: Do you furnish the wire and fixtures, or charge that to the patrons?

Mr. RHODES: That is a question that has come up several times—what to do with fixtures. We have not yet arrived at any conclusion. I think the one we will arrive at will be to insist on having everything done well, and, if necessary, to put in our own fixtures. We will put in such for you at our own expense, doing the entire work and paying for it ourselves, not charging the customers either for the wiring or for the glass globes and shades in connection. This point of charging for fixtures has become a serious one in cities where there is a good deal of competition, and in order to get the business one company and then the other will make sacrifices, and hence the companies have come to do all the work themselves without any charge to their customers. Of course where there is only one company, and that has all the business it can get, it can make the charge against the customers what it pleases. In small towns like our own, where it is necessary in order to get a large amount of business to make some sacrifice, it comes to be nearly a necessity to do the thing yourself. That is a matter to be judged of in each community separately. We believe that in the way we propose to adopt we can get our wiring done more satisfactorily to ourselves, and that we can obtain a sufficient additional number of customers to make it profitable to ourselves. We have had quite a little trouble from poor wiring and from hanging incandescent lights with poor fixtures. We find that it will pay us to furnish proper fixtures, even if they are combination fixtures, having them well insulated and the incandescents properly attached.

Mr. RIDLON: For how long a time do you make a contract with your customers?

Mr. RHODES: For a year. But we have come to the conclusion that whether a customer signs a contract or not it is rather immaterial, because if we have a customer who is dissatisfied with his lamp from any reason whatever, it is much better for us, if such a case should happen, or for any other company, to take the light out immediately and release the man from his contract than to insist upon his using the light against his will until the close of the time. It is better for the company to see in the first place whether the man will continue; and if he is not likely to continue, it is best not to put in the lamp at all.

Dr. GARRATT said he did not believe that with any system of light, whether electricity, gas, kerosene or candles, the party supplying the light should be called upon to furnish the fixtures too. Any man wishful to have the light was willing, he thought, to pay for wiring and fitting up the house. It was thus with gas, and he did not see why an electric lighting company should not be similarly disposed.

Mr. DUNCAN wanted to know who stood the breakage of the lamps.

Mr. RHODES: The company, I suppose, in all cases furnishes the incandescent lamps when breakage happens. Certainly our company does.

Mr. DE CAMP: On the question as to who should repair the lamp. If they charged the customer with half the breakage, that seemed to be equitable. He thought that a company with a number of these lights on an extended system and entirely responsible for the breakage could not afford to neglect them, and that the attendance on them to the extent of inspection would be very nearly equal to that on the arc light. If, however, the parties using these lights knew that when broken the lights were to be replaced at their expense, they would undoubtedly take better care of the property than if the case were reversed.

Mr. GILBERT said that in New England they had been running 125 candle-power lamps on the arc circuit for about three months. They now found they could use them in multiple series without the box, and could certainly get three of them for less than a box would cost. They made their estimates as to the necessary life of lamps, and as to the price that should make them willing to displace the arc. If the lamp lived 400 hours they were going to put in more. For some of them the average time now is 500 hours. They were getting a great deal longer life than they estimated. If the lamps lived 100 hours, they would still get their money back, but not make any profit. He found there was a field for the large incandescent lights just below where the arc lights stop, with people who felt they could not afford the arc light, and they could put in ten of them where they put in one arc light in the dull season. Their insurance inspector was satisfied with them. With the guarantee of the inspector and the experience they had they were going to increase their commercial business much more than with the arc system.

The following paper was also read :—

ON THE TRANSMISSION OF POWER TO THE DYNAMO.

BY JAMES A. PENTZ.

The first essential in the employment of power is to get it transferred to the dynamo by means of, and through, the least number of organs of transmission; and it is likewise important to do it mechanically, in the most direct manner. This brings us face to face with the high-speed engine, and the one-belt method of power transmission from the engine pulley to the pulley of the dynamo as the simplest and the best. Countershafts as applied to electric lighting are quite unnecessary. They require more space than is usually allotted to the driving plant, adding also to its first cost and to the cost of keeping them in good working order. Any increase in shafting and pulleys must require additional attention, and furthermore, additional power to drive them, thereby lessening the effective force of the engine. A few tests of shafts are given herewith, to reinforce the general statement just made:—Fifty-five carefully made experiments, on factory engines, developing under full load from 26 horse-power to 1,485 horse-power, showed the percentum of the extremes of resistance of engines and shafting to full load to be from 16·5 per cent. to 39·2 per cent. of the horse-power, and an average of 25·9 per cent. of the horse-power, while that of the engine alone averaged but 7 per cent. In another series of eight tests of factory engines, the average proved to be 22 per cent., and in another case, where the total horse-power employed was but 120, the resistance amounted to 33 per cent.

If, then, all these drawbacks are to be found in counter-shafting, it should be dispensed with, and some good plan produced whereby electric light plants may be run more economically. No doubt plants run by low speed engines driving to a countershaft have given good results, but if we can do better without this useless auxiliary had we not better do so? It brings us not only to the discussion of the benefits to be derived by belting direct from the engine pulley to the dynamo pulley, but to the superiority of the high speed engine in connection with electric lighting. In the employment of this type of engine we gain these points:—I. Economy of fuel and space occupied by the plant. II. Economy in first cost of the plant. III. Uniformity of speed and regulation. IV. Reduction of cost of repairs and maintenance. Engines of this type must be of the best material and workmanship to insure good running and long life, and should be of ample weight. There should be not the slightest deflection or tremor in the bed under the most trying conditions consequent upon the greatest variation in the load. The revolving parts must be correctly balanced, the reciprocating parts light and strong, the bearings of proper materials and of ample size, the lubrication automatic, and the parts containing steam should be well clothed to prevent loss by radiation. The steam in these engines is utilised in the cylinder to much better advantage than in the cylinders of engines running at low speed, and for obvious reasons.

It is a well-known fact that steam must be used as quickly as possible after it is generated, to avoid loss of efficiency by condensation and radiation of the heat, which is very rapid from the pipes and vessels containing it, as they are usually made and employed. In the early use of steam in running engines, which were necessarily of slow speed, steam jackets were found absolutely indispensable to the proper action of the engine, but later practice with moderately-speeded engines has shown the warming of steam cylinders by jackets to be unnecessary. The modern high-speed engine uses the steam as quickly as possible after it is generated, reducing the time of its transmission to the engine to the least, by which the loss of heat is reduced to a minimum. The saving from this source alone is considerable, and as the steam cylinders of high-speed engines are small in proportion to their power, the losses by reduction of cooling surfaces become smaller also. The economy of fuel as bearing directly upon the engine may be said to begin at this point, and is carried higher by the nearer approach to perfect regulation given by the engine. The action of the governor of the high-speed engine being quicker, the steam is controlled more easily, and the speed of the engine more readily kept uniform. It has been stated that the friction of the engine is increased when it is run at high speed, but recent experiments made at Cornell University, under directions of Prof. Thurston, and with a modern high-speed engine, clearly demonstrated that such is not the case, and, indeed, such a result would be contrary to accepted mechanical theories.

We now come to the most efficient, economical, and decidedly the most satisfactory method of dealing with this question, that of belting direct from the driving pulley of the engines to the dynamo pulley. By this means the connection between the engine and dynamo is single and direct. With the best of dynamos, when driven by engines well adapted to the purpose, good belting is necessary to the securing of uniform results. Belts for driving dynamos should, therefore, be made of the best material, of uniform thickness and density, and practically straight in their run through the air and over the pulleys. They should be soft and pliable and kept so by proper application of the usual and obtainable unguents prepared for this purpose. In the use of belts for driving dynamos, they should be made endless—that is, without unevenly made joints—and when made of double thickness, care should be taken to select such makes as will give an even and full contact surface of the leather constantly to the faces of the pulleys. The best form of engine to drive one or two dynamos is that in which the steam acts upon a centre crank, with ample shaft bearings on each side, and with the pulleys on overhanging shaft ends. From each of these pulleys a belt is run to the dynamo pulley. Either belt may be removed by hand when one dynamo only is required.

Where the number of dynamos required is more than two, the simplest method of belting direct to the dynamos is to use two engines, made right and left, set parallel with each other, and with the main shaft connected to, and running in line, with both engine shafts, supported by proper intermediate bearings from the floor. This practically makes it the same

Digitized by Google

as if the engine shafts were extended, and is usually of the same diameter. This being practically inflexible, and running at the same speed as the engine, makes it an easy matter to belt from the pulleys which it supports to the pulleys of the dynamos, thereby delivering the power, with least loss to the electric machinery, direct. Each pulley on this shaft can be made independent, running by a friction clutch, so that, if by any reason a certain dynamo is not required to be run, it can be stopped, and without interfering with the working of the others. At either end of the engine shaft, and directly next to the engines, a cut-off friction coupling should be provided. This is to insure against stoppage of the whole plant, if accident should occur to either engine. By this means one engine can continue to do the work.

Without extending these remarks too far, it is proper to add that numerous experiments have proved that better engineering expedients lie within the limits of the larger diameters for shafting, which secures rigidity from the known fact that the flexibility of the smaller shafts usually employed on the score of economy creates more friction by being drawn "out of line" by the pull of the belts in action upon the dynamo. Again, with regard to the question of perfect regulation of engines, a single engine running at a slow speed will not produce, relatively, as equable a motion as a single engine running at a high speed. To effect regular motion with slow running engines, it is necessary to employ them in pairs, with their cranks set at right angles. Even then the results attained will be no more satisfactory than that effected by a high-speed single engine. There is a normal speed for every build of engine. It is very certain that an engine made for low speed will not run at a high speed without injury to itself, and possible destruction; but we have abundant testimony proving high speed in engine work to be a pronounced success. It involves, of course, many of the less-known elements of design and construction, and ever and always the best of materials, workmanship, and attendance; all of which, however, are within the reach of modern shop practice, as they are of moderate price. If proper care be taken in the selection of steam motors after intelligent examination of such as are already in use; if particular attention be given also to the installation and management of the whole plant; and if no part or parcel thereof be accepted, believing it to be cheapest in the end, because its first cost is least, then will the production of electricity for lighting and other purposes make great and permanent advances.

CHEMISTRY AS A SCIENCE.

(Concluded from page 438.)

I have said that the original *protyle* contained within itself the potentiality of all possible atomic weights. It may well be questioned whether there is an absolute uniformity in the mass of every ultimate atom of the same chemical element. Probably our atomic weights merely represent a mean value around which the actual atomic weights of the atoms vary within certain narrow limits.

Each well-defined element represents a platform of stability connected by ladders of unstable bodies. In the first accreting together of the primitive stuff the smallest atoms would form, then these would join together to form larger groups, the gulf across from one stage to another would be gradually bridged over, and the stable element appropriate to that stage would absorb, as it were, the unstable rungs of the ladder which led up to it. I conceive, therefore, that when we say the atomic weight of, for instance, calcium is 40, we really express the fact that, while the majority of calcium atoms have an actual atomic weight of 40, there are not a few which are represented by 39 or 41, a less number by 38 or 42, and so on. We are here reminded of Newton's "old worn particles."

Is it not possible, or even feasible, that these heavier and lighter atoms may have been in some cases subsequently sorted out by a process resembling chemical fractionation? This sorting out may have taken place in part while atomic matter was condensing from the primal state of intense ignition, but also it may have been partly effected in geological ages by successive solutions and reprecipitations of the various earths.

This may seem an audacious speculation, but I do not think it is beyond the power of chemistry to test its feasibility. An investigation on which I have been occupied for several years has yielded results which to me appear apposite to the question, and I therefore beg permission here to allude briefly to some of the results, reserving details to a subsequent communication to the section.

My work has been with the earths present in samarskite and gadolinite, separating them by systematic fractionation. Chemical fractionation, on which I hope to say more on another occasion, is very similar to the formation of a spectrum with a wide slit and a succession of shallow prisms. The centre portion remains unchanged for a long time, and the only approach to purity at first is at the two ends, while a considerable series of operations is needed to produce an appreciable change in the centre. The groups of didymium and yttrium earths are those which have chiefly occupied my attention. On comparing these rare earths we are at once struck with the close mutual similarity, verging almost into identity, of the members of the same group.

The phosphorescent spectra of these earths when their anhydrous sulphates are submitted to the induction discharge *in vacuo* are extremely complicated, and change in their details in a puzzling manner. For many years I have been persistently groping on in almost hopeless endeavour to get a clue to the meaning I felt convinced was locked up in these systems of bands and lines. It was impossible to divest myself of the conviction that I was looking at a series of autograph inscriptions from the molecular world, evidently of intense interest, but written in a strange and baffling tongue. All attempts to decipher the mysterious signs were, however, for a long time fruitless. I required a Rosetta stone.

Down to a date comparatively recent nothing was more firmly fixed in my mind than the notion that yttria was the oxide of a simple body, and that its phosphorescent spectrum gave a definite system of coloured bands. Broadly speaking, there is a deep red band, a red band, a very luminous citron-coloured band, a pair of greenish blue bands, and a blue band. It is true these bands varied slightly in the relative intensities and in sharpness with almost every sample of yttria I examined; but the general character of the spectrum remained unchanged, and I had got into the way of looking upon this spectrum as characteristic of yttria, all the bands being visible when the earth was present in quantity, whilst only the strongest band of all—the citron band—was visible when traces, such as millionths, were present. But that the whole system of bands spelled yttria, and nothing but yttria, I was firmly convinced. During the latter fractionations of the yttria earths, and the continued observations of their spectra, certain suspicions which had troubled me for some time assumed consistent form. The bands which hitherto I had thought belonged to yttria began to vary in intensity among themselves, and continued fractionation increased the differences first observed. Whilst I was in this state of doubt and uncertainty, and only beginning to see my way towards arranging into a consistent whole the facts daily coming to light, help came from an unexpected quarter. M. de Marignac, with whom I had been for some time in correspondence, kindly sent me a small specimen of the earth which he had discovered and provisionally named Yα (now Gadolinia). In the radiant-matter tube this earth gave a bright spectrum, like the one in the diagram before you. The spectrum above it is that ascribed to yttria. Look at the two. Omitting minor details, Yα is yttria with the chief characteristic band—the citron band—left out, and with the double green band of samaria added to it. Now look at this diagram, which represents the spectrum of a mixture of sixty-one parts of yttria and thirty-nine parts of samaria. It is identical almost to its minutest detail with the spectrum of Yα, with this not unimportant difference—the citron band is as prominent as any other line. Yα consists, therefore, of samaria with the greenish blue of yttria and some of the other yttria bands added to it.

I may aptly call the Yα spectrum my Rosetta stone. It threw a flood of light on all the obscurities and contradictions I had found so plentiful, and showed me that a much wider law than the one I had been working upon was the true law governing the occurrence of these obscure phenomena. For what does the spectrum of Yα show? It proves that what I had hitherto thought was one of the chief bands in the yttria spectrum—the citron band—could be entirely removed, whilst another characteristic group—the double green of yttria—could also be separated from the citron.

It would exceed legitimate limits were I to enter into details respecting the chemical and physical reasons which led me to these definite conclusions. To settle one single point more than 2,000 fractionations have been performed.

The meaning of the strongly marked symbolic lines had first to be ascertained. For a long time I had to be content with roughly translating one group of coloured symbols as "yttrium" and another group as "samarium," disregarding the fainter lines, shadows, and wings frequently common to both. Constant practice in the decipherment has now given me fuller insight into what I may call the grammar of these hieroglyphic inscriptions. Every line and shadow of a line, each faint wing attached to a strong band, and every variation in intensity of the shadows and wings among themselves, now has a definite meaning which can be translated into the common symbolism of chemistry.

In a mineral containing the rarer earths those most widely separated in chemical properties are most easily obtained in a state of comparative purity by simple chemical means. For instance, in separating didymium from lanthanum, or samarium from yttrium, a few simple chemical reactions and a little waste will give these bodies in a state of purity; but when it comes to splitting up yttrium into its components ordinary chemical separation is useless, and fractionation must be pushed to the utmost limit, many thousand operations and enormous waste of material being necessary to effect even a partial separation.

Returning, therefore, after this explanatory digression, to the idea of heavy and light atoms, we see how well this hypothesis accords with the new facts here brought to light. From every chemical point of view the stable molecular group, yttrium, behaves as an element. Excessive and systematic fractionation has acted the part of a chemical "sorting Demon," distributing the atoms of yttrium into several groups, with certainly different phosphorescent spectra and presumably different atomic weights, though all these groups behave alike from the usual chemical point of view. Here, then, is one of the elements the spectrum of which does not emanate equally from all its atoms, but some atoms furnish some, other atoms others, of the lines and bands of the compound spectrum of the element. And as this is the case with one element, it is probably so in a greater or less degree with all. Hence the atoms of this element differ probably in weight, certainly in the internal motions they undergo.

Another important inference which may be drawn from the facts is that the atoms of which yttrium consists, though differing, do not differ continuously, but *per saltum*. We have evidence of this in the fact that the spectroscopic bands characteristic of each group are distinct from those of the other groups, and do not pass gradually into them. We must accordingly expect, in the present state of science, that this is probably the case with the other elements. And the atoms of a chemical element being known to differ in one respect may differ in other respects, and presumably do somewhat differ in mass.

Restricted by limited time and means, even a partial separation of these atomic groupings is possible to me only with enormous difficulty. Have we any evidence that Nature has effected such a separation? The following facts I think supply this evidence.

The earth yttria occurs in several minerals, all extremely rare. These minerals are of a very diverse chemical composition, and occur in

Digitized by Google

localities widely separated geographically. Does the pure yttria (*pure* in respect to every other known element) from these different sources behave differently to the radiant-matter test? To the chemist hitherto the earth yttria has been the same thing and has possessed the same properties, whatever its source; but armed with this new power of seeing into the atomic groupings which go to make up yttrium, we find evidence of differentation between one yttrium and another.

Thus, when the samarskite yttrium was formed all the constituent atoms—deep red, red, orange, citron, greenish blue, and blue*—condensed together in fair proportion, the deep red being faintest. In gandolinite yttrium the citron and greenish blue constituents are plentiful, the red is very deficient, the orange is absent, and the others occur in moderate quantities. In the yttrium from xenotime the citron is most plentiful, the greenish blue occurs in smaller proportion, the red is all but absent, and the orange is quite absent. Yttrium from monazite contains the greenish blue and citron, with a fair proportion of the other constituents; the greenish blue is plentiful, and the red is good. Yttrium from fluocerite is very similar to that from monazite, but the blue is weaker. Yttrium from hielmite is very rich in citron, has a fair quantity of blue and greenish blue, less of red, no orange, and only a very faint trace of deep red. Yttria from euxenite is almost identical with that from hielmite. Yttria from cerite contains most red and citron, less greenish blue and blue, only a trace of deep red, and no orange.

This is unlikely to be an isolated case. The principle is very probably of general application to all the elements. In some, possibly in all elements, the whole spectrum does not emanate from all its atoms, but different spectral rays may come from different atoms, and in the spectrum as we see it all these partial spectra are present together. This being interpreted means that there are definite differences in the internal motions which go on in the several groups of which the atoms of a chemical element consist. For example, we must now be prepared for some such events as that the seven series of bands in the absorption-spectrum of iodine may prove not all to emanate from every molecule, but that some of these molecules emit some of these series, others others, and in the jumble of all these kinds of molecules, to which is given the name of "iodine vapour," the whole seven series are contributors.

To me it appears the theory I here venture to formulate, taken in conjunction with the diagram in Fig. 1 (see *ante*, p. 437), may aid the scientific imagination to proceed a step or two further in the order of elemental evolution. In the undulating curve may be seen the action of two forces, one acting in the direction of the vertical line, and the other pulsating backwards and forwards like a pendulum. Assume the vertical line to represent temperature slowly sinking through an unknown number of degrees, from the dissociation point of the first formed element down to the dissociation point of those last shown on the scale. But what form of energy is represented by the oscillating line? Swinging to and fro like a mighty pendulum to points equi-distant from a neutral centre; the divergence from neutrality conferring atomicity of one, two, three, and four degrees as the distance from the centre is one, two, three, or four divisions; and the approach to, or retreat from the neutral line deciding the electro-negative or electro-positive character of the element—all on the retreating half of the swing being positive, and all on the approaching half negative—this oscillating force must be intimately connected with the imponderable matter, essence, or source of energy we call electricity.

Let us examine this a little more closely. Let us start at the moment when the first element came into existence. Before this time matter, as we know it, was not. It is equally impossible to conceive of matter without energy, as of energy without matter; from one point of view the two are convertible terms. Before the birth of atoms all those forms of energy which become evident when matter acts upon matter could not have existed—they were locked up in the *protyle* as latent potentialities only. Coincident with the creation of atoms all those attributes and properties which form the means of discriminating one chemical element from another start into existence fully endowed with energy.

The pendulum begins its swing from the electro-positive side; lithium, next to hydrogen in simplicity of atomic weight, is now formed; then glucinum, boron, and carbon. Definite quantities of electricity are bestowed on each element at the moment of birth, on these quantities its atomicity depends,† and the types of monatomic, diatomic, triatomic, and tetratomic elements are fixed. The electro-negative part of the swing now commences; nitrogen appears, and notice how curiously position governs the mean dominant atomicity. Nitrogen occupies the position below boron, a triatomic element, therefore nitrogen is triatomic. But nitrogen also follows carbon, a tetratomic body, and occupies the fifth position counting from the place of origin. How beautifully these opposing tendencies are harmonised by the endowment of nitrogen with at least a double atomicity, and making its atom capable of acting as tri- and pentatomic. With oxygen (di- and hexatomic) and fluorine (non- and heptatomic) the same law holds, and one-half oscillation of the pendulum is completed. Again passing the neutral line the electro-positive elements sodium (monatomic), magnesium (diatomic), aluminium (triatomic), and silicon (tetretomic) are successively formed, and the first complete oscillation of the pendulum is finished by the birth of the electro-negative elements, phosphorus, sulphur, and chlorine; these three—like the corresponding elements formed on the opposite homeward swing—having each at least a double atomicity depending on position.

Let us pause at the end of the first complete vibration and examine the result. We have already formed the elements of water, ammonia, carbonic acid, the atmosphere, plant and animal life, phosphorus for the brain, salt for the sea, clay for the solid earth, two alkalies, an alkaline earth, an earth, together with their carbonates, borates, nitrates, fluorides, chlorides, sulphates, phosphates, and silicates, sufficient for a world and inhabitants not so very different from what we enjoy at the present day. True, the human inhabitants would have to live in a state of more than Arcadian simplicity, and the absence of calcic phosphate would be awkward as far as bone is concerned. But what a happy world it would be! No silver or gold coinage, no iron for machinery, no platinum for chemists, no copper wire for telegraphy, no zinc for batteries, no mercury for pumps, and, alas! no rare earths to be separated.

The pendulum does not, however, stop at the end of the first complete vibration; it crosses the neutral point, and now the forces at work are in the same position as they were at the beginning. Had everything been as it was at first the next element again would have been lithium, and the original cycle would have recurred, repeating for ever the same elements. But the conditions are not quite the same; the form of energy represented by the vertical line has declined a little—the temperature has sunk—and not lithium, but the one next allied to it in the series comes into existence—potassium, which may be regarded as the lineal descendant of lithium, with the same hereditary tendencies, but with less molecular mobility and higher atomic weight.

Pass we rapidly along the to and fro curve, and in nearly every case the same law is seen to hold good. The last element of the first complete vibration is chlorine. In the corresponding place in the second vibration we do not have an exact repetition of chlorine, but the very similar body bromine; and when for a third time the position recurs we see iodine. I need not multiply examples.

In this far-reaching evolutionary scheme it could not come to pass that the potential elements would all be equal to one another. Some would be unable to resist the slightest disturbance of the unstable equilibrium in which they took their rise; others would endure longer, but would ultimately break down as temperature and pressure varied. Many degress of stability would be here represented; not all the chemical elements are equally stable, and if we look with scrutinising eyes we shall still see our old friend the missing link, coarse enough to be detected by ordinary chemical processes, associated in the groups containing such elements as iron, nickel, and cobalt; palladium, ruthenium, and rhodium; iridium, osmium, and platinum. Whilst in their more subtile form these missing links present themselves as the representative of the differences which I have detected and described between the atoms of the same chemical element.

Dr. Carnelley has pointed out that "those elements belonging to the even series of Mendeleeff's classification are always paramagnetic, whereas the elements belonging to the odd series are always diamagnetic." On this curve the even series to the left, as far as can be ascertained, are paramagnetic, and, with a few exceptions, all to the right are diamagnetic. The very powerful magnetic metals, iron, nickel, cobalt, and manganese, occur close together on the proper side. The interperiodic groups of which palladium and platinum are examples are said to be feebly magnetic, and if so they form the exceptions. Oxygen, which weight for weight is more magnetic than iron, comes near the beginning of the curve, while the powerfully diamagnetic metals, bismuth and thallium, are at the opposite end of the curve.

On the odd, or diamagnetic half of the swing, the energy appears to have considerable regularity, whilst it is very irregular on the opposite side of the curve. Thus, between the extreme odd elements, silicon (28), germanium (73), tin (118), the missing element (163), and lead (208), there is a difference of exactly 45 units, conferring remarkable symmetry on one half of the curve. The differences on the even side are 36, 42, 51, 39, and 53 (giving the missing element between cerium and thorium an atomic weight of 180); these at first sight appear conformable to no law, but they become of great interest when it is seen that the mean difference of these figures is almost exactly the same as that on the other side of the curve—viz., 44·2.

This uniformity of difference—actual on the one side and average on the other—brings out the important inference that, whilst on the odd side there has been little or no variation in the vertical force, minor irregularities have been the rule on the even side. That is to say, the fall of temperature has been very uniform on the odd side—where every element formed during this half of the vibration is the representative of a strongly marked group—sodium, magnesium, aluminium, silicium, phosphorus, sulphur, and chlorine, whilst on the even side of the swing the temperature has sunk with considerable fluctuations, which have prevented the formation here of any well-marked groups of elements, with the exception of those of which lithium and glucinum are the types.

If we can thus trace irregularities in the fall of temperature, can we also detect any variation in the force represented by the pendulous movement? I have assumed that this represents chemical energy. In the early formed elements we have those in which chemical energy is at its maximum intensity, while, as we descend, affinities for oxygen are getting less and the chemism is becoming more and more sluggish. Part may be due to the lower temperature of generation not permitting such molecular mobility in the elements, but there can be little doubt that the chemism-forming energy, like the fires of the cosmical furnace, is itself dying out. I have endeavoured to represent this gradual fading out by a diminution of amplitude, the curve being traced from a photographic record of the diminution of the arc of vibration of a body swinging in a resisting medium.

* For brevity I call them by their dominant spectre band.

† "Nature presents us with a single definite quantity of electricity. . . . . For each chemical bond which is ruptured within an electrolyte a certain quantity of electricity traverses the electrolyte, which is the same in all cases."—G. Johnstone Stoney, "On the Physical Units of Nature." British Association Meeting, 1874, Section A. *Phil. Mag.*, May, 1881.

"The same definite quantity of either positive or negative electricity moves always with each univalent ion, or with every unit of affinity of a multivalent ion."—Helmholtz, Faraday Lecture, 1881.

"Every monad atom has associated with it a certain definite quantity of electricity; every dyad has twice this quantity associated with it; every triad three times as much, and so on."—O. Lodge, "On Electrolysis," British Association Report, 1885.

When we look on a curve of this kind there is a tendency to ask, what is there above and below the portion which is seen? At the lower end of our curve what is there to be noted? We see a great hiatus between barium (137) and iridum (192·5), which it seems likely will be filled up by the so-called rare elements. Judging from my own researches, it is probable that many of these earthy elements will be found included in one or more interperiodic groups, whilst the higher members of the calcium, the potassium, the chlorine, and the sulphur groups, together with the elements between silver and gold, cadmium and mercury, indium and thallium, and antimony and bismuth, are still waiting to be discovered. We now come to an oasis in the desert of blanks. Platinum, gold, mercury, thallium, lead, and bismuth, all familiar friends, form a close little group by themselves, and then after another desert space the list is closed with thorium (233) and uranium (240).

This oasis and the blanks which precede and follow it may be referred with much probability to the particular way in which our earth developed into a member of our solar system. If this be so, it may be that on our earth only these blanks occur, and not generally throughout the universe.

What comes after uranium? I should consider that there is little prospect of the existence of an element much lower than this. Look at the vertical line of temperature slowly sinking from the upper to the lower part of the curve; the figures representing the scale of atomic weights may be also supposed to represent, inversely, the scale of a gigantic pyrometer dipping into the caldron where suns and worlds are in process of formation. Our thermometer shows us that the heat has been sinking gradually, and, *pari passu*, the elements formed have increased in density and atomic weight. This cannot go on for an indefinite extent. Below the uranium point the temperature may be so reduced that some of the earlier formed elements which have the strongest affinities are able to enter into combination among themselves, and the result of the next fall in temperature will then be—instead of elements lower in the scale than uranium—the combination of oxygen with hydrogen, and the formation of those known compounds the dissociation of which is not beyond the powers of our terrestrial sources of heat.

Let us now turn to the upper portion of the scheme. With hydrogen of atomic weight=1, there is little room for other elements, save perhaps for hypothetical helium. But what if we get "through the looking-glass," and cross the zero-line in search of new principles—what shall we find the other side of zero? Dr. Carnelley asks for an element of negative atomic weight; here is ample room and verge enough for a shadow series of such unsubstantialities. Helmholtz says that electricity is probably as atomic as matter;* is electricity one of the negative elements? and the luminiferous ether another? Matter, as we now know it, does not here exist; the forms of energy which are apparent in the motions of matter are as yet only latent possibilities. A substance of negative weight is not inconceivable.† But can we form a clear conception of a body which combines with other bodies in proportions expressible by negative quantities?

A genesis of the elements such as is here sketched out would not be confined to our little solar system, but would probably follow the same general sequence of events in every centre of energy now visible as a star.

Before the birth of atoms to gravitate towards one another, no pressure could be exercised; but at the outskirts of the fire-mist sphere, within which all is protyle—at the shell on which the tremendous forces involved in the birth of a chemical element exert full sway—the fierce heat would be accompanied by gravitation sufficient to keep the newly-born elements from flying off into space. As temperature increases expansion and molecular motion increase, molecules tend to fly asunder, and their chemical affinities become deadened; but the enormous pressure of the gravitation of the mass of atomic matter outside what I may for brevity call the birth-shell would counteract this action of heat.

Beyond this birth-shell would be a space in which no chemical action could take place, owing to the temperature there being above what is called the dissociation-point for compounds. In this space the lion and the lamb would lie down together; phosphorous and oxygen would mix without union; hydrogen and chlorine would show no tendency to closer bonds; and even fluorine, that energetic gas which chemists have only isolated within the last month or two, would float about free and uncombined.

Outside this space of free atomic matter would be another shell, in which the formed chemical elements would have cooled down to the combination-point, and the sequence of events so graphically described by Mr. Mattieu Williams in "The Fuel of the Sun" would now take place, culminating in the solid earth and the commencement of geological time.

And now I must draw to a close, having exhausted not indeed my subject, but the time I may reasonably occupy. We have glanced at the difficulty of defining an element; we have noticed, too, the revolt of many leading physicists and chemists against the ordinary acceptation of the term element. We have weighed the improbability of their eternal self-existence or their origination by chance. As a remaining alternative we have suggested their origin by a process of evolution like that of the heavenly bodies according to Laplace, and the plants and animals of our globe according to Lamarck, Darwin, and Wallace. In the general array of the elements, as known to us, we have seen a striking approximation to that of the organic world. In lack of direct evidence of the decomposition of any element, we have sought and found indirect evidence; we have taken into consideration the light thrown on this subject by Prout's law, and by the researches of Mr. Lockyer in solar spectroscopy; we have reviewed the very important evidence drawn from the distribution and collocation of the elements in the crust of our earth; we have studied Dr. Carnelley's weighty argument in favour of the compound nature of the so-called elements from their analogy to the compound radicles; we have next glanced at the view of the genesis of the element; and, lastly, we have reviewed a scheme of their origin suggested by Prof. Reynolds's method of illustrating the periodic classification.

Summing up all the above considerations we cannot, indeed, venture to assert positively that our so-called elements have been evolved from one primordial matter; but we may contend that the balance of evidence, I think, fairly weighs in favour of this speculation.

This, then, is the intricate question which I have striven to unfold before you, a question which I especially commend to the young generation of chemists, not only as the most interesting but the most profoundly important in the entire compass of our science.

I say deliberately and advisedly the *most interesting*. The doctrine of evolution, as you well know, has thrown a new light upon, and given a new impetus to, every department of biology, leading us, may we not hope, to anticipate a corresponding wakening light in the domain of chemistry?

I would ask investigators not necessarily either to accept or to reject the hypothesis of chemical evolution, but to treat it as a provisional hypothesis; to keep it in view in their researches, to inquire how far it lends itself to the interpretation of the phenomenon observed, and to test experimentally every line of thought which points in this direction. Of the difficulties of this investigation none can be more fully aware than myself. I sincerely hope that this, my imperfect attempt, may lead some minds to enter upon the study of this fundamental chemical question, and to examine closely and in detail what I, as if amidst the clouds and mists of a far distance, have striven to point out.

* "If we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid concluding that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity."—Helmholtz, Faraday Lecture, 1881.

† "I can easily conceive that there are plenty of bodies about us not subject to this intermutual action, and therefore not subject to the law of gravitation."—Sir George Airy. "Faraday's Life and Letters," Vol. II., p. 364.

NOTES.

MEXICO.—Seventeen electric clocks are about to be erected by the Municipal Authority in the city of Mexico.

NEWCASTLE-ON-TYNE.—The Northern District Telephone Company have opened a public call office at the Newcastle Exchange.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 8th inst. were £2,904, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE INCANDESCENT LAMP LITIGATION.—We have received from Messrs. Woodhouse and Rawson a circular relating to the present position of this dispute and the course of action which they propose to pursue. The circular is much too long for us to reproduce, but we have no doubt that copies may be obtained upon application to Messrs. Woodhouse and Rawson.

THE OLYMPIA HALL, KENSINGTON.—This portion of the large building of iron and glass which is now nearing its completion at Kensington, and is intended to rival the Islington Agricultural Hall, is to be lighted by electricity. The installation will be provided by the Anglo-American Brush Corporation. The engines and boilers will be supplied by Messrs. Davey, Paxman, and Co., of Colchester.

THE GLOBE TELEGRAPH AND TRUST COMPANY.—The directors of this company have declared the payment of an interim dividend on and after the 21st inst. of 3s. per share on the preference shares, less income-tax, and of 6d. per share on the ordinary shares, income-tax having already been deducted for the quarter ending the 18th inst. The transfer books of the company are closed from the 14th to the 21st inst. inclusive.

THUNDERSTORMS.—On Sunday last the Manchester district was visited by a severe thunderstorm. Two houses are reported to have been struck by lightning, and considerable damage was done.—The Telephone Exchange at Sandusky, a town in Ohio, was recently struck by lightning, which, we are told, melted the 450 wires of the switch-board, and set fire to the tower of the exchange. Three girls climbed to the roof and put out the fire.

THE FRANKLIN INSTITUTE. — We have received the "Announcement and Programme of Lectures" of the Franklin Institute for the ensuing session. Out of thirty two lectures announced only three are on electrical subjects. Of these, two are by Mr. Carl Hering, on "The different forms in which electricity is manifested" and on "The electrical transmission of energy;" the third is by Mr. C. O. Mailloux, on "The storage of electrical energy."

BOOKS RECEIVED.—From Messrs. Longmans, Green and Co. we have received a copy of "The Gas Engine," by Mr. Dugald Clerk. We have also received from Mr. Brown, of Queen Victoria-street, a copy of the "Advertiser's A B C."—Mr. Rankin Kennedy, of Glasgow, sends us his illustrated descriptive price list of electric light appliances.—The Commissioners of the Victoria exhibit have sent us a copy of the "Illustrated Handbook of Victoria."

THE BRUSSELS EXHIBITION OF 1888.—At the Brussels International Exhibtion, to be held in 1888, it is proposed to erect a bridge spanning the exhibition buildings, and to run an electric railway up one side, down the other, and thence *viâ* a subterranean tunnel to the starting point. Without venturing to express too positive an opinion, we should like to ask if the Belgians are satisfied that this is really the very best and most useful thing that could be got for their money.

ELECTRICITY AND EDUCATION.—M. Henri Paget, Schoolmaster, of Geneva, has effected a reform as regards the vexed question of corporal punishment in schools. He employs a static machine and sparks his pupils' hands. We scarcely think this innovation is likely to commend itself to the London School Board; still, in the interests of the makers of scientific apparatus, we deem it our duty respectfully to direct the attention of the authorities to this mode of chastisement.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—At the general meeting of this company, to be held on the 4th Nov., the directors will recommend the declaration of a final dividend of 3s. per share, payable on the 5th proximo, making, with interim dividends already paid, a total of 6 per cent. per annum for the year ended 30th June last. £13,000 has been transferred to the reserve fund from the profits of the half year. The traffic receipts for the week ended 8th inst. amounted to £3,585.

TELEPHONY EXTRAORDINARY.—We have recently quoted an account of some remarkable experiments, which are alleged to have proved that a person in a mesmeric trance is capable of interpreting a telephonic message by mere contact with the line wire. We have now the authority of the *Journal d'Hygiéne* for the statement that a young lady, employed in a telephone exchange, who happened to be in a highly nervous condition, found that she was able to understand a conversation without lifting the receiver to her ears, by merely holding it in her hand.

THE HOLROYD SMITH TRAM LINE SYSTEM.—For purposes of demonstration a short tram line upon the Holroyd Smith system has been laid down near Paris, in a field not far from the Porte Maillot. The track is about 230 yards in length, and takes the form of a horseshoe, while the level also dips considerably in the sharpest part of the curve. The line is thus well calculated to exhibit the capacities of the system, and we are pleased to hear that a car carrying 45 passengers has been tried upon it very successfully. The line has already been visited by several prominent French engineers.

FRENCH JUBILEE OF RAILWAYS.—The Jubilee of the introduction of railways into France will be celebrated in Paris next year. On this occasion there will be held:—1. An international exhibition of railways and industries connected with them, including electrical appliances, which will be open from May to October, 1887. 2. An international congress, composed of delegates of railway companies, chambers of commerce, scientific societies, and others. Every information can be obtained from M. A. Lewis, Commissioner-General for England and the Colonies, New Broad-street House, E.C.

POPULAR ELECTRICITY IN THE MIDLANDS.—Messrs. Chamberlain and Hookham send us an amusing account of the effects produced upon the minds of rural excursionists who have inspected their exhibits at Bingley Hall. One countryman was hard to persuade that a dynamo and a gas engine were not convertible terms. Others thought that dynamite and diamond cutting must be intimately related with dynamos; while the more scientific explained to their benighted relatives that the current was produced by the friction of the armature coils. The latter view, however, is by no means confined to the Birmingham district.

THE ELEVATED RAILWAY OF NEW YORK.—In addition to the Sprague system of electric railways, which we describe at some length in the present number, the Daft system is also being experimentally tried upon the New York elevated lines. It will be remembered that this system had a trial some months ago. Owing, however, to an error in the data supplied to the Daft Company as to the amount of power which would

Digitized by Google

be actually required for the ascent of the steepest gradient, the motors at first supplied were not sufficiently powerful, and had to be withdrawn. We understand that the cars will very shortly be replaced upon the lines with proper equipment.

THE CUSHMAN TELEPHONE.—A suit is pending in the United States Circuit Court at Chicago, in which the Bell Telephone Company is the complainant. The defendant is the American Cushman Telephone Company. This company claims to ante date all known telephone patents, on the ground that Cushman constructed and publicly operated a telephone at Racine, Wis., in 1851. The Cushman patent is claimed to be identical with that of Prof. Bell. The American Cushman Telephone Company was incorporated a short time ago, and set out to manufacture and sell telephones, but the Bell Company immediately filed a bill in the Circuit Court, praying for an injunction.

THE ST. ETIENNE INSTALLATION.—A singular thing happened the other day at St. Etienne, where there is a large central station on the Edison system, of which we recently gave some account. During a severe thunderstorm it was observed that many of the incandescent lamps were repeatedly illuminated for several minutes at a time. This story has been going the round of the French press, under the title of "Curious Effects of Lightning." The case is one of those in which the explanation would appear the most satisfactory to those who least understand the conditions involved. However, a very simple and satisfactory explanation of the phenomenon has now been given. It appears that upon the day of the storm a new ammeter was being tested at the central station—that is all.

TELEPHONES IN THE WEST.—The Western Counties and South Wales Telephone Company continue to extend their operations in various directions. Exchanges will shortly be opened in the following towns, in addition to the list which we gave some few weeks since:—Llanelly, Shrewsbury, Hereford, Weston-super-Mare, and Weymouth. The trunk line which is now being erected between Bristol and Swansea (a distance of 106 miles) will have intermediate stations at Newport, Cardiff, Pontypridd, Treherbert, and Briton Ferry, Another trunk line, forty miles in length, will connect Swansea, Landore, Morriston, Neath, Briton Ferry, and Port Talbot; and a third will run from Pontypridd to Merthyr Tydvill, *via* Aberdare. It is expected that all these extensions will be in operation before the close of the year.

THE POLLAK CELL.—This cell may now be seen in action at the offices of Messrs. G. Binswanger and Co., 5, Great St. Thomas Apostle, E.C., and we should recommend those electricians who are interested in primary batteries to avail themselves of the opportunity of inspecting it. To prevent misapprehension it may be useful to state that although the cell is well adapted for maintaining a limited number of small lights for a few hours at a time, yet it does not pretend to compete with other batteries which have been specially designed for incandescent lighting on a large scale. The special value of the cell arises from the fact that owing to its self-regenerative powers, it may be left entirely without attention for months together, while continuing every day to furnish a certain quantity of current. This is a feature which will recommend it for telegraphic, telephonic, and electric bell work, and for all purposes where batteries are to be placed in unskilled hands.

TELEPHONE DEVELOPMENT IN AUSTRIA.—The Austrian Government has authorised the connection of the various telegraph offices in the towns of Prag, Graz, Trieste, Bielitz, and Reichenberg, with the Telephone Exchanges there, for the purpose of telephonic transmission and delivery of telegrams to subscribers. The increase of subscribers in the towns worked by the Consolidated Telephone Construction and Maintenance Company, viz., Prag, Graz, Trieste, Lemberg, Czemoritz, Bielitz-Biala, Pilsen, and Reichenberg, has of late been very marked, the number of subscribers now amounting to 1,600. The average price of subscription is about 85 florins, out of which 10 florins have to be paid as royalties. In spite of this the Company has successfully overcome the numerous difficulties which had to be surmounted in introducing the telephone into Austria, and is now in a fairly prosperous condition.

LIGHTING OF THE "GREAT EASTERN."—The "Great Eastern," which left Liverpool for Holyhead on the 8th inst., has been lighted since the middle of May last by the Jablochkoff and General Electricity Company. The deck of the "Great Eastern" is lighted by forty 400-candle Jablochkoff candles, mounted on standards 12ft. high, and presenting an imposing appearance from the river. They are maintained by two of the company's 20-light dynamos, with a 10-light machine in reserve. The motive power is supplied by a horizontal single-cylinder donkey engine, which, in the daytime, drives the bilge and other pumps. This heavy and almost constant work is not conducive to a good maintenance of the joints or regularity of action, and great difficulty was experienced in consequence by the electrician, Mr. H. E. Mitchell. One day the governor belt slipped off, but the engine did not seem to run more unsteadily, and so it was not put on again, and the working has been more regular than before. It is intended to light the saloon with incandescent lamps.

A TELEPHONE "RETURN SIGNAL."—In a paper read before the Electrical Section of the American Institute by Mr. P. Gannon, the author remarks that battery call bells have an advantage over magnetos, because by listening at the telephone the person giving the call can hear the vibrator at the other end if the circuit is in good order. Whenever battery calls are used, this method may be employed with advantage as a daily test. Nevertheless, the undoubted advantages of the magneto call led the author to devise a comparatively simple attachment whereby the same advantage may be secured for the latter system. This consists of a freely suspended pendulum carrying either a wire coil or a permanent magnet attached to the bob; the pendulum is set in motion by the stems of the vibrators of the magneto bells, and continues to swing for a few seconds after the call has been given. It is easily seen that induced currents may be sent upon the line by this means, and in this way by listening on the telephone at the first station, it is known at once whether the call has been received—always provided, however, that the "induction" already on the line is not too great.

THE BARTHOLDI STATUE OF LIBERTY.—"After nearly three years of study and deliberation," says the (New York) *Electrical World*, "the manner of lighting the Bartholdi statue of 'Liberty Enlightening the World' has been definitely decided upon. The plan adopted is one which is in conformity with the general design of the statue itself, and which will add to its beauty in a marked degree. The torch of the statue will contain 8 lamps of 6,000 candle-power, the light from which will be thrown directly up into the clouds. This powerful beam, together with the cloud illumination, will constitute a beacon which will be visible probably a hundred miles out to sea, and will thus, afar off, be symbolic of the light and liberty to be enjoyed by the visitors to our shores. At the foot of the statue four or eight lights of 6,000 candle-power each will be distributed. Their light will

Digitized by Google

be reflected upon the statue, and will illuminate it brightly. All these arc lamps will be invisible themselves, so that the objections raised by the river pilots against the blinding effects of the light will be entirely removed. Besides the arc lights all around the statue, the diadem upon the head of the figure of Liberty will contain incandescent lamps, to give the effect of jewels."

THE TOWER SYSTEM OF ELECTRIC LIGHTING.—Although it can scarcely be doubted that the system of illuminating a town by means of a number of powerful arc lights placed upon lofty towers or posts, from 100 to 150 feet in height, is one of the most extravagant that could be devised, it yet appears that the system gives great satisfaction to the inhabitants of the towns in America where it has been introduced. In writing of the recent meeting of the American National Electric Light Association, the (New York) *Electrician and Electrical Engineer* says :—"In advocating the claims of Detroit as a suitable place for holding the August meeting, the inspection of the tower lighting system proved a most successful argument in favour of that city. We have never experienced so general a change in opinion, caused by actual observation, as there was upon this subject. A large number of the visitors were strongly prejudiced against the tower system, but after thorough examination became its earnest supporters." An enthusiastic correspondent of the same paper, after describing the avenues for which Detroit is famous, writes :—"At the entrance to one of these high-arched primeval temples we would suddenly come pat upon an arc light on a telegraph pole, its daring brigand-like flicker and stare nearly blinding every one, while everywhere apart from these uncanny spots, the diffused rays of a portion of the 576 tower lights, either too high above us to be unpleasant, or too far away to be dazzling, cast in every direction a gentle, soft, moonlight sort of illumination, which was a complete and glorious surprise to all."

COMPASS ERRORS.—We have lately heard of several remarkable stories as to deviation of the compass, but it would be difficult to beat the following, which we take from the *Toronto Mail* :—"A strange phase of the mystery of the compass was made manifest on the occasion of a recent cruise of the 'Cygnet.' The yacht left Toronto for a run across the lake to Niagara. Everything was fair and smiling. A large party of jolly people were on board, who enjoyed the trip greatly. It was found when they came within hail of land that they were seven miles out of their course, having come out opposite Wilson, N.Y. The commander was greatly troubled. It was decidedly a reflection on his seamanship, and he was exceedingly annoyed. He regarded the compass suspiciously, and carefully examined its surroundings, but could discover nothing that would account for any vagaries on its part. While he was standing gazing gloomily at the tremulous needle it gave a sudden start. The commander looked up and found that a stout member of the party had in the meantime approached. As he passed the needle followed his movements, and finally when he stopped at the bow the needle pointed straight at him. A series of experiments were then instituted, and it was found, when the stout gentleman was near, that the pointer followed him. He admitted that for some weeks past he had been indulging in the wild delights of an iron tonic, and he was afraid that his system had become permeated with the metal. This explanation was accepted by all, and the secretary was requested to communicate the facts to the Philosophical Society."

TUNING FORKS MAINTAINED BY ELECTRICITY.—In a recent number of the *Philosophical Magazine*, Prof. S. P. Thompson suggests an improvement in the method usually adopted for maintaining the vibration of tuning forks by electricity. This arrangement, which is originally due to Koenig, consists of an electro-magnet placed between the prongs and a stylus which makes contact with a platinum headed screw, and breaks the circuit when the magnet is excited, just as in the ordinary bell "trembler." With this arrangement it is, however, impossible to obtain a perfectly uniform and regular rate of vibration. Even when the pitch is approximately constant, the phase is continuously varying. Prof. Thompson points out that these irregularities arise from the fact that the impetus is given at the wrong instant of the motion, namely, at some other instant than that during which the fork is passing with maximum velocity through zero position of displacement. The professor is, however, able to indicate a very simple solution of the difficulty. He proposes to take two forks (which must, however, be in perfect unison with each other), and let each act as interruptor to the other, but not to itself, the electro-magnets of either fork being included in the circuit of the contact points of the other. One battery will suffice for the two, for they will not both make contact at the same time. The forks, when once started, will settle down to a difference of phase corresponding to an almost exact quarter of a period; hence each will close the circuit of the other when the latter is passing through the most favourable position, that, namely, of its normal position when at rest. Under these circumstances there will be no further tendency to vary either in phase or in period. It is also pointed out that the contact points should be affixed at, or near, the middle of the length of the prong, and not at the end, as is usually the case. In the former position the contact is much more firmly made, and is quite sufficiently long in duration.

SUBMARINE CABLES IN TIME OF WAR.—In the document published by the *Pall Mall Gazette* on Wednesday evening, purporting to be a copy of a memorandum addressed to the Admiralty by the junior lord (Lord Charles Beresford), the following paragraph occurs. We offer no opinion as to the authenticity of the *Pall Mall's* information, but have no doubt that its statements relating to our cables are substantially true :—"In these days of electricity and great speed the first point scored may save millions to the country which secures it, and have the probable effect of winning the campaign. This remark applies with particular force to our foreign stations. Through want of organisation and systematic instruction, as well as want of ordinary foresight, the Admiralty render it possible for an enterprising enemy, like France or Russia might be, to easily score this first advantage, because a delay of two days is allowed to elapse owing to the antiquated formalities of the present system before the Admiralty could communicate the proclamation of war to the Commanders-in-Chief of different stations. It should be arranged immediately that the English commanders on foreign stations shall be in a position to receive the news of war being declared as soon as, if not before, the enemy. The delay which must occur under the present system would be fatal on such stations as China or Australia, where there is floating wealth of enormous value, as the enemy during the interval referred to would cut the cables, and so the first intimation of hostilities to the English fleet might be the sinking of valuable merchant vessels or even English men-of-war. I know for a fact from a conversation with Captain S——, of the Russian ship L——, that it is one of the chief provisions in their scheme of preparations for war that the enemy's telegraph wires should be cut at certain indicated places, and it was inferred that, whatever country Russia was at war with, the British submarine wires would be cut, as the news of the whole world passes through them. There is

Digitized by Google

good reason to believe this was contemplated in 1885, as it is an actual fact that Russian men-of-war were stationed at all the most important cable centres."

ATMOSPHERIC ELECTRICITY.—Since the month of October, 1883, constant observations of the electrical condition of the atmosphere have been undertaken at the meteorological observatory at the University of Odessa. The observations have been made by means of a water collector, having a nozzle 1·5 meter in length, and placed at such a height that the jet of the water breaks into globules at a distance of 14 metres above the ground. It is well known that under these conditions the collector will assume the same electrical potential as that of the air at the point where the jet is broken up. The potential is measured by means of a Thomson quadrant electrometer. The potentials are given in terms of the number of elements of a copper-zinc-water battery, which served to balance the deflections of the electrometer index. The lowest potential recorded was on a very calm day in October, 1883, when it was equal to 90 elements. On January 16th of the following year, under a cloudless sky and a low temperature, the potential was found to be equal to that of 24,600 elements (assuming a proportionate deviation of the index), while a few days later the needle for the space of three minutes reached the extremity of the scale, and indicated still higher figures. The readings frequently vary over a wide range from one minute to the next. Some tables are given as examples, showing that in the space of a few minutes the potential has ranged from 1,200 up to 4,500 units. On another occasion, in ten minutes the potential fell from 24,600 to 1,050 elements. On the other hand, periods of considerable electric stability are sometimes recorded. On 27th December, 1883, the needle was observed to remain absolutely motionless for thirty minutes, although a slight wind was blowing at the time; again on the 23rd October of the same year the deflection of the needle continued constant for one hour. In each of these cases the potential reading was very low. The observations are believed to have established the fact of the existence of an intimate connection between the variations of atmospheric pressure and electricity. But the interpretation of the phenomena observed is so greatly complicated by local conditions, such as fogs, smoke, and dust that it is extremely difficult to obtain decisive evidence. Some of the figures given above seem to us to be highly remarkable, and we deem it unfortunate that further information has not been given as to the meteorological conditions on these occasions.

QUANTITATIVE CHEMICAL ANALYSIS BY ELECTROLYSIS.—The *Chemical News* contains a paper upon this subject by Mr. T. Moore, of which the following is an abstract:—"When solutions containing either iron, cobalt, nickel, zinc, cadmium, aluminium, chromium, or manganese, are treated with phosphoric acid and ammonium carbonate, and are electrolysed, the first five are completely precipitated, chromium forms a soluble chromate, manganese is partially deposited as oxide on the other electrode, whilst the aluminium is unaltered. For separate determinations of the first five, the following plan answers well:—The slightly acid solution of ferric (or other) *sulphate* or *chloride* is treated with a solution containing 15 per cent. of glacial phosphoric acid until the yellow colour disappears, ammonium carbonate is added in large excess, and the whole warmed gently until the solution is clear. On electrolysing the hot solution (70°) with a current equal to 1,200 or 1,300 c.c. mixed gases per hour, the iron (or other metal) is deposited rapidly and completely. A current equal to 100 to 300 c.c. of mixed gases per hour is sufficient to effect the deposition of the zinc, whilst a current of 40 c.c., which gives no deposit with zinc, is strong enough for cadmium. A good solution for the electric deposition of either zinc or cadmium is prepared by precipitating the solution of a zinc or cadmium salt with sodium phosphate, dissolving the precipitate in potassium cyanide, and adding excess of ammonium carbonate. This solution when electrolysed at 80° with a current equal to 1,000 c.c. of mixed gases per hour gives a rapid and complete deposit. Zinc is best deposited on silver-plated electrodes. For copper, the freshly precipitated sulphide dissolved in potassium cyanide, and mixed with excess of ammonium carbonate, is recommended. Manganese is best estimated by deposition as oxide on the positive electrode from a slightly acid solution of nitrate or sulphate; it is, however, interesting to note that a large proportion is deposited as metal by electrolysing with a powerful current a neutral solution containing a large excess of ammonium thiocyanate. For bismuth, sufficient tartaric acid is added to prevent precipitation of basic salt, the solution is rendered strongly alkaline with ammonia, mixed with considerable excess of glacial phosphoric acid, and electrolysed at first with a weak (20 to 30 c.c. gas per hour) current, subsequently with a current = 450 c.c. gas. Tin is easily precipitated from either acid or alkaline glacial phosphoric acid solutions. An attempt to estimate arsenic as AsH_3 by electrolysing its acid solution in presence of zinc sulphate was not successful."

AMERICAN VIEWS UPON ELECTRIC LIGHTING.—The following extract from the (New York) *Mail and Express* will serve to show in what light electrical matters are at present regarded by the American public:—"The Electric Light Convention that has just closed its sessions in Detroit not only showed what an important illuminator electricity has come to be in this country, but also what a variety of interests and industries are bound up in the general business of electric lighting. If specialisation is a sign of progress in any industry—as it must be, according to the evolution theory—electric lighting must have made tremendous strides in the few years of its existence. And it has. It is past the first period of speculative existence, and has settled down into a conservative business on pretty well established principles. If the electric light has done nothing more than stir up the gas companies, and frighten them into providing better light for less money, it would have been of immense benefit to the public. Since it became evident that there was a serious probability that electricity would become a competitor of gas, more attention has been paid to the improvement and cheapening of processes of gas manufacture, and to economising in its use. In almost every place where the electric light has been introduced at all, the gas service has been cheapened and bettered; and even the rumour of a possible establishment of an electric plant has often sufficed to bring down the gas companies. All this, however, is what may be called the negative result accomplished by the application of electricity to illumination. Its positive results have been far more important and beneficial. Local companies are organising in all directions; manufacturers have their facilities taxed to the utmost to keep up with the demands of their business; in many places even the gas companies, with wise foresight, have taken the bull by the horns, as it were, and themselves established plants for electric lighting. In the early days of the new industry, there was necessarily a good deal of speculation about it; but now there are a dozen systems of lighting that have demonstrated their practicability and usefulness; and it is a business enterprise on the same footing as any other—with no greater uncertainties and no greater prospective profits—to organise a

Digitized by Google

company for this purpose. Constant improvements are being made in the details of manufacture and construction of machinery and other 'plant' for electric lighting; and these improvements for the most part available for the use of the trade. We may expect, therefore, to see constant advances made in the efficiency of the machinery, and constant reductions made in the expense. It is as certain as anything future can be that American cities, and, eventually, all civilised cities, will be well and cheaply lighted."

ON THE ELECTRICAL CONDUCTIVITY OF GASES AND VAPOURS.—M. Jean Luvini, in the *Comptes Rendus* for September 13th, writes as follows:—From the experiments of Becquerel, Grove, Matteucci, Marrangoni, Agostini, and others, it follows that gases and vapours are very bad conductors of electricity. Grove demonstrated this proposition for air at very high pressures; Becquerel and Matteucci for very low pressures (1 to 3 millim). MM. Mascart and Joubert place air and vapours and generally all gases in the class of bad conductors; and Sir W. Thomson has stated that aqueous vapour is an excellent insulator. Notwithstanding this we still read in treatises on physics, and it is repeated in lectures, that moist air and vapours conduct electricity; and this very serious error is the base of several theories. I have made several sets of experiments on this subject, the results of which, combined with those of other experimenters, have led me to conclude that *gases and vapours, whatever be the pressure and temperatures, are perfect insulators, and cannot be electrified either by friction with each other or with solids or liquids.* I arrange the experiment so that the fluids in which the electrified bodies are introduced cannot be deposited as liquid on the whole length of the insulating supports. In a large room a long thread consisting of seven cocoon fibres, without torsion and without joints, is stretched. In its centre is suspended a hollow brass sphere 5in. in diameter. A second thread, similar and parallel to the first, supports a pith ball pendulum, which, when not electrified, is in contact with the brass sphere. I usually electrify the sphere with the conducting disc of an electrophorus. The extent of the room and the purity of the air enable me to fill the space about the electrified bodies with a considerable quantity of the gas or vapour which I am investigating, without these fluids settling for a time on the long thread. In this way, apart from the small conductivity of the wires, and the losses due to dust in the air, any diminution of the electrical tension observed must have been due to the conductivity of the fluids experimented on. I always electrified the sphere almost to the same tension; I then observed the time in which the deflection fell a certain number of degrees, first in air and then by surrounding the sphere and the pendulum by a dense atmosphere of the gas to be studied. I worked thus with air saturated with aqueous vapour at various temparatures from 16° to 100°; hydrogen and carbonic acid not dried, but as they emerge from the bath in which they are produced; air heated by charcoal or by the flame of a candle, the smoke of an extinguished candle, the fumes of burnt sugar, incense, &c. None of these substances showed any trace of conductivity. In one set of experiments, instead of cocoon threads I used ordinary sewing-thread stretched horizontally, and with a double pendulum in the centre provided with pith balls. The results did not change, but when I worked with aqueous vapour at high temperatures, the divergence diminished rapidly by a certain quantity and then became again almost constant. This effect is due to the vapour which is deposited on the larger and less insulating wire, and to the fact that the small quantity of electricity of the balls becomes divided between the thread and the balls themselves.

THE PARIS CREIL EXPERIMENTS.—We learn from *L'Electricien* that a further report upon the Paris Creil experiments has recently been privately circulated among certain circles in Paris. This document seems to be of considerable length, consisting of fourteen distinct sections; but, judging from the abstracts given by our contemporary, we gather that the only matter of any general interest is that contained in the two last sections, and which *L'Electricien* reproduces at full length. From these statements it appears that upon the 27th of May a special meeting of the sub-committee charged with the experimental work was held at Creil in order to determine the characteristic of the generator. But we venture to think that by the time our readers have grasped the facts which we are about to place before them they will agree with us that the curve obtained is much more strongly characteristic of the committee itself than of the dynamo under discussion. A few words will explain our meaning. The machine at Creil has always been described, hitherto, as having its field-magnets separately excited. It is therefore scarcely necessary to say that the characteristic of the machine might be expected to follow a (very nearly) right line, commencing at some height upon axis Y, and, more or less, inclining towards axis X, owing to the increasing strength of the magnetic field of the armature. But, so far from conforming to this type, the curve before us looks very much as if it had been taken from a well-designed compound-wound dynamo. Commencing at the point of origin it rapidly rises, and soon becomes sensibly parallel to the axis X. The explanation which will naturally suggest itself at first sight is that for the purposes of this particular experiment the machine had been made to excite itself, though even upon this supposition it would be difficult to account for the phenomenon of the horizontal limb. But accompanying the figure is a table containing the numerical data from which the curve is supposed to have been drawn, and from this we find that the current through the field-magnets was usually about ten times as great as that through the armature, so that the fact of separate excitation is fully established. *L'Electricien*, after having noted this discrepancy, dismisses the subject with a few highly sarcastic observations. We confess, however, that our own curiosity was somewhat aroused, and we were anxious to discover, if possible, in what way the curve could possibly have been obtained from the figures in the table. In the first place it appears, both from the table and from an accompanying note, that the curve has been constructed from only three sets of co-ordinates. And on further examination it appeared that these points all lay well outside the curve as given—which, by-the-bye, it should be mentioned is reproduced in fac-simile by our contemporary. Now, these points are all situated near the upper part of the curve, *and would equally well suit the normal characteristic of a separately excited dynamo.* It is true that the third point, if plotted from the volts and amperes given in the table, would be about 25 per cent. too high; but upon referring to the column of velocities it appears that the speed had now increased from 121 to 158 revolutions per minute. At the same time the exciting current seems to have been considerably increased. If, however, the ordinate be reduced in proportion we get a perfectly normal curve. It is superfluous to add further comment, but it can scarcely be doubted that had the members of the committee taken the trouble to acquaint themselves with the elementary facts of electrical engineering they would not have been at the pains of plotting an imaginary curve when a straight line would have certainly answered the purpose so very much better.

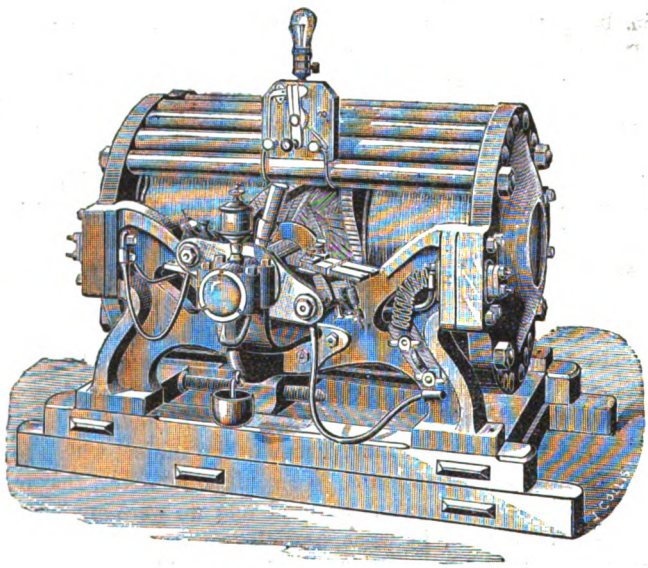
THE NEW THOMSON INCANDESCENT DYNAMO.

The Thomson-Houston Company have hitherto achieved all their success by means of their remarkable high-tension machine, and when incandescent lamps have been demanded they have hitherto contented themselves with running them upon multiple-series circuits furnished with automatic switches for maintaining constant resistance in each branch. Prof. Thomson has, however, at length designed a low tension machine specially for incandescent lighting work. This machine is illustrated in the accompanying engraving, which we reproduce from the columns of the (New York) *Electrical World*.

It will be seen that in its general arrangement the new dynamo bears a very close resemblance to its predecessor; there is the same disposition of the field-magnets and the same spherical armature. The coils of the latter, however, no longer conform to the "open circuit" type; but are, in fact, wound in numerous sections in a manner very much resembling the well-known "Siemens" winding. The arrangement of the connections between the coils and the bars of the commutator is somewhat peculiar. The wires are carried along the shaft into the body of the armature as far as its middle point, then radiate outwards, and are soldered to the coils around a "great circle" of the sphere. The armature



The new Thomson Incandescent Dynamo.

core is constructed of rings of annealed sheet iron (of different diameters presumably), which are carried by hubs on the shaft.

The field excitation is in some respects unique. Although the machine is compounded for constant potential, yet the magnets are wound with shunt coils only. This paradox is explained by the fact that the series coils are placed *between* the field-magnets, and directly over and around the armature, so as to exercise an immediate influence upon the armature core and wire. And further, the plane of this series coil is inclined at an acute angle to the plane of the principal magnetic field, this angle being so adjusted as exactly to compensate for the distortion of the field which would otherwise be produced by the polarity of the armature.

Considering the comparatively small amount of iron in the field-magnets, it is probable that but for this arrangement the machine would suffer considerably from sparking. It will be seen that Prof. Thomson has overcome the difficulty with his usual originality and ingenuity, and this new departure will certainly be watched with much interest. We learn that machines of 75, 110, and 150 volts have been constructed upon this plan with considerable success.

We hope before long to be able to publish some further electrical details.

A NEW RESISTANCE GOVERNOR.

We illustrate this week a resistance governor, lately brought out by the Woodhouse and Rawson Electric Manufacturing Company. These apparatus are intended to automatically regulate the amount of resistance in any electric circuit, and are made in two different types, the larger form being intended for heavy currents, and consequently principally used with resistances in a main circuit, and the lighter form being for smaller currents and adapted for use in the field-magnet circuits of dynamos when resistances have to be inserted or withdrawn to keep the E.M.F. of the machines constant.

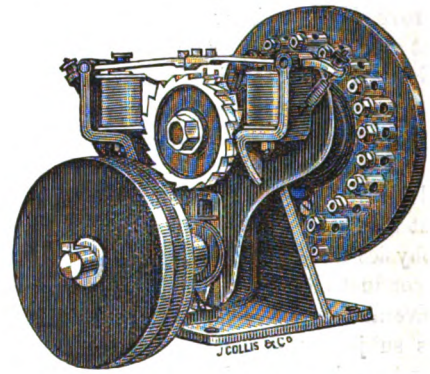


Fig. 1.—The Woodhouse and Rawson Resistance Governor.

A very short description will make the action of these governors quite clear. A switch arm attached to the same spindle as a pair of ratchet wheels with teeth in opposite directions, moves over a number of contact plates, between which are connected the units of resistance. These contact plates, as will be seen by the engraving, Fig. 1, are placed on a circular insulating disc attached to one end of the standard in the large governor, and in the small governor are mounted on the base board. On a continuation of the spindle carrying the switch arm and ratchet wheels is mounted a rocking frame, which is continually driven, through a crank disc, pin and block, by any convenient part of the moving machinery, from which a belt passes over the pulleys of the governor. The rocking frame carries two electro-magnets, the armatures of which act as pawls on the two ratchet wheels respectively when one or other of the magnets is excited.

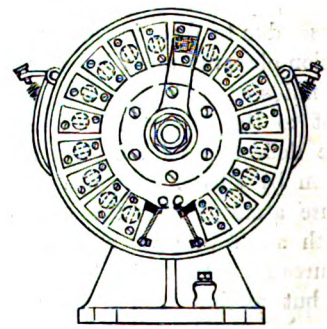

Fig. 2.—Front Elevation.

These governors are controlled by a regulator, arranged to make one of two contacts, and close one or other of the two electro-magnet circuits on the governor, when the E.M.F. or the current (whichever the apparatus is arranged to control) in the regulator is above or below its normal value. When this takes place, the electro-magnet excited draws down its armature, which engages with its ratchet wheel, and drives it and the switch arm forward to the next contact plate. By making the pitch of the teeth of the ratchet wheels of the same angular dimension as the distance between the centres of the contact plates, and properly arranging the travel of the rocking frame, the switch arm always moves forward until it is in its proper position on one of the contact plates.

Digitized by Google

By slightly altering the switch part of the governor it can also be arranged as an automatic accumulator switch to cut in or out cells, as the condition of the E.M.F. of the circuit may require.

We are assured that the governor is perfectly positive and dead-beat in its action, and it is thoroughly well designed and strongly made.

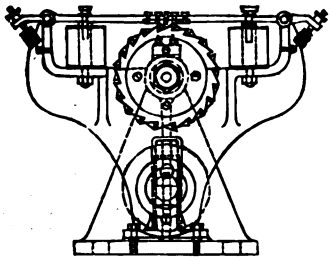

Fig. 3.—Back Elevation.

It is well understood by electrical engineers that governors of this type, which directly control the dynamo, are chiefly of use where the engine employed has to do other work, in order that the machine may thereby be rendered independent of fluctuations in the speed of the engine. This resistance governor is a modification of the Porte-Manville Electric Engine Governor, which our readers will remember was described some time ago in our columns.

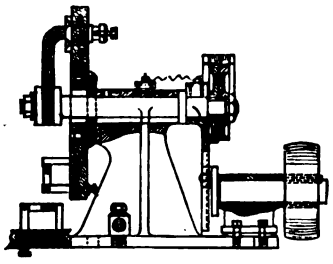

Fig. 4.—Section.

We understand that the first four of these governors were made for Sir David Salomons, and are now in daily use for the regulation of resistances and accumulators in his large installation at Broomhill.

THE GREAT BRUSH DYNAMO.*

By Dr. Robert H. Thurston, Director Sibley College, Cornell University.

The process of reduction of aluminum and other metals, and production of alloys, invented by Messrs. E. H. and A. H. Cowles, and perfected with the assistance of Prof. Mabery, of Cleveland, O., has attracted the attention of engineers, as well as of men of science, not only on account of the ingenuity, simplicity, and effectiveness of the process itself, but also, and probably quite as much, because of its bringing into use the voltaic arc and dynamo-electric machines of exceptional and enormous power.

The writer was recently so fortunate as to be able to stop in Cleveland long enough to witness the operation of the process, and to be present at the first trial of the great dynamo recently completed by the British Electric Company for the Cowles Electric Smelting and Aluminium Company.

The Cowles process, it will be remembered, consists in the passage of a powerful current of electricity from a "dynamo" through a mass of ore mixed with carbon and other material forming the "charge," until the action of the heat, and possibly of the electrical force, causes a reduction of the ores and the formation of an alloy of the metals so reduced.

* Read at the Buffalo Meeting of the American Association for the Advancement of Science, August, 1886. From the *Journal* of the Franklin Institute.

The apparatus consists simply of a powerful dynamo-electrical machine, connected with a pair of carbon electrodes of correspondingly exceptional size, these electrodes being enclosed in a furnace of brickwork, lined with the most refractory available material. The Cowles Company have several dynamos all of large size, but it is the intention of the writer to describe but one, the latest built and the largest. The next smaller, which was until recently considered a very powerful machine, weighs about two tons and a half, is driven at 900 revolutions per minute, and produces a current of 1,575 amperes, with an E.M.F. of 45 volts. These machines are "shunt-wound" and very nicely proportioned under the direction of the inventor, Mr. Charles F. Brush, whose interest in the work induced him to give to this construction his personal attention. The largest machine, recently completed, and under test at the time of the visit of the writer to the works, weighs 21,900 pounds (9,934 kgs.), a so-called 42in. (1060·6 mm.) machine, the armature having that diameter. The armature contains 1,600 pounds (725·7 kgs.) of iron; it carries 825 pounds (378 kgs.) of copper wire, while the field-magnets are wound with about six times that weight, 5,424 pounds (2641·8 kgs.).

The armature of this great dynamo consists of 16 bobbins, each carrying 21 turns of best copper wire, two strands lying side by side, the wire being 0·35in. in diameter (8·89 mm.). These 16 bobbins are operated in multiple arc, thus giving about 32 strands of copper wire of the diameter above stated, and about 65ft. (19·8 m.) long. Sixteen copper bars carry the current from the bobbins to the commutator, each car being 1in. by ½in. (25·4 mm. by 12·7 mm.) in section. The two commutators are coupled in multiple arc.

The field-magnets are eight in number, and consist of a cylindrical cast-iron core, 11in. (279·4mm.) in diameter, by 16in. (406·4mm.) in length, and wound with thirty layers of one hundred and two turns each, of copper wire, 0·134in. (3·404mm.) in diameter; all the eight wires are coupled in multiple arc as in a shuntfield. Thus combined they have a resistance of about one ohm, total, cold. The pole pieces are of peculiar form, and fitted carefully to the field.

The driving shaft, carrying the armature, is 13ft. (3·962m.) long, and 5½in. (139·7mm.) in diameter in the main bearing; it is made of open hearth steel, furnished by the Otis Company. The machine is driven by means of a 44in. (1117·6mm) double belt, turning a 40in. (1,016mm.) pulley on the armature shaft. The machine occupies a space on the floor about 15ft. (4·572m.) long, and 4ft. (1·219m.) wide, and stands about 5ft. (1·52m.) high.

This dynamo was calculated to furnish a current of 3,200 amperes, with an electromotive force of eighty volts, with a normal maximum current in the field of eighty amperes, the speed of rotation not to exceed 600 revolutions per minute. Its actual speed was a little above 400 when doing the full amount of work demanded. The maximum field is thus obtained with but about two and one-half per cent. of the normal current (3,200 amperes), and falling to one per cent. when less E.M.F. is needed. When in operation, the writer found no observable heating in any part of the machine, and the bearings ran perfectly free from heating or cutting. The efficiency of the machine must be very great, as, after its longest run of two hours, the armature was cool enough to handle with perfect comfort. The writer could bear his hand on every accessible part of the machine, which included all parts liable to any serious heating. The belt was new and stiff, and occasionally slipped as the limit of the power of the machine was approached; but that was a fault which a little work would cure, by making the belt flexible and giving it a better bearing on its pulleys. Had the engine driving it been of sufficient power, it was evident much more work could have been done than was actually performed on the trial. It was judged that it might have been driven up to 300,000 watts with safety. The conductors provided, and the resistance coil used in measuring the power developed, were, however, about at the limit of their endurance, as it was, the former heating until they were blue, and the latter requiring constant watching and cooling by application of water. The maximum reached was 249,000 watts, or 334 electrical horse-power, the engine probably

Digitized by Google

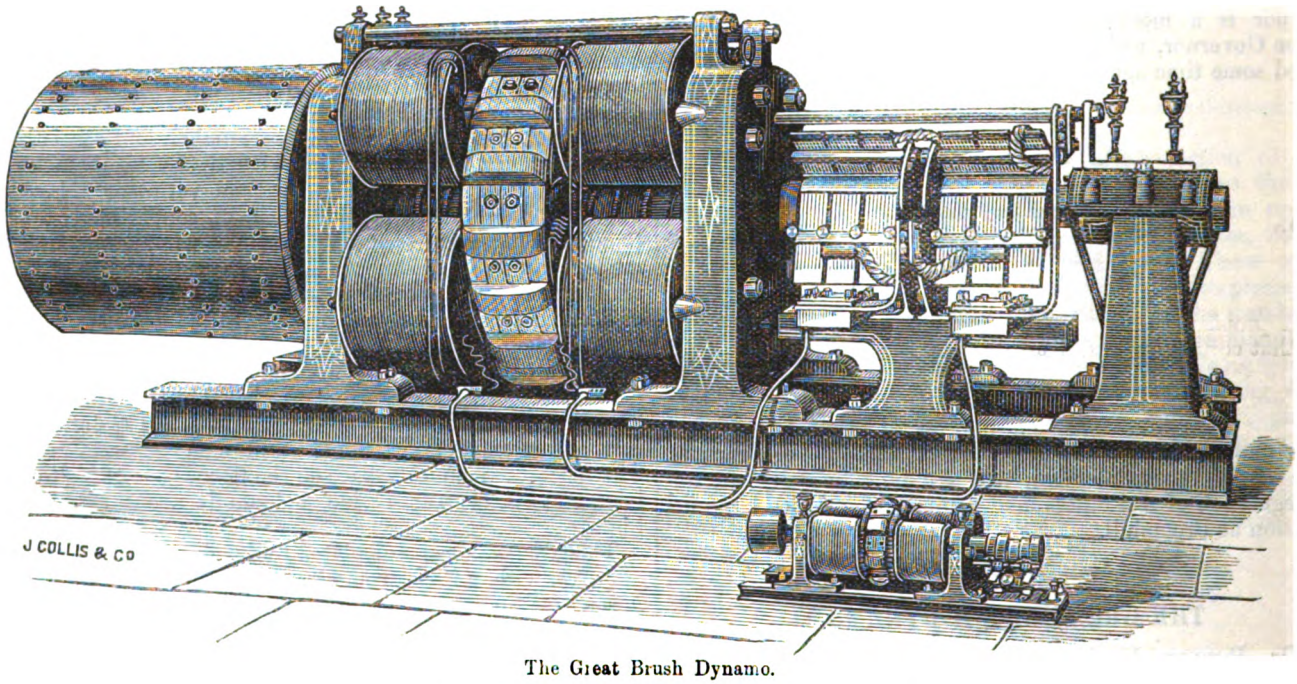
developing not far from 400 indicated horse-power. No indicators had been fitted, and it was impossible to measure this factor. The limit of its power was reached, however, and the power of the dynamo could not be tested to its maximum. The speed intended was, for the dynamo, 430 revolutions, but at eighty volts it could not be driven by the engine up to that speed.

The dynamo was built, complete, in all its details, from the specifications of Mr. Brush, and without preliminary experiment, and, when tested, was found to require no alterations of any kind, and came fully up to the requirements of the specifications and contract. Its capacity is very much greater than that of any machine yet built in the United States, or in the world. Its successful construction is considered by its designer to indicate that it is possible to design a machine of any desired size and power, with perfect confidence that it will come fully up to the calculated performance. No limit is to be seen, as yet, to the size and power of the machines, if properly designed. Their construction is a matter of definite calculation, and is to-day independent of direct experiment. The fact that a dynamo may be precisely designed and proportioned for any kind and amount of work that may be demanded, for any purpose whatever, without limit, so far as can be to-day perceived, is one of the most interesting and important revelations of recent work in in this field. The fact, also plainly shown by the experience of the Cowles Company, in the use of these enormous machines, that the larger the machine the higher the duty of the plant, is no less interesting and important. The economy secured in the production of their aluminum and other alloys, by the increased size of the later dynamos put in operation, is so great as to be a very valuable factor in the operation of the business, each new and larger machine very considerably reducing the price at which the metals can be put on the market.

The tabulated statement shown herewith presents the figures obtained at the trial of the ten-ton dynamo above described, and will repay careful study, as they exhibit the effect of variation of speed, of variation of current in the field shunt, and of electromotive force, in the production of energy in the external circuit. The highest power attained on this occasion was 249,000 watts, the speed of revolution being 405 (25 turns below the regular speed), the electromotive force being eighty-three volts (three above the standard), and the current measuring 3,200 amperes. The electromotive force in the shunt coils was eighty volts. The heaviest current measured 3,400 amperes, the electromotive force being sixty-eight in the main current and fifty-two in the shunt, the current energy measuring 231,000 watts at the terminals. At the standard speed of rotation, the circuit being broken, the measured electromotive force was 100 volts.

This remarkable and powerful machine was driven at the time of the visit of the writer to the works by a Corliss engine through a heavy counter shaft, the engine belt being carried over the belt from the jack shaft pulley to the machine. This arrangement is an unusual, but perfectly practicable one, and, in this case, worked admirably. It was occasionally necessary to readjust the position of the dynamo, as the belt, which was new and stiff and smooth, stretched more on one side than on the other; but this stretching will soon cease—probably has ceased—and, as the belt becomes more flexible and more perfectly fitted to its pulley, and as it takes its maximum stretch, it is evident that it will work with perfect accuracy, and will be competent to transmit any load that the dynamo can be expected to throw upon it.

The current from the machine to the furnace was conveyed by ropes of fine copper wire, or by conductors made up of several heavy wires. At the furnace they were connected to the terminals, which latter were of bar copper, apparently about two and one-fourth inches in diameter, armed with four carbons each, the latter of about the same diameter and four feet long. Between these was arranged the conducting material which furnished the incandescent bed in which the operation of reduction was carried on. This process is not, as is very often assumed, by professionals as well as non-professionals, an application of the voltaic arc to the production of high temperatures. Such an application was made by Sir William Siemens and by other experimenters from the time of the discovery of the intense heat of the arc; but it is, in the Cowles process, an application of the incandescent, as distinguished from the arc system. A connection is established between the carbon terminals, by means of a mass of carbon and other material, which mass is carefully kept continuous and incandescent throughout the whole operation. This is essential both to the success, actual and economical, of the process, and as distinguishing it from the older and wasteful systems of melting. By this system, the intense, the immeasurable heat of the arc is tempered and diffused throughout a large volume of incandescent material, and becomes adjustable and capable of regulation with comparative ease and exactness. Such control is thus secured as to make it convenient and economical in application to the reduction of ores and the melting of alloys and metals. Actual contact carries, everywhere, probably



The Great Brush Dynamo.

Digitized by Google

a very large proportion of the current, and the heat is distributed among numberless little particles of highly-heated carbon, which lend each its share to the numberless particles of the compounds to be reduced.

Experiments with 42-in. Brush Machine. June 25, 1886.

It is probably only by some such application of the electric heat that corundum can be made to surrender its aluminum to form an alloy with copper. It has been stated recently, in the discussion of this process, as described by Dr. Mehner, before the Association for the Advancement of Science in the kingdom of Prussia, at the Berlin meeting of the present year, that this reduction had been accomplished in a furnace heated in the ordinary manner; but it would seem that this must be a mistake, since alumina is one of the most refractory substances known in nature; it is said to be even more so than the materials of our furnaces and of our crucibles. The Messrs. Cowles have subjected it to the highest temperatures that a Dixon crucible would bear, without being able to reduce it or to melt it, in the presence of carbon and copper. Further, it would be probably impossible to successfully maintain a reducing flame, if that were attempted, or to avoid the reoxidisation of the metal were its reduction primarily possible. The reducing temperature of the compound is above the temperature of volatilisation, also, of the pure metal, and this would make it improbable that its reduction in this way should be successfully performed, far less with commercial success. The volatilised metal would rapidly escape from the Siemens furnace or from any other familiar form of furnace, while no other process than that above described would be capable of forming the volatilised metal in a closed furnace. In the Cowles furnace it is practicable to reduce alumina either with or without the presence of copper or other alloying metal, and one of the first intimations of the production of the working temperatures in that furnace is the appearance of fumes, indicating some volatilisation to be produced. As ordinarily conducted, this is not important in amount. Alloys of aluminum have been made in this furnace with nearly all familiar metals, a proof that copper, at least, is not essential to secure the reduction. So far as the writer has been informed, this is the only process by which reduction of this metal with carbon alone can be accomplished. The production of the metal commercially, in this manner, is expected to soon become an accomplished fact. The manufacture of the aluminum alloys has now for some time been successfully carried on, the cost of the aluminum in the alloy having been reduced to a small fraction of the price for which the metal is sold as made by the older methods. The Messrs. Cowles and Prof. Mabery have opened a new and broad field of experiment, and no one can surmise, even, what may come of the infinite range of possibilities so presented.

CORRESPONDENCE.

A PRACTICAL QUESTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have had my house lighted up for nearly two years with the electric light, supplied from Elwell-Parker's accumulators and dynamo driven by gas engine. Many of the lamps (16 candle) are now dull, and use 50 volts 38 amperes to give a good light. New ones give an equal light with 46 volts 32 amperes. Is it more economical to keep the old lamps in use longer and use more volts and amperes, or put new lamps and use less? The new lamps cost about 4s. each.

I shall be glad if you will kindly reply in your paper, so that others as well as myself may have the benefit of your opinion.—Yours, &c., S. A.

Manchester, October 11th, 1886.

[The following considerations will easily enable our correspondent to determine for himself which of the two courses is the more economical to pursue. From the data supplied it appears that with the old lamps the electrical horse-power consumed is equal to

$$\frac{50 \times 38}{746} = 2{\cdot}55 \text{ E.H.P.}$$

while with the new lamps he would get the same light by the expenditure of

$$\frac{46 \times 32}{746} = 1{\cdot}96 \text{ E.H.P.}$$

It therefore requires just one-half horse-power additional to run the old lamps, or 25 per cent. more than the total power required with new lamps. Our correspondent probably knows with sufficient accuracy how much a horse-power per annum is costing him. He also knows probably about how many lamps he has lost during the two years; he can therefore judge at what rate the charge for interest and depreciation upon the whole number of lamps should be estimated. Comparing this with the annual value of one-half horse-power he will at once see whether new lamps or extra power is the more expensive item. The calculation will not have any pretence to scientific accuracy, but it should be amply sufficient to answer the practical question. We have little doubt that he will find a considerable saving to be effected by renewing the lamps; but we shall be pleased to hear from our correspondent as to the conclusion at which he himself may arrive.—ED. *E.*]

ANTI-INDUCTION TELEPHONE CABLES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We notice in your issue of 24th ult., in speaking of our anti-induction telephone cables, an error has occurred which might mislead if not corrected. In referring to the experiments conducted at our works, it is stated the cable had a capacity of 29 microfarads, which should be *0·29 microfarad per mile at 0°C.*—Yours, &c., FELTEN AND GUILLEAUME.

Mulheim-on-the-Rhine, 6th Oct., 1886.

ROYAL VISIT TO BURNLEY.—On the occasion of the visit of Prince Albert Victor to Burnley on Tuesday last we learn from a local journal that the town was brilliantly illuminated by electricity.

LETTERS.

A letter awaits Mr. O. C. D. ROSS, M.I.C.E.

THE ELECTRICAL TRAMCAR.

Much hostility was aroused in this country when the earlier attempts were made to naturalise the American tramcar; chiefly, however, because of those preferential rights over the roadway which are indispensable to the tramcar's existence. That objection has gradually been condoned in the immense convenience which this method of locomotion has afforded the inhabitants of populous towns and cities; and for public conveyance between centre and suburb the tramcar is rapidly driving the omnibus off the road. One other objection, but of a quite different character, soon became manifest in the working of the system, namely, the exhausting effect on the horses. So serious is the expenditure under this head that the idea of working by steam locomotion soon took a practical shape, and in certain places where steam power was not unfamiliar in the streets the steam tram has actually invaded the precincts of the town. For suburban locomotion it is by no means uncommon, and where steep gradients have to be climbed, steam has been freely used, and without serious opposition, the general public arguing that only in this way can they enjoy the advantage of swift and smooth travelling.

Nevertheless, it cannot be denied that there is a very strong and a very natural prejudice against the steam tram. Its advent is immediately followed by the hoisting of signals of distress which are the sure indication that property in the neighbourhood is being depreciated. Residential thoroughfares are "to let" the instant any lines are laid for the accommodation of a steam tram; and although the convenience to passengers is the same whether horse or steam is the motive power, the devastation effected by the latter on house property is far worse than anything laid to the charge of the former. Nor can we wonder at it. If the makers of this hideous type of engine had deliberately designed the worst possible affront to a decent neighbourhood they could not have succeeded better. Whether they have consulted utility or economy most in the construction of what looks like a gigantic fish kettle with a stove pipe stuck on we are not in a position to say; but they have consulted nothing else. Even their own passengers are begrimed with soot, and sickened with the smell of burning oil. But passengers must put up with what they can get. Not so the inhabitants, past whose doors this frightful monster growls and pants, belching its grimy breath into their first floor windows, and who consequently hasten away to more secluded neighbourhoods, where the tyranny of vulgar utility is not so supreme.

There is something, too, about the steam tram which makes it an object of ridicule as well as of disgust. The absurd disproportion of means to end is obtrusively exemplified in the single car being sleepily dragged two or three miles by an engine which, judged by dimension, might speed a score of Pulmans to Birmingham at the rate of fifty miles an hour. Here, perhaps, the exigencies of frequent stoppages and startings, which tell upon the horses, prevail, even when the power is steam. Be that as it may, the steam car is a nuisance at best, and one which is not likely to be generally tolerated. Meanwhile, the waste of horseflesh on the ordinary tram-lines goes on apace, and proprietors are casting about for some motive power free from the objections we have enumerated. Some experiments on the North Metropolitan Tramway Company's lines at Manor Park last week point in this direction. Our readers are already familiar with the special gearing, which is the only peculiar feature of this system. We are inclined to think that the adoption of a separate locomotive car, though in itself a retrograde step, would have the practical merit of enabling every tramway company to give the electric system a trial, without having to make any change whatever in their present rolling stock. It is claimed for the Elieson system that a saving of 40 per cent. will be effected as compared with the cost of horses. Such claims are usually put forward; and all we need say about them is that we sincerely hope Mr. ELIESON'S methods will be subjected to a fair and practical test, we ourselves being perfectly satisfied that electrical propulsion has merits of its own which will commend it to favourable consideration apart from any such sanguine calculations as to saving in cost, though no doubt there is a saving.

One of its merits, over and above those we have already indicated, is that almost every one of the public objections to the laying down of tram lines would disappear were it known that they are to be worked by electrical power. The electrical tramcar is self-contained, perfectly clean, and rather handsome. The companies would effect an enormous gain on this account, if on no other. But so far as we have any trustworthy statistics to guide us, there is a real economy to be obtained by the construction and working of electrical tramways instead of horse or steam. Mr. HOLROYD SMITH, whose paper on the two mile electrical tram line at Blackpool was read at the British Association meeting, gave some very encouraging figures at the time, and some further details which we have published since go to confirm his estimate. For carrying 44,306 passengers over 2,760 miles during the week ended 10th September, the total working expenses were £45. 16s. 2d., the receipts being £347. 15s. 3d. Taking these figures on

Digitized by Google

the basis of the capital expended in the construction of a very difficult line, under what may be called almost tentative and experimental conditions, there is every reason to regard them as satisfactory. Mr. VOLK'S experiment at Brighton, though on somewhat different principles, has been equally successful in proving the practicability of working a tram line by electrical means with perfect efficiency and the certainty of being remunerative. Our latest intelligence is that Mr. HOLROYD SMITH'S system has been put to a severe trial in the vicinity of Paris, where a number of eminent French engineers were present to witness it, and that their verdict was extremely gratifying to the promoter. On the whole we see good reason to anticipate that the question of tramway locomotion may soon be solved in a way at once satisfactory to the public and to the owners of existing tram lines.

THE SPRAGUE ELECTRIC RAILWAY SYSTEM.*

In December of last year a paper was read before the Society of Arts, Boston, by Mr. F. J. Sprague, on the subject of the application of electricity to the propulsion of motors on the elevated railroads of New York. This paper contained a thorough investigation of the power used and its distribution, and indicated some of the methods which the writer proposed to carry out in the system that he had devised. The Third-avenue Elevated Road was taken as an example. It was shown that on this road the work was expended in three different ways, viz.:—

1. In overcoming the inertia of the train, which was 59 per cent. of the total.
2. In lifting the train on up-grades, which amounted to 24 per cent.
3. In traction, 17 per cent.

It was pointed out that because of the great frequency of stoppages and the necessity of high speeds on this road, most of the energy of the train which was put into it on getting under way and lifting it on up-grades was of little value for traction. At the time this paper was written there were at commission hours sixty-three trains in operation at one time on the up and down tracks. This was on a double track line of only 8½ miles length. The aggregate power that the engines on this road were capable of exerting was nearly 11,700 horses, the engines being of about 185 horse-power capacity. The average power exerted during the time trains were in motion was 7,640 horses, or, for the entire time on a trip, including stoppages, about seventy-four horses for each train of four cars.

The problem of how to handle this tremendous power on grades running up as high as 105ft. to the mile, with trains stopping every third of a mile, and sometimes not half a station apart, and sometimes reaching a speed of twenty to twenty-two miles an hour, is no mean one. It is true that small roads have been operated, among them one six miles long at Portrush, Ireland; but the conditions are totally different, and the demands which would be made upon an electrical system by the conditions of service on the elevated railroads present a new problem, and this problem not alone an electrical but also a mechanical one.

The elevated system presents the results of a great many years of careful thought in engineering study. It is the culmination of a great many improvements. It has been carried to a degree of efficiency far higher than its most earnest supporter thought possible. It has been taxed to its uttermost. Recognising these difficulties, Mr. Sprague, backed by private enterprise, has been for a long time engaged in the elaboration of a system. Announcement was made some time ago that this system was under trial, and for some time past it has been in experimental operation on the north track of the Thirty-fourth street branch of the Manhattan Railroad. A full-sized standard passenger car was placed at his disposal by the officers of the Manhattan Company, and by this means a great many problems are being worked out.

* From the New York *Electrical World*, September 25th, 1886.

The great amount of power which is used on the elevated railroad and the distance over which the trains are handled necessitate in the electric circuit large currents of a high potential. The potential decided on was 600 volts, and the experiments on the Thirty-fourth street section have been carried on with that pressure. No such electrical potential has ever been used in practice for this particular class of work, and motors which might be used with small powers over short distances and with low potentials would not avail here.

As mentioned above, there are at one time 4,640 horse-power actually being developed. With an efficiency of 80 per cent. for the motors, this would mean a current of 7,215 amperes with 600 volts. The handling of a current of 7,215 amperes, and of from 600 to 665 volts electromotive force is a somewhat difficult matter. A conductor to carry this amount of energy without a very large loss under ordinary conditions must be large, but with the stations properly put in and with the rails properly reinforced, together with the methods of working, which will be described more in detail below, it will be seen that the difficulty of handling this has been very largely reduced. We will now enter into a somewhat technical description of this system, both with regard to what is being done and what will probably be done in the future.

The first subject to be considered is the generating station. The system preferred by Mr. Sprague is the operation of a number of dynamos wound so as to generate at their normal speed and with a full load an electromotive force of about 670 volts at their terminals. These dynamos are wound for constant potential circuits. They are of very low armature resistance, and have high resistance shunt fields. The dynamos may be built so as to maintain a constant potential under all loads at the junction of the mains with the track. There is one disadvantage, however, about this, and that is, if there should be any very serious cross on the line the machines might be burned out. Where they are wound with the field-magnets in a simple shunt circuit, and no cumulative coil in series with the armature, any very bad cross on a line will lower the potential at the terminals of the machines, and while a very heavy load will come upon them for a brief interval of time, the drop of potential at the terminals will be sufficient to so far demagnetise the field-magnets that the machines cannot be burnt out. In addition, however, to the ordinary shunt coil, Mr. Sprague employs a special winding, one which appears in his railroad motors. This special winding is a coil in series with the armature, whose polarity is exactly at right angles to the polarity set up by the shunt coils, and is so proportioned that it automatically maintains the point of non-sparking coincident with the line of contact with the brushes on the commutators. This series coil would not have the effect of an ordinary cumulative coil. It would not raise the potential of the dynamos, but simply makes them non-sparking with fixed brushes under all loads.

Considering the length of road and the amount of power used it would be better to have two central stations rather than one. The engines would be compound, condensing, and placed near the water. By this means the coal consumption could be reduced at the central station to as low as 2lb. of coal per indicated horse-power. By having two stations, each removed about a quarter of the distance of the length of the road from either end, the size of conductor which is necessary for the middle rail is only one-fourth that which would be required were there only one station in the middle. Furthermore, the points of supply of current from each station should be maintained at the same difference of potential, to obtain which Mr. Sprague runs an independent line wire from station to station, with suitable indicators in it, showing whenever there is any inequality of potential existing at the supply points. This is done because the highest possible economy requires perfectly equal differences of potential at all points of supply, no matter how many the trains nor where they may be situated on the track. The combined capacity of the two stations would be something more than equal to the highest total horse-power appearing at any one time on the road, which, as we have seen, is about 4,700 horse-power. It will be noted that there

Digitized by Google

are no losses allowed for here. Why this is so will be explained in describing the system of braking which is used. This, then, would give a capacity at each station of about 2,500 horse-power. On account of the rise and fall of the work done on the line, it being light at night, somewhat heavier during the middle of the day, and at its maximum during the morning and evening, this 2,500 horse-power would be divided up into about four units, and to allow for any breakdown of an engine these units would be of about 800 horse-power each. The travel on the road is so perfectly known, and follows such a well-defined law of increase and decrease, that there would be no difficulty whatsoever in starting the engines at the proper time and throwing the dynamos into circuit.

We come now to the system of distribution, and this will be described more particularly with regard to the demands of the elevated railroads, leaving out particular reference to street roads, which form a department by themselves. There are many things which pertain to this system of distribution which would, of course, appertain to street work. The main rails are grounded, and form one side of the circuit, being connected to the structure of the road at suitable intervals. Four single rails, together with the superstructure and the ground connections, form a path of very low resistance. The other part of the circuit consists of a very light rail of special construction, thoroughly well insulated in a simple manner, and raised so that its top is from three to four inches above the plane of the ordinary traffic rails. This rail is not continuous, being of necessity broken at all switches, turn-outs, sidings, and cross-overs. The ends terminate about 18in. from all crossing traffic rails, and instead of ending abruptly, they are bent down slightly, so that when the collecting wheels, running on the central rail, leave or enter them, they do so without any shock or jar to the spring mechanism which carries them. This middle rail is further divided up into sections of any convenient length desired, say at intervals of 500 or 600ft.

In addition to this middle rail, there extends along the entire length of the line a heavy, continuous conductor, thoroughly insulated. This is connected to both ends of each section by fusible plugs or cut-outs and a short branch circuit. The branch circuits of the cut-outs form a Y connection, the main conductor being secured to the stem of the Y, and one end of each section to the arms of the Y. It will be seen now that in the normal condition of affairs if current is flowing from one part of the road to another part, and there is no train between these two parts, this current is carried over a double ladder-like circuit. The main conductor carries the major part of the current and the sectional working conductors a smaller part. So long as there is no train on the sections adjacent to any connection, it is evident that there is no difference of potential existing at the two opposite ends of the connecting branch, and no current will flow over it, although very powerful currents are flowing past each end of it. These currents will, of course, be in the same direction. When, however, a train enters a section it does not make any contact whatever with the main continuous conductors, but only with the working conductor, and current is supplied to this working conductor from both ends, partially, it may be, through the working conductors next adjacent, but mainly through the branches connecting it to the main conductor; that is, there is a difference of potential set up in the different parts of this circuit, and parts which were inert before become active the moment a train passes on to a section, no matter whether the train be taking current from the line or giving it to it. The current that flows through these branches may be made to actuate any kind of special device which is necessary, and thus forms a perfect block system of signalling, which operates by the presence of a train upon a section, since this train automatically sets signals at both ends of its section. These signals are of a variety of kinds, visual or audible, or both. Some are day and some night signals; and incandescent lamps, preferably two or more in multiple circuit with each other, are used for the night signals. Since the current on a motor is under perfect control, it follows that even if the train is at rest on the section the engineer is able to set his signals.

One of the great advantages of this system of main and working conductors is this:—If there is any bad cross or accident on the line the section will be cut out. The rest of the road will not be interfered with in the slightest, but the whole circuit will remain intact with the exception of the one particular branch of 500 or 600ft., which has been affected. The signals may be made of that automatic character such that when a cross does occur sufficient to break the safety catches of that particular section a signal is set and cannot be replaced until the section is repaired. We have here a perfect safeguard against any extended disabling of the line. Furthermore, if it becomes desirable at any time to operate a signal at only one end of the section the other end of the section can be cut out. If repairs are made, a section of the road being taken out or replaced, the track foreman can at once cut that particular section out of circuit, and after his repairs are made put it in again without interfering with the main line. In addition to these devices, the main working conductor can be divided up into sections and switches inserted, so that if it be desirable to cut out any extended portion of the track in case of any accident which makes the passage over a section of the track inadvisable, as in case of a fire, that portion can be cut out without the necessity of disconnecting each individual section.

In addition to these arrangements, the conductors of like potentials on different tracks and switches are connected by cross circuits which tend to equalise the potentials on the line, especially where there are any bad joints in the rail, and also when one track is more heavily loaded than the other. Another great advantage of these cross connections is that the current generated by trains running on down grades and stopping, can not only be sent back to the conductor on its own particular track and circulate through the system, but it can take a shorter and more direct path to the opposite track, where a train may be moving on the up grade or just starting. It should be further stated that both tracks are supplied from the same source, forming one complete circulating system. All motors are run in parallel circuit with each other, the current in each being independent of the current in all others, and the motors on the one track are in parallel circuit with the motors on the other.

We now come to the question of motor construction. The elevated railroad presents a special problem, as the strength of the superstructure is limited. At present the trains are drawn by locomotives which aggregate about twenty-two and a half tons in weight. Of this weight only fifteen tons is available for traction, this being the weight on the drivers. This weight of twenty-two and a half tons is centered in a very small space. Immediately behind the locomotive is the forward truck of a car, with a proportionate weight of nearly nine tons. There is then a total weight of over thirty-one tons in a space of about thirty-six feet, which is less than the distance between two columns. The consequence is that the strains, both tensile and shearing, are very great; but these strains are not the only source of danger. The vibration set up by a moving train, both vertical, due to the weight, and longitudinal, due to the motion of the train, has a shattering effect which is very great. It tends to loosen the bolts and badly strain the whole structure. There is an additional vibration due to the reciprocal strokes of the steam locomotive and its consequent unevenness of pull. If an electric locomotive were applied to handle a train, and it was made of 15 tons weight, it would pull more than a steam locomotive of equal weight, since all of it could be put upon the driving wheels, and there would be no necessity of additional truck wheels. But a fifteen-ton electric locomotive properly constructed and handled would pull even more than a twenty-two and a half ton steam locomotive with fifteen tons on its drivers. If the weight was distributed on four wheels, the wheels being on two perfectly independent axles, there would be absolutely equal pressure on each. This, however, is not the case with a steam locomotive. In addition to this, the strain could be simultaneously brought on all the wheels of an electric locomotive with such a perfect progression that they would adhere to the rail more firmly than an equal weight where the motion is derived from a reciprocal movement. Furthermore, there is a certain amount of increased adhesion of the wheels,

Digitized by Google

just how much it is impossible to say, because it varies under different conditions, and this is probably due to the heating effect of the current passing from the rail into the wheel.

Another method of handling the cars, and this is the most logical, although it may be a somewhat more costly method of working when dealing with old rolling stock, is the placing of the motors underneath the cars on the trucks which carry them. In this way at least one-half of the weight of the car and the passengers, as well as the motors, is available for traction.

If the motors are thus placed under the cars, each can be made an independent unit, or a dozen cars can be operated

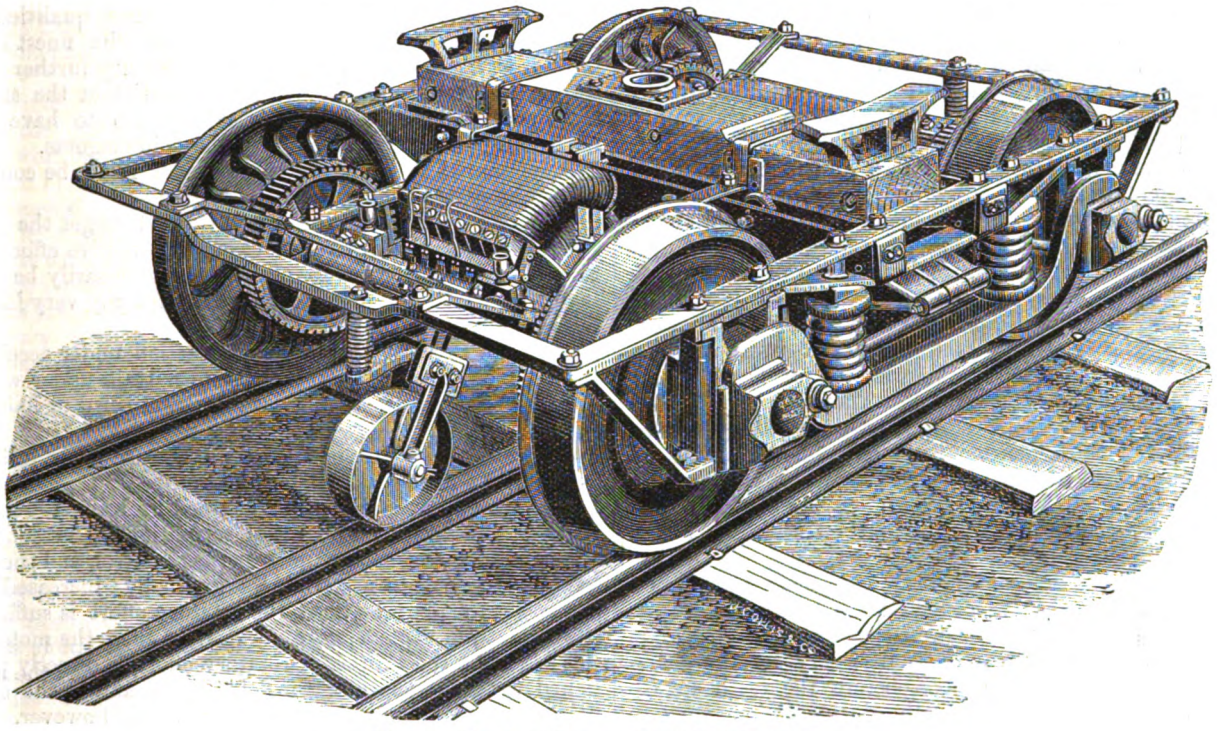

FIG. 1.—Truck of Sprague Electric Railway Car.

in a single train by a small regulating truck placed ahead of them.

This is the manner in which a single car is now being operated on the Thirty-fourth-street branch of the Third-avenue elevated railroad in New York City. The truck upon which the car is mounted is shown in perspective in Fig. 1, and in elevation in Fig. 2.

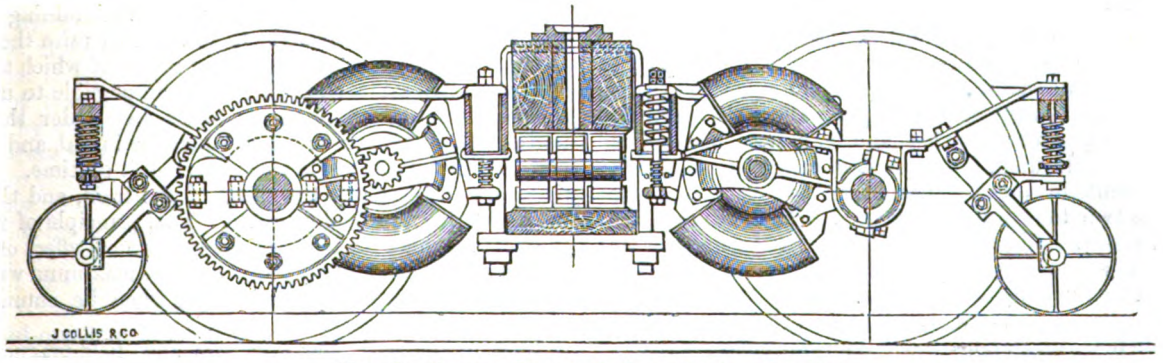

FIG. 2.—Sprague Electric Railway Truck—Elevation.

As will be seen, the latter represent a standard iron truck such as is in use on all the new cars of the elevated railroad, with, of course, some omissions and changes which were necessary for attaching the motors. The principal omission is that of all ordinary braking apparatus. There are two motors carried on this truck, each of the space between the axle and the centre cross-piece. The field-magnets, which are made of the finest selected scrap wrought iron, are built up of four segments, all forming parts of circles. Two of these form the pole pieces, and to these are attached heavy bronze hangers. The latter carry the armature, which is wound on a special modification of the Siemens system, and has at each end forged steel pinions of 3in. face and 3·7in. diameter on the pitch line. There are 13 teeth only. The hangers are extended and embrace the axle, which is turned off to a perfectly smooth surface, leaving a small shoulder at each side. Part of the hangers extending from the magnet pole pieces embrace one half of the axle, and the opposite half is embraced by heavy bronze caps, and inside each there are split liners to take up the wear. The armature shaft, as it passes through the hanger, is carried by two curved self-concentrating sleeves.

On the axles, close to the hub of the wheels on each side, are two split gears. These differ in character. One is keyed and bolted directly on to the axle, which is first turned off, and is a fixture. The other is composed of four parts, two being inner webs which are keyed on to the axle; the two outer ones form the geared section and are bolted together and have corresponding webs projecting inwardly, and fit snugly both on the outer edge and on the face of the webs which are keyed to the axle. The outer and inner webs are held together partially by the method in which they are turned up, but principally by bolts passing through them which work in curved slots. These, then, constitute adjustable split gears, and are probably a new thing in mechanics The gear wheels are of an especially fine grade of cast-iron, and are of the same face as the pinions which mesh into them. The number of teeth in these gears is 66; they are of the involute cut, so that if the motor should be moved to or from the axles slightly, the gears will still run perfectly true, with only a little more or less closeness of meshing. The pinions on the armature shaft

Digitized by Google

are set so that the one is half a tooth in advance of the other. Ordinarily, it would be a very difficult matter to get the splines on both the armature shaft and the axle and in the pinion and gears, so that they would mesh smoothly when running forward and backward, and it was for the purpose of getting rid of this trouble that the adjustable split gear was designed. It is now only necessary to key the two pinions, one fixed gear, and the web of the other gear in position without any regard to their meshing. The motor is then swung into position, the hangers made to engage the axle, the caps are put on, and the motor being moved forward and backward two or three times while the bolts of the adjustable gear are slack, this gear will assume a perfectly correct position. The bolts are now tightened up, and there is thus a nest of double pinions and double gears all meshing with absolute precision, no matter whether the motor runs backward or forward. The method of mounting produces a concentric motion, and by this means the driving and the driven axles are maintained absolutely parallel in two planes under all circumstances.

To allow the motor freedom to follow all the movements of the independent axles over frogs and switches, and also for taking part of the weight of the motor off the body of the axles and to throw it on to the boxes, one end of the motor is suspended at its centre by a bolt passing through the cross girders. This bolt is adjustable, and the upper part is held by a very stiff spring in a state of compression, which spring is in turn supported by a wrought-iron saddle. The motor is then, so to speak, weighed or flexibly supported from the body of the truck. There is also a smaller spring to take up any back movement or tendency to lift of the motor. This suspension is directly in the centre of the pole piece, and the field magnets, which are grooved in the form of a circle, are independently detached from the pole pieces, one of them being put on after the motor is in place.

The operation of this mechanical movement or method of mounting motors has exceeded the expectations of its designer. Because of the relation between the teeth in the pinion and the split gear, it is necessary for the armature shaft to make 66 revolutions before the teeth engage in the same way, and each tooth of the pinion must in turn engage every tooth in the gears. It will be seen also, since the motor is suspended at one end by the truck axle and at the other by compression springs operating in both directions, that whenever the axle is in motion there is always a spring touch, so to speak, of the pinions upon the gears. Barring friction, a single pound of pressure exerted in either direction will lift or depress the motor a slight amount. It follows that, no matter how sudden a strain, nor how great, it is impossible to strip the gears unless the resultant strain is greater than that of the tensile strength of the iron ; because the moment that the motor exerts a pressure upon the gears, at the same instant do the spring supports allow the motor to rise or fall so as to give somewhat, and no matter how sudden the strain is brought upon the gears it is always a progressive one. The result in practice has been that with a weight equivalent to two tons upon each 30in. wheel these wheels have actually been skidded in continuous rotation upon a dry track, and the strain necessary to do this amounts to from 1,500 to 2,000 pounds upon each gear. Strain has also been put upon these gears as suddenly as it is possible to close a circuit across 600 volts, and without injurious effect.

This method of mounting motors tends to produce an absolutely perfect form of gear, and has practically obviated the noise which was at first anticipated.

Designs for motors of from 200 to 300 horse-power mounted on these same principles will soon be finished, and the motors constructed and put into operation.

We now come to the electrical features of the motor. The armatures shown in the drawing have a special modified form of Siemens winding. The shafts are built up of the finest forged steel, and the body of the armature is built up with alternating layers of tissue paper and very thin iron discs. The difficulties first experienced in dealing with currents of such high electromotive force and large volume have now been overcome. The bodies of the armatures are thoroughly japanned and baked, and the utmost precaution is taken in putting on the different coils of wire to insulate them both from the body of the armature and from each other by the use of a material which offers very high resistance to inductive discharges. The commutators are built of the finest copper, and no insulating material is used other than that just mentioned and fine selected mica.

One of the fundamental features of this system of electrical propulsion is to get rid of all adjustments and to reduce it to the simplest possible system of working and at the same time to maintain as high an efficiency as possible of the motors themselves. For this purpose it was necessary, because of the limited space available, to make the motors of light weight and yet capable of developing a very intense magnetic field. The form adopted for these motors has given these qualities. The motors themselves are built entirely of the finest selected scrap iron specially forged. It was necessary further to have a wide range of speed under full potential at the armature terminals, and hence it was necessary also to have a wide range in the magnetic intensity of the field-magnets.

A motor when acting in this manner is to be considered under three entirely different conditions :—

1. When it is at rest, and it is desired to get the greatest possible torque or tractive effort. This tractive effort should be under perfect control, and should necessarily be greater than that which the motor could exert for any very long continued time.

2. When exerting a continuous traction under accelerating speed. This is necessary in getting a train under way, and this effort ordinarily extends over the first third or half of its speed.

3. Variation in the speed of the armature after full potential has been reached at its terminals.

The first characteristic is obtained by bringing the field-magnets to a very high degree of saturation. Current is then admitted to the armature under perfect control, and the potential at the armature terminals gradually increased, thus increasing the current until the rotatory effort is sufficient to start the train from a state of rest. When the motor is in this condition the torque, or rotatory effort, is directly proportioned to the strength of the field-magnet and to the current flowing through the armature. As soon, however, as the armature starts to rotate a different condition exists. It is now necessary to exert a continuous traction ; but the motor, on account of its accelerating speed, is generating an increasing electromotive force of its own which is counter to that of the line, and the difference between this counter electromotive force and the line electromotive force determines the current through the armature. Consequently, it is necessary, while maintaining the field-magnet at the same strength, to still further raise the potential at the terminals of the armature by means of which the current is kept at the same strength. It is impossible to maintain a constant tractive effort in any other way under these conditions. The potential will soon equal the initial, and the motor will be doing its maximum work per unit of time. It is now necessary to accelerate the speed of the train, and this is done by weakening the field-magnets. This principle of weakening the field-magnets to increase the mechanical effect of a motor at all times when not working up to the maximum was brought out by Mr. Sprague some time ago, when he enunciated the following principle :—

In a motor with the armature and field-magnet independently supplied, the work which the motor will do in a given time, its economy and efficiency, are all independent of the strength of the field-magnet, provided the translating devices intermediate between the motor and whatever is the recipient of its energy are not limited as to the rate of transmission of the motor speed ; and that in all cases where a motor is working on a constant potential circuit and not up to its maximum capacity, in order to increase the mechanical effect either of speed or power or both, or to compensate for any falling off of the potential on a line, it is necessary to weaken the field-magnets, instead of strengthening them. The result is that, if running on a level at a certain speed and a grade is met, and it is desired to get up that grade at the same speed, it is necessary to weaken the field-magnets. If the potential falls

Digitized by Google

off, and it is desired to keep up the same speed, it is necessary to weaken the field-magnets, and, conversely, if it is desired to slow down, it is necessary to strengthen the field-magnets.

A motor, when running, may be considered as a dynamo driven by a current. It generates an electromotive force dependent upon its resultant strength of field and the speed of the armature, and is independent of all other things. It follows that if the field-magnet be under proper control, this counter electromotive force is under perfect control under different speeds, and can be made greater or less in relation to the initial electromotive force, and consequently the motor can be made to do whatever work is desired of it.

This system of handling a motor, which is an essential departure from previous methods, has been carried out to its logical conclusion in braking the train, as will be indicated later.

The winding of the field-magnets of the motors is peculiar. One of the great difficulties which has invariably been met with in working with motors is the change of lead necessary to get the brushes at the point of non-sparking. It is absolutely necessary when dealing with large powers, if there is going to be continuous and successful running, to maintain the brushes at such a point. This change of the lead is caused by a distortion which is set up by the armature, varies with every change of load, with every change of armature current, and with every change in the field-magnet strength. It has furthermore been the habit where any considerable power has been developed to use two sets of brushes, one for forward and the other for backward motion. Mr. Sprague has entirely obviated the necessity for doing this by an arrangement which is as simple as it is efficient. This consists in the method of constructing, winding, and connecting up the field-magnets. The latter are wound with two sets of coils. One of these is a fine shunt coil, which is in series with an independent regulating resistance, and produces the normal poles; the other is a coarse coil in series with the armature which tends to produce poles at right angles to the normal poles, and this circuit is included in the reversing switch, so that when the armature circuit is reversed the current in the coarse coil is also reversed. There are then four poles set up in this machine, two being normal and variable at will, the other two being abnormal variable poles dependent upon the current flowing through the armature.

In the normal arrangement of circuits, the two sets of field coils, fine and coarse, combine to set up a resultant polar line which is distorted or rotated in the plane of rotation of the armature. Since any increase in the armature current causes the same increase in the series field coils, the tendency to distortion by these two elements will always vary to the same extent, and the resultant position will be always the same no matter what is the extent of variation of current. If the strength of the field-magnet is varied independently of the armature, by changing the resistance in the shunt field circuit or by a variation of potential on the line, while there is a tendency to change the armature distortion, there is an equal and opposite tendency to change the distortion due to the series field coils, and so this, also, has no effect. If the direction of the armature current is changed, so also is that of the current in the series field, and hence the direction of each distortion is changed; but they still oppose each other and vary equally and oppositely as before, and there is still no change in the non-sparking points. It is immaterial whether the change in direction of armature current is due to a change of terminals in changing the direction of rotation of the motor, or is caused in changing the motor into a generator by strengthening the field. Hence, the motor will run in either direction on a circuit of constant or varying potential, with a single or double set of tangential or end-contact brushes, with no change of lead, and, consequently, with no necessity for changing the position of the brushes. The position of the brushes having been once properly adjusted, it is made independent of the amount of work the machine is doing, or the speed at which it runs, or whether it is acting as a dynamo or as a motor. It is likewise independent of the strength of field and of the armature current so long as the magnetic moment of the field sufficiently exceeds that of the armature.

At each end of the car there are three vertical switch rods, connected by movable links with rods running through from one end of the car to the other. These rods have projecting fingers which operate the levers of three very rapidly-moving switches; the movement of these switches is independent of the rapidity of movement of the hand, which simply stores up energy until a certain point is reached, when the lever is freed, and the switch thrown over automatically. These three switches are employed as follows:—One for breaking the main circuit, another for reversing the armature circuit, and a third for detaching the armature partially from the line and closing it upon a local regulating apparatus. The movement of the handles on the vertical rods are similar at each end. Forward motion of one means forward movement of the car; forward movement of another means closing the main circuit, and a forward movement of the third means also a throwing off of the brake circuit. So that when a man stands at either end of the car, precisely the same movements mean the same thing as he looks up the track. In addition to these three vertical rods, there is a fourth rod which connects by a bevelled gear with a rod running through underneath the car, and provided with universal joints so as to allow of any necessary adjustment. The top of this rod carries a wheel very much like a brake wheel, and it connects with a regulator which consists of a series of resistance coils. These are so arranged that by the continuous movement of the regulator handle they are first cut out of the armature circuit, while the field is maintained at a high saturation, thereby raising the armature potential, and then cut into the field circuit in reverse manner, thereby weakening the field. This regulator governs also both steps of braking the train.

The current is taken from the centre rail by three conductors, two of which are bronze wheels working on pivoted arms under compression springs. They are provided with adjustable nuts to regulate the tension, and lock nuts to prevent the wheels dropping more than a certain limited amount when leaving the middle rail. The arrangement of contacts is such that the car will span 30ft. spaces without breaking the circuit. The other part of the circuit comes through the wheels of the truck, so that one part of the apparatus is continually grounded. The collector and the main circuits both run to fusible cut-outs before they reach the main braking circuit, and the armatures are also independently supplied at both ends with similar cut-outs. The armatures and the field-magnets are all in parallel circuit with each other.

This is the first instance in which two independent motors have been simultaneously controlled from the same regulating source, and by the methods employed it is perfectly possible to control 20 motors in the same way. When it is considered that the speeds vary from zero to 1,200 revolutions a minute, and the speeds of the two motors should be same, it will be seen how important a step has been taken. The torque or rotary effort of these motors under slow speeds is very great, and they are able to start from rest and propel two full-sized cars up the maximum grade on the elevated railroad. The motors weigh about 1,200lbs. each.

We come now to the system of braking, which is the logical sequence of the system of controlling motors originated by Mr. Sprague. As is well known, when a motor is in operation it is generating an electromotive force. In other words, it is acting like a dynamo, and since this depends upon the strength of the field-magnet and the speed, and since the field-magnet strength is under positive control, it follows that this motor electromotive force can be made to equal the initial motive force and even to exceed it. When this electromotive force of the motor thus predominates, the machine will become a generator and give current to the line, and its mechanical effects are reversed so that it brakes the train instead of propelling it; and the current generated by it, and the braking power, or reversed mechanical effect, are now controllable by further increasing or re-diminishing the strength of the field, and the new dynamo can now be changed back into a motor instantly at will. The mechanical energy received by the reversed motor and delivered as electricity to the line depends upon the mass of the train and its velocity. In running on a down grade there would naturally be an acceleration of speed, but this method of braking can limit that accelera-

Digitized by Google

tion at any desired point, or the motor can be slowed down when running on the down grade. This is done, of course, by strengthening the field-magnets. Since the energy of the train is now being used to run the motors as braking dynamos, the train will be run at a certain constant speed down grade ; or if the field-magnets be still further strengthened, the train will slow down ; this occurs also in the ordinary process of stopping. The diminution of speed, however, reduces again this motor electromotive force, and hence the field-magnet has to be strengthened still further as a train slows, until the speed is reached which, with the strongest field-magnet, will give a motor electromotive force equal to that of the line. This point with the motors in question is at about one-third speed, or seven miles an hour. Hence, eight-ninths of the energy of a train moving 21 miles an hour is sent back to the line in current to relieve the generating station. In fact, the system as here set out has the advantages of a cable road, together with other advantages which the cable road does not possess, because not only do the trains running on down grades help the trains running on up grades, but those which are slowing down likewise give up their energy to the system. In fact, this system is one in which trains slowing down and running on down grades supply the current for trains running on up grades and starting, and the central station becomes a differential factor to make up for the loss of conversion and reconversion and to provide for traction and loss in the conductors.

Were the machines perfect converters of energy, this would make the power taken by a system almost independent of grades and stops, and would simply be that necessary to provide for continuous traction and for loss on conductors. Of course, this perfection of conversion can never be reached. It does, however, make a difference of 40 per cent. in the power required to operate the electric railroads at the central stations, in the losses on conductors of a given size, and in the investment necessary in the central stations. As a matter of fact, there would be required at the central station only such horse-power as is to-day actually developed at any one moment on the elevated railroads, which is only about two-fifths of the capacity of the motors or engines.

Hence, instead of 7,215 amperes of current being supplied from the central stations at two points, it is supplied from as many additional moving stations as there are trains being checked on a down grade and stopping. Sixty per cent. only of this current would come from the main station ; that is, 4,329 amperes, or 2,165 from each.

The final step of braking is done by partially detaching the armature from the main line when its motor electromotive force is equal to that of the initial, at which moment there is no current flowing through it, and closing it upon the same local regulating apparatus which is used for regulating the speed and power, and the first step of braking. By this means the train can be brought to a full stop. All these steps of braking are under the most perfect control, but if necessary the breaking can be so sudden as to cause the wheels to have a continuous skidding rotation ; not such a skidding as is caused when an air brake is put on too hard, but a rotating slip which will be just enough to relieve the armature when the strain on it has come to a certain point. This is the most perfect possible method of braking, because fixed skidding is an impossibility, and the wheels will turn until the train comes to a dead stop, although where the braking power is put on too suddenly and exceeds the grip of the wheels, they will relieve themselves by slipping just enough to keep the braking at the maximum limit. With the switch in position for the last step of braking, the car can be allowed to creep down the maximum grades at a snail's pace with a movement so slow as to be almost imperceptible.

It is the customary practice to stop at the Second-avenue station of the elevated railroad station, which is on a 95-foot grade, without the use of any shoe brakes, although the rear truck is fitted with these and can be operated at either end of the car.

By a slight reversal of the armature effort, the car will stand at a dead rest on this grade. The energy of the train which is expended in the last step of braking can be used in heating the car, and some interesting experiments are now being carried on at the Thirty-fourth street station.

It should be noted that at present the generating station for this experiment is situated on Twenty-fourth street, so that the current at times is carried about three-fourths of a mile. The proper electromotive force is obtained by coupling together five Edison machines in series. The wire used is No. 1 B.W.G., and is carried on the Western Union Telegraph poles. Mr. Sprague has by no means rested satisfied in developing his system of railway and carrying it to the advanced condition in which it now is, but he is now engaged in equipping the station and cars along the line of the road with Edison lamps, which are run in series from the same high constant potential circuit that supplies the car, on a system which has been developed by Mr. E. H. Johnson, the president of the company. A *résumé* of the special and distinctive features of Mr. Sprague's system may not be uninteresting, and is therefore given below :—A double-track system with motors working in parallel circuit with each other on a constant potential circuit, the two tracks being supplied from the same source and from the same main conductors. A supply at two or more points by independent automatically non-sparking machines, the points of supply being maintained at the same differences of potential. A system of continuous main conductors intersected by switches, and sectional working conductors connected therewith through automatic safety devices. Means for cutting out, either automatically, in case of accident, or at will, if desired, any portion of the circuit. An automatic block signal system for day and night use. Methods for the equalisation of potential by cross connections between conductors of like polarity and on different tracks. A very simple construction of the motor proper. The centering of the motor upon the axles so as to maintain parallelism between the driving shaft and the driven axle.

The method of flexibly supporting a part of the weight of the motor from the truck, so as to allow perfect freedom in following the motions of the independent axles. The method of doing away with all shock and jar and danger of stripping the gears, and the maintaining at all times of a spring touch so as to prevent any backlash and to insure quiet running. Double driving from opposite ends of the motor shaft. The use of fixed and adjustable split gears. The means for getting a very intense rotary effort in starting by having an intense magnetic field and raising the armature potential gradually. The means for maintaining a continuous and equal traction until full potential has been reached. The method of increasing or decreasing the mechanical effects, whether of speed or power, or both, by an inverse varying of the field-magnet strength. The method of controlling two or more independent motors simultaneously from the same source and by the same apparatus.

MILLER'S PORTABLE TORSION MAGNETOMETER.*

BY PROF. BLYTH.

The armature is formed of five small bars *of soft iron* 5mm. long and weighing one gramme. The index wheel has its rim divided into $\frac{1}{100}$ths, and carries the outer end of a flat spiral spring, the inner end of which is firmly fixed to the long axis which carries the small armature bars. A fixed pointer projects from the ends of the case across the edge of the disc, and another pointer is fixed to the armature axis. In the normal position the pointers both point to the zero of the scale. When the armatures are placed in a magnetic field they are turned round and brought back to their zero position by coiling the spring through a definite angle depending upon the strength of the field. A constant is determined for the instrument by experiments in a field of known strength, or, if necessary, it can be empirically guaranteed. It is hoped that the instrument will be found of service to makers of dynamos for finding the strength of the field in various parts, and also for finding the best forms of pole pieces. There is also exhibited a form of small attraction magnetometer.

COMPARISON OF HARCOURT AND METHVEN PHOTOMETRIC STANDARDS.*

Perhaps no subject has received greater attention during the last few years than that of light and lighting in general. Public and private lighting have received an impetus which is gaining in strength every day.

The competition of the electric light has done an enormous amount of good in opening the eyes of the public to the defects of the old methods and the necessity for new.

Where a few years ago we could have found only a few persons who had any practical knowledge of photometry we now find hundreds. We have boys and girls making accurate photometrical tests by hundreds every day in the manufactories of glow lamps. We have the leading scientific men of the day devoting themselves to the comparison and analysis of all kinds and quantities of light, and yet when we are asked by what standard is light measured, and what is the meaning of a candle-power, how completely unsatisfactory is the answer.

It is true that many text books give full particulars of the various standards of light, and the relative values which the standards in different countries bear to one another; but who is there bold enough to assert that an expert in Berlin will give the same value to a particular light as one in Paris or London?

And this unsatisfactory state of things is not due, as many think, to the fact that A's eyes are not the same as B's, for if the two meet for the purpose of comparison they probably find that their personal error is an extremely small quantity.

But we may confidently assert that the variations are mainly due to the absence of the necessary standard, which in the case of weight, length, time, and heat is irrevocably fixed.

Science has not been idle in its attempts to settle the question, and many are the methods proposed as a solution of the difficulty, some feasible, others eminently impracticable; but Government authorities alone can settle the question for each country, and to them we naturally look for information.

And here we are immediately brought face to face with the anomalous state of things that the Government standard, as at present fixed, is absolutely the last which any experienced person would adopt except under legal compulsion, and instead of it we find various standards recommended and adopted according to the requirements of the work to be done.

Having been for a considerable time engaged in the measurement of the light of glow lamps and other sources of light at the factory of Messrs. Woodhouse and Rawson, at Hammersmith, in London, it has been of the utmost importance for us to procure a perfectly reliable standard by which we may determine the correct electomotive force which should be supplied to the various types of glow lamps made by us to produce the normal candle-power at which the lamps are intended to be used.

It may, perhaps, be of interest to those of you here present who are technically acquainted with the subject, and also to others, if I put shortly before you our experience of two of the standards at present employed in work of this kind. The result of a committee appointed by the Board of Trade in 1881 to report upon photometric standards was to bring prominently into notice two standards, viz., the Harcourt air gas lamp and the Methven screen. These two I have here on the table, and it is with regard to them that I wish to speak to-day.

Description of Methven screen and improvements made in the Harcourt lamp since last meeting of the British Association.—Having both standards in our possession it was naturally a matter of some interest to compare the two, and a considerable time ago we made a rough comparison of them, but about eight months ago my colleague, Mr. W. F. Donkin, and I commenced a series of experiments to determine the exact comparative value of the two, and to find the extent and probable cause of the variations observable in the Methven screen.

The report of the above-mentioned committee on photometric standards stated with regard to this standard that "where there is not any liability to a greater alteration in the quality of the coal gas than about two candles, the ease and rapidity of this system may render it extremely useful in determining the illuminating power of gas" (or other sources of light), "but the lamp in its present form has not that exactness for such a range as is necessary for a standard of light." In other words, the report stated that this was a fair commercial standard for employment in places such as London, where the normal variation of the value of the gas does not exceed two or three candles. As there was at that time a great demand for such a commodity, owing to the great inaccuracies of measurements by standard candles (which errors are very well set forth in the above report), the Methven screen was taken up as a distinct advance upon the time-honoured "parliamentary candle," and rapidly came into general use.

Since then it has found its way largely to America and the Continent, and, we believe, has lately been supplied to the Canadian Government.

In its original form the standard was so constructed that the centre support was in a vertical line with the screen, and from this point all measurements of distance were made.

The instructions now issued with the standard state that "the measurements are to be made from the centre of the burner, which position in a 60in. Letheby photometer is 30in. from the centre of the graduated bar."

Now, these instructions certainly lead to the conclusion that the standard is fitted for employment in a Letheby photometer, and as ours is of that pattern we should expect to obtain good results with it. Our earlier experiments were made with a bar of 80in. length; but, as we wished to work at greater distances, we had a new photometer constructed with a bar of 144in., in which great care was taken to verify all measurements. In addition to the ordinary bar graduated in candle-powers, we have a brass bar divided into tenths of an inch, which enables us to take readings by estimation to one hundredth of an inch.

At first the Methven screen was fixed at the right hand end of the bar, and the Harcourt lamp was mounted upon a carriage which moved in the same grooves as the disc holder. In our later experiments these positions have been reversed.

The position of each was very carefully determined at the commencement of each test, and the chimneys were scrupulously cleaned—an important point too often overlooked. The table is so marked that the carriage can be placed at any required point with great exactness. The distance between centres which we usually have employed are multiples of 10in. from 20in. to 120in. It was only necessary, therefore, to place one standard at any required distance from the other, and then take a series of readings, from the mean of which we could calculate the value of one in terms of the other. We have always taken the value of the Methven in terms of the Harcourt as unity.

Both standards were carefully watched by one observer, through blue glass, while the other took his readings; by this we guarded against any change taking place in the heights of the flames, and causing an error in the readings. The constant flickering of the flame in the Methven standard makes it difficult to determine accurately when the flame is at the right height, and this may constitute a source of error, as we have found a change taking place in the quantity of gas passing, and consequently in the value of the light when the eye was hardly able to detect a change in the height of the flame.

At first we worked with a Harcourt lamp without a chimney, and we were obliged to be very careful to exclude draughts, as the height could not be accurately determined unless the flame were steady, but latterly we have used the form which you see here, and the flame of this is absolutely steady, and no difficulty arises on this ground. The earlier values found for the Methven were so far below what is given as its normal value, viz., two candles, that we sent our screen to the makers, asking them to verify its correctness, and it was returned to us with the value of 1·98, or 1 per cent. below normal.

At the same time we verified the accuracy of the Harcourt by comparison with the official standard at the gas referee's office, and it was found to be correct within the limits of skilled observation.

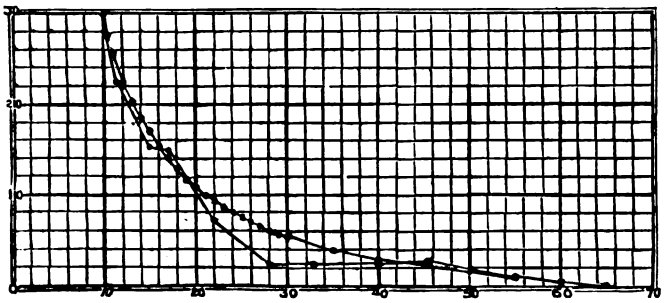
I may state that the standard had been carefully compared two years previously with Mr. Harcourt's standard at Oxford, and had been found by him to be correct. Now, I think you will not have much difficulty in seeing that with this form of the Methven standard as the disc recedes from the screen the light falling on the former will gradually decrease, from a cause different from that known as the decrease according to the law of the inverse square of the distance.

To explain this I would ask you to think of the case of looking through a casemate or loophole at the country beyond. As you come nearer to the opening more and more of the landscape appears, while if you recede from it the view contracts gradually till at last a further movement makes little or no difference to the amount seen through the opening. The disc then represents the observer's eye, and the luminous flame is in place of the country seen beyond.

This objection applies equally to all standards which employ what is known as the slot method, unless the slot is so close to the plane as to be practically touching it or the measurements of the distance are made from the slot.

It may be shown mathematically that the diminution of light due to this cause does not depend upon the size of the slot, but only upon the distance of the slot from the flame, whereas, if measurements are made from the slot and the light behind can be regarded as a flat homogeneous flame, the law of inverse squares holds as rigidly as with a naked flame.



Theoretical Curve of Variation of Methven Standard.

The above diagram shows the theoretical curve of variation determined from the measured distance in our standard of 1·4in., between the slot and the centre of the flame, which may be regarded as the mean position of the luminous source. I have also marked the mean curve deducted from a number of observations made by Mr. Donkin and myself. In order to show the curve more plainly, I have taken for abscissæ the distances of the Methven from the disc, and for ordinates the rise per cent. of its value above that which it has at 65in. from the disc.

The curve is the mean of values observed between February and April of this year, and though by no means perfectly agreeing with the theoretical curve in some places, yet the discrepancies are small, in no case being more than 3½ per cent. and in some cases less than 1 per cent. The curve shows, I think, that a considerable rise, amounting in one place to 25 per cent., takes place in the value of the Methven as the disc approaches it.

On one occasion we investigated the point as to whether the light is absolutely constant, even when measurements are made from the slot. We found, as others also have, that a slight increase takes place as the disc approaches, due to the greater thickness of flame subtended by the disc. The values on each occasion were taken with the wire of the Harcourt, set at 2½in., and the proper reduction made according to the formula established by Mr. Harcourt for changes due to alteration of barometrical pressure.

In order to satisfy ourselves still further as to the nature of the variation at different distances we employed the following method :—An incandescent lamp was made with two filaments, so that either could be run separately or both at once either in parallel or in series. These were made of different sizes, so as to give three different amounts of light according as one or the other or both were run.

If a perfectly constant E.M.F. be maintained at the terminals of the lamp, the light emitted by the two filaments together should be the sum of the lights of each observed separately. But it will be plain that if the above variations exist, the observed sum, when using the Methven as the unit of light, will be less than the true sum, because the value of the Methven is greater at the shorter distance of the disc from it.

We found, as was to be expected, that this was always the case ; but we made a more rigorous test of the accuracy of the theoretical values by taking the theoretical values for the longer distances corresponding to the values of the lights from the filaments observed separately, and then deducing from the observed sum the real value of the Methven at the distance corresponding to the sum of the lights. This value should of course be the same as the theoretical value at that distance. By properly choosing the E.M.F. this method could be employed to establish the variation over the whole range of the bar.

In order to keep the E.M.F. perfectly constant secondary batteries were employed, and any minute variations noted by a Thomson voltmeter, and corrected by an adjustable resistance in circuit. A delicate ammeter in circuit was also used to check the accuracy of the current passing when both filaments were run, being equal to the sum of the currents observed with each filament separately. The result of three carefully made series of tests gave us a mean deviation from the theoretical curve of less than one per cent. The lamp was so arranged that it was not moved during the tests, and the contacts were all made by mercury cups, except at the terminals of the lamp, which were carefully cleaned and clamped by broad pieces of metal.

I have quite recently made a fresh determination of our earlier results, as I found that the disc we had employed had become slightly tinged with yellow by atmospheric action, which would give us results slightly in favour of the yellower of the two lights. These determinations have been made nearly continuously during the month of August, and I have unfortunately been deprived of the assistance of Mr. Donkin, who has been absent during the time, though I have generally had the help of a qualified person in determining the setting of the distances and other details. A change in the construction of the photometer necessitated a reversal of the positions of the standards, the Harcourt now being at the right-hand end of the bar and the Methven mounted upon the movable carriage.

The results at first were manifestly incorrect, and I soon found that this was due to reflected light from the large body of light in the Argand flame, which, in spite of black curtains for sides and back ground, threw sufficient extra light upon the disc to render the results plainly wrong. In our earlier experiments this was prevented by a large fixed screen in front of the Methven slot. The difficulty was easily cured by placing perforated screens between the disc and both standards, allowing only direct rays to fall upon the disc. In spite of this I was unable to obtain results over the whole scale at all comparable in uniformity with our previous readings.

The value of the Methven was far lower than could be accounted for by the change of disc, and it was impossible to obtain concordant results extending over a period of four or five hours. Portions of the readings would be fairly correct, and then a deviation would take place from the theoretical curve, and on returning to a previously tested position a change would be found to have taken place. I therefore obtained a meter of the well-known makers, Sugg and Co., in order to test the quantity of gas passing with a 3in. flame, and also the total light given by the flame with the normal 5ft. of gas. I found, to my surprise, that 5·8ft. were required to produce a 3in. flame—this is 16 per cent. in excess of the normal—also the total light of this flame was on August 2nd only 15 candles, whereas it should be 16 candles with 5ft.

But on August 28th, at 4:30 p.m., I tested the amount of light with a 3in. flame consuming 6ft. of gas, and also with 5ft. of gas passing. I found the former only 13·2 candles, and the latter 9·2, instead of the normal 16. This probably was the cause of the inaccuracies in my later readings, for though the Methven is practically constant for small variations of quality of gas above and below the normal, yet when the quality is so far below normal as I found it it seems to be

Digitized by Google

remarkably sensitive to small variations in quality, such as are constantly occurring in the evening. I can only suppose that in the winter months we were more fortunate in obtaining gas of a tolerably constant quality during our experiments, although from the low value of the Methven I think it must have been considerably below normal.

I have been informed that deposition of heavy hydrocarbons in the service pipes causes a serious diminution in the quality of gas reaching a consumer, especially if he, like myself, has the misfortune to be at the far end of a long service pipe, and something like four miles from the gas works, so that I can hardly suppose that a sample of gas taken straight from our main in the Hammersmith-road would produce such poor results; but, however that may be, we have obtained exactly the conditions in which the committee foresaw so much danger in a standard founded upon the consumption of gas which is subject to considerable variation.

I think that I have sufficiently pointed out the difficulties we have encountered with this standard, and I have only to add that in its present form it is obviously faulty; and even if it were altered back to its old form, and measurements made from the slot, it would be still unreliable unless a constant check could be kept upon the quality of gas passing through it, and allowance would always have to be made for the variation due to increased thickness of flame, as mentioned before.

I am only expressing the opinion of nearly all those who have any acquaintance with the Harcourt lamp when I say that a three years' experience of it as it has developed its practicability and handiness, and increased its accuracy by the employment of a reduction table for barometrical changes, enables me to say, with perfect confidence, that though, perhaps, it may not be the ideal standard of white light of which we are in search, yet it is a unit of light which is practical in construction and adjustment, and as regards its extreme accuracy is well worthy to be classified as a recognised standard unit.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION OF THE UNITED STATES.

(Continued from page 460.)

Among the remaining subjects which came before the Association were several whose interest was rather of a national than of a general character. For instance, a paper was read protesting against the enforcement of electrical subways; another on the United States Patent and Common Law, as affecting the various electrical interests, particularly with regard to the question of the interference of the electric light conductors with telegraph and telephone work. A third paper on "wire joints," although treating the subject in a sound and able manner, can scarcely be said to have had more than a local interest. It dealt mainly with the necessity for making all joints with scrupulous care, above all things avoiding a mere twist; but as we really think that, as a class, the electrical engineers of this country at least have already mastered the A B C of their profession, we forbear to reproduce the essay. The last paper of importance was the following:—

Carbons for Incandescent Lighting.

BY MR. A. S. HICKLEY.

It is not my object in this paper to enter into a lengthy description of carbons of various makes or to criticise what others are doing in that branch of electrical industry, but to offer a few remarks especially connected with the manufacture and testing of carbons, as far as I have been connected with the production of the same. A long-lived lamp is not always an efficient one; you may have a lamp that lives 1,000 hours, but costs you too much to run. Better have one which lives only half that time, but which remains clear, or comparatively so, to the end, and requires one-third the power to run it. Of course, the consumers want both qualities, longevity and efficiency. With a view of meeting these requirements, I commenced a series of experiments with carbon of every conceivable description of material and compound I could obtain. It is not necessary to refer back to the many disappointments and failures of first experiences, for we all have been through that more or less. Suffice it to say, it soon became apparent that, as a general rule, an efficient carbon was not a long-lived one, and *vice versa*.

The question then arose: Why is that so? and after many experiments, both in baking, preparing and treating, exhausting with and without gases within the globe, I gathered some facts which I have the honour of bringing before you to-day. I soon discovered what is now a recognised fact, that after reaching a certain point of incandescence the candle-power doubled up with the increase of a very few volts. A 16 candle-power carbon at 100 volts, made of a certain material, became 32 candle-power upon the potential at its terminals being increased to 120 volts; again, the E.M.F. falling to 95 volts reduced the candle-power to 10. The size of the carbon had little to do with this in many cases. Thus a carbon of a certain size and 6in. long, took 8 amperes with an E.M.F. of 100 volts to produce a 16 candle-power light; another of the same diameter and length took 4 amperes and 100 volts to produce the same light. But let us watch them burn; at the end of 100 hours the 8 ampere lamp was becoming dark upon the inside, the 4 ampere one remaining as clear as when new; at 500 hours the 8 ampere lamp was so black that the carbon could be seen only when burning, and gave a light externally of but 6 candles. The 4 ampere lamp still remained clear, but burnt out at 550 hours, and had given not less than 15 candle-power until the end. Upon breaking the 8 amp. lamp the carbon was found to be roughened all over, the roughness being evidently caused by small particles of carbon being thrown off, these particles not only causing the carbon to increase in resistance by their separation from the main carbon, but carbonising the interior of the globe as mentioned before.

Carbons of the same material but of different diameter were then tested, all, I may say, being carefully examined before and after the tests through a powerful microscope. Two carbons were tested, each one being 100 volts, but one being twice as thick as the other. The thicker one gave a 16 candle-power light with the consumption of energy equal to 70 watts. The thinner one gave 40 candle-power with the same power, but the latter soon burnt out, and upon microscopic examination it was found that the fibres were cracked all over, and were bent at right angles to the grain of the material, and sticking out, as it were, towards the glass. I tried this upon a large scale, and made a carbon as large as a No. 13 wire. It behaved precisely the same, but now the fibres were quite visible to the naked eye and stood out all over the filament as though it had become indignant at being abused and roughened, its coat resembling an electrified cat or a porcupine. With this carbon I could produce a light equal to a candle for every watt, with lamps of 50 candle-power, but it would show fight and throw off his jacket. This was overcome at last in a manner I will explain later.

A carbon composed principally of the mushrooms formed between some arc-lamp carbons, forced through a small hole under great pressure, threw off some particles as soon as they were rendered sufficiently incandescent to be efficient. Structureless filaments behaved the same way, especially when not treated in a hydro-carbon. Much depends upon the manner in which carbons are treated. A rapidly deposited carbon is very hard and more efficient than one deposited at a lower temperature, which is soft and mealy; but the hard deposit is in lumps, which appear under the microscope to be united only to the main carbon at their basis; a hard, almost flint-hard, carbon (for there is such) is longer lived than a soft one, but the latter is oftentimes the more efficient. I refer here to untreated ones.

The fact then appeared to me that the soft carbon (porcupine description) with a jacket forced upon it which it cannot throw off or ruffle, would be *the* carbon. So, having decided the first or base, the question then arose, With what sort of jacket should it be covered? I was not entirely satisfied with the treating or improving in hydrocarbon alone, and having exhausted, as far as I knew, the vegetable fibres, I tried animal of all kinds except the Chinaman's hair, which, I learn, some one has actually patented; and I found that, size for size, the animal carbons were behind the vegetable in efficiency, but they could be used much smaller, considering that they were not so disposed to disintegrate.

Experiments then showed that a carbon, which was exceedingly efficient but too soft, coated with a fine animal carbon, wonderfully lengthened its life and allowed of its being brought to a very high incandescence without destroying it. The vegetable may be softened by an alkali and wrapped with an animal filament, and, after carbonising, both are found to be united almost as one. In fact, the vegetable has a coat upon its back which fits so tightly that it is compelled to keep its own on. Again, in large carbons for ten amperes a large amount of heat is produced, and if that heat could in some way be used before it left the carbon it would be beneficial. It will be found that a large carbon built up of a number of small ones intermixed with glass in a very finely spun state, and then wrapped, as described above, with any good animal carbon (of course this is done before carbonising) will be very efficient, the carbon communicating sufficient heat to the finely divided particles of glass throughout its structure, and rendering them conductors for the time being. A carbon of this construction appears to remain hot for a considerable time after the current is cut off. Coating the vegetable fibre with another material, whether animal or vegetable, greatly increases the surface. If this carbon is heated to a high state of incandescence innumerable miniature semi-arcs appear to be formed all over its surface, wonderfully increasing its light-giving powers.

Another important point to be considered is the preparation of the material before carbonising. Many substances require little or none, but the greater portion must pass through a certain change first; some have a gelatinous or sappy substance contained therein, which if not removed or changed will cause miniature explosions within the material itself and the fibres will be ruptured. This must be most carefully avoided. A carbon which under the microscope appears to be a bundle of loose threads is of little value for incandescent lamps. You may treat or improve it if you like, and so cement the fibres together that to all appearances you have a good, hard carbon; but its backbone is weak, and an overcoat upon that, buttoned ever so tightly, provided it is made up of semi-detached particles (only cemented together at their bases and extremities, which is the case with a deposited carbon deposited in the usual

Digitized by Google

way), will never make it long-lived. But it will be constantly increasing in resistance from the time it is put upon the circuit. If you have a fibre which, when baked, cakes or cements itself in a solid homogeneous mass, exhibiting no loose, hair-like projections, then you need not trouble about subjecting that material to any process before carbonising. On the other hand, as I have tried to show, a good material which cakes or cements itself to itself and to any substance upon which it is wound or braided, will sometimes save the weaker fibrous material upon which it is so wound.

In baking, also, it is of the utmost importance that that process be not carried too far, for you want the life of the carbon in the lamp not burnt out in the furnace. But at the same time you must bake enough. It is possible to bake so little that the filament when removed from the moulds, although to all appearance perfect, is virtually no conductor at all. Carry this a little farther and it becomes a poor conductor, but is not sufficiently changed to be of any use, for as soon as the current is forced through it, it bursts with a snap and a ring, like steel wire. After this stage the conductivity increases to a certain point, when it again decreases, this time on account of the carbon gradually wasting away, and you are in fact burning the very life out of it. The point is to catch it just when it is the best conductor and before the unnecessary wasting away process commences. This can only be ascertained by repeated tests and great attention to the regularity of the heat. The heat should also be applied to the mould, crucible, or whatever form of receptacle you use to contain your fibres, as evenly as possible. The whole should be brought to a glow throughout and at all parts at one time. I have carbons which were baked so that their extremities, that is, where they are connected to the platinum, were overbaked and ruined, while the bow or upper part was scarcely done. Examining this carefully through a microscope, the ends were found to be weak and frayed out and useless, while the upper part, or bow, was solid, glossy, and appeared to consist of an entirely different material.

Again, some substances may be baked in bundles bound together, each one keeping its neighbour in place, while others would cement together in such a manner as to render them useless. Do not bake too many in the same receptacle at one time, or so much gas will be given out that partial combustion will ensue unless you have some means of pumping out the occluded gas as fast as produced. Some substance, such as camphor, placed within the retort will sometimes enable you to bake successfully a material which otherwise would be useless. I have burning at the Russel House lamps which contain a vegetable carbon surrounded by an animal carbon. The vegetable alone in this case would be useless, but the animal covering preserves it and renders a high state of incandescence possible without disintegration. In fact it can, without injury, be maintained at so high a state of incandescence as to produce a bluish tint which enables you to readily distinguish colours. The efficiency of the carbon in this lamp is a little over one watt per candle-power. I am manufacturing these lamps for the Jenney Electric Company, of Indianopolis, and find them very efficient.

Mr. SLATTERY expressed briefly his dissidence from Mr. Hickley on some points, and avowed some incredulity with regard to the "one watt lamp," Mr. Hickley claiming a consumption of only 425 watts for 400 candle-power.

Mr. HICKLEY remarked that his materials and line of research were different from Mr. Slattery's ; hence, perhaps, the variant results arrived at.

COMPANIES' MEETINGS.

The United Telephone Company of the River Plate.

The fourth ordinary general meeting of the United Telephone Company of the River Plate (Limited) was held at the offices of the Company, 131, Wool Exchange, London, E.C., on Tuesday, the 12th October, Mr. F. W. Jones in the chair.

The SECRETARY (Mr. Geo. W. Rhodes) read the notice convening the meeting, after which

The CHAIRMAN, in alluding to the three and a half years' of the Company's working in the River Plate, said that the capital expenditure during that period, as well as the working expenses, had been paid out of the earnings, and that it was very gratifying to be able to state, as the result of this expenditure, that the paying subscribers had increased from about 300 to over 1,600, and their annual value from £6,400 to over £30,000. In addition, he would say that the contingent and other debt of the Company had been lessened during the same period by over £4,000. The increase of subscribers during the last nine months had more than doubled the increase of the preceding nine months, and the income of the current year would doubtless exceed that of the last by upwards of £5,000. Continued progress was never so well assured as at present, as the growth and development of the River Plate, which have been great factors in the progress of the Company, were now more than at any time in the past to be relied upon. Amalgamation in Buenos Ayres with the River Plate Telephone and Electric Light Company, had been under discussion for a long time, and a provisional agreement on the subject had been signed in Buenos Ayres last March. Several conferences upon this agreement had taken place, but up to the present time it was not possible to announce that there had been any definite settlement in regard to its provisions. The Directors had been prepared to recommend the acceptance of this agreement by the shareholders, but as a decision in regard to the details attending amalgamation had not been arrived at by the Directors of the River Plate Company, no recommendation could at present be made. Since the signing of the agreement the relative positions of the two companies in Buenos Ayres had materially changed. The revenue, which six months ago appeared to be about equal, was now about 12 per cent. in our favour, and everything indicated a rapid increase in this percentage. Delay in amalgamation, though for some reasons to be very much regretted, was not likely to result to the ultimate disadvantage of this Company. The rates had been raised from below to above those of the River Plate Company, without loss in the number of subscribers. The new subscribers in the last three months had exceeded those of any other like period in the history of the Company. The reports and accounts having been adopted, the Chairman moved a vote of thanks to the Resident Director in the River Plate (Mr. Adolph Fels) for the able manner in which he has conducted the affairs of the Company there. A vote of thanks was also passed to the *employés* in Buenos Ayres for their energy and devotion to the Company's business. The retiring Director and Auditor having been re-elected, the meeting terminated with a vote of thanks to the Chairman.

Direct Spanish Telegraph Company.

Notice is given that an extraordinary general meeting of this Company will be held at Winchester House, 50, Old Broad-street, E.C., on Tuesday next, at three o'clock, when the subjoined resolutions, which were passed at the extraordinary general meeting of the Company held on the 30th ult., will be submitted for confirmation as special resolutions, viz :—"That in consequence of the abandonment of the Company's original cable, the capital of the Company be reduced from £190,000 (at present represented by 6,000 preference shares of £10 each, all issued and fully paid up, and 13,000 ordinary shares of £10 each, whereof 12,931 are issued, and have £9 per share paid up, and 69 are unissued) to £95,000, and that such reduction be effected by writing off £5 per share from the amount credited as paid up on each issued share, and £5 per share from the nominal amount of each unissued share, the amount so written off the issued shares being capital not represented by available assets."—"That the Directors may make such regulations as they think fit for exchanging the certificates of shares for certificates in conformity with the foregoing resolution."

NOTES.

THE WEST INDIAN CABLES.—The cable between St. Vincent and Barbadoes is now repaired.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 15th inst. amounted to £4,044.

THE THOMSON-HOUSTON COMPANY.—This company reports an output of plant for 621 arcs and 2,600 incandescents during the month of September.

INDO-EUROPEAN TELEGRAPH COMPANY.—The Board have declared an interim dividend for the half-year ended June 30 last at the rate of 5 per cent. per annum, being the same as at this time last year.

THE WEST AFRICAN CABLES.—Telegraphic communication has now been established with Gaboon, Grand Bassam, Loanda (St. Paul de), Porto Novo (Kotoonou), and the Islands of Principe and San Thomas.

OBITUARY.—The death is announced of M. Dubosc, the Paris optician, whose name is associated with that of M. Leon Foucault in the construction of the earliest form of automatically regulated arc lamps.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th inst. are £1,816, as compared with £1,998 in the corresponding period of 1885.

MEXICO.—The Mexican telegraph system is undergoing a thorough re-organisation. More than 30,000 new posts and 400 kilometres of wire have been re-erected, and several important new lines are about to be undertaken.

SHEFFIELD.—The number of messages passed through the Sheffield Telephone Exchange last week was 32,096. This is the largest number since its establishment, being an increase of 13,556 on the corresponding week of last year.

NEW ENGINEERING TREATISE.—We are informed that Messrs. Whittaker and Co. will issue in the course of next week a book "On the Conversion of Heat into Work," a practical handbook on heat engines, by Wm. Anderson, M.I.C.E.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 15th were £3,215, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ACCIDENT IN FRANCE.—According to the Paris correspondent of the *Daily Telegraph*, a "peculiar and serious accident" happened on Wednesday last at the Grand Hotel, Paris. The "generating tube of the electric light machine burst," and two men were severely scalded.

AN UNFOUNDED REPORT.—One of the daily journals recently contained a report that a fatal accident had occurred at the works of Mr. H. J. Dale, the electrical instrument maker. We are glad to be able to state that the report is entirely without foundation.

ANGLO-AMERICAN TELEGRAPH COMPANY.—At the last meeting of the Board of Directors of this Company it was resolved that the balance of the revenue account for the quarter ended September 30th last, amounting to £16,500, be placed to the credit of the renewal fund.

SPANISH TENDERS.—The Madrid *Gazette* announces that on November 2nd tenders will be received at the office of the Director-General of Posts and Telegraphs, for the supply of 5,700 posts for the State telegraphs, viz., 3,500 of a length of 6 metres, 1,000 of 7 metres, and 1,200 of 8 metres.

DIRECT UNITED STATES CABLE COMPANY.—The Board of Directors of this Company have resolved upon the payment of an interim dividend of 2s. per share, being at the rate of 2 per cent. per annum for the quarter ended 30th September last, the dividend to be payable on and after the 30th inst.

THE RECENT STORM.—The terrific storm which visited the south and south-west coasts on Friday last caused considerable devastation to the telegraph lines. For about twenty-four hours many parts of these districts could not be reached by telegraph, and one of the Atlantic cables belonging to the American Cable Company was disabled.

THE LIGHTING OF THE HOTEL DES POSTES.—We recently stated that it had been decided not to adopt the electric light for the new Post Office in Paris. This decision has been carried into effect, and the work of laying the gas pipes is just completed. At this stage it has just been determined to reconsider the question, and it appears probable that, after all, an electric installation will be provided.

THUNDERSTORMS.—Severe thunderstorms occurred on Tuesday night last in the districts of Windsor, Aldershot, Guildford, and Oxford. At Aldershot Camp several telegraph posts were split up and the lines destroyed. Rosehill House, an isolated residence in the neighbourhood of Maidenhead, was set on fire by the lightning and burnt to the ground. On the following day Essex, Cambridge, Hertfordshire, and Derby were visited by the storm.

ELECTRIC SIGNALLING IN THE NAVY.—The Admiralty have issued instructions for a flotilla of gunboats, consisting of the "Avon," "Cherub," "Firm," "Forester," "Argus," and "Amelia," to be despatched on a short cruise in the Channel for a series of experiments with electric semaphores for night signalling. The tests will be made under the superintendence of Admiral Sir William Dowell, K.C.B., and the members of the Signalling Committee.

ELECTRIC LIGHT STATISTICS FOR FRANCE.—According to a statement recently published the following figures are supposed to represent the present state of electric lighting inFrance :—1,044 installations, 5,870 arcs, 55,321 incandescents. We do not quite understand how precise and reliable statistics (note the odd lamp) of this character are obtained, if we did we should be glad to avail ourselves of the process to obtain the figures for this country.

BURNLEY.—The public illuminations at Burnley, to which we recently referred, were maintained from a 5A Gülcher low tension dynamo, driven by a Marshall 14 horse-power compound portable engine. Thirty-five horse-power (actual) are absorbed at the dynamo, for which a total light was obtained equal to 55,000 to 60,000 candles. Although heavy rain was falling almost incessantly nearly every day, the whole of the work was completed in five days.

THE MACHINERY AND HARDWARE EXPORT CATALOGUE.—The second annual edition of this useful publication has just been issued by "The Machinery and Hardware Company," of 147, Queen Victoria-street. The work is carefully indexed and has been compiled from the latest obtainable information and price lists. We have pleasure in recommending the publication to the attention of electrical firms wishing to extend their connections with Foreign and Colonial buyers.

MAGNETITE FOR DETERMINING LINES OF FORCE.—The mineral known as magnetite, which consists chiefly of the magnetic oxide of iron, when finely powdered may be used with great advantage for determining the direction of the lines of force in a magnetic field. It readily admits of being reduced to the condition of a very fine powder, and its specific gravity

Digitized by Google

being much less than that of iron, good figures can be obtained from fields too weak to give satisfactory results with iron plugs.

THE PARIS INTERNATIONAL LABORATORY.—The Municipality of Paris has granted a portion of the site of the old Collège Rollin to the International Society of Electricians for the purpose of the electrical laboratory which is to be built and equipped out of the surplus funds of the Electrical Exhibition of 1881. The laboratory will be open for purpose of research to electricians of every nation, under regulations which will be drawn up by the International Society of Electricians.

INSTALLATION AT MESSRS. PETER ROBINSON'S.—Mr. E. Carver is putting down an extensive installation of electric light at Messrs. Peter Robinson's, the well-known drapers in Oxford-street. The installation when completed will comprise three Phœnix dynamos to supply 40 Pilsen arc lamps and one Edison-Hopkinson, which, in conjunction with 53 E.P.S. cells, will supply 300 20 candle-power incandescent lamps. We may shortly avail ourselves of an opportunity to describe this installation at greater length.

NEW SECONDARY BATTERY.—A new accumulator cell has been brought out by M. P. Gadot. The principal feature of novelty appears to be in the shape of the holes in which the active material is placed. The plates are cast in two halves, and the holes have the shape of truncated cones or pyramids. The two halves are then placed one on top of the other with the widest sides of the holes in juxtaposition. In this way cells are formed, having a large interval capacity with comparatively small openings upon either side.

ROYAL ENGINEERS AND THE POST OFFICE.—The Postmaster-General notifies that arrangements have been made at the instance of the Secretary of State for War that non-commissioned officers and men of the Royal Engineers, on being pensioned or discharged, or transferred to the reserve, may, at the discretion of the Postmaster-General, be appointed to certain situations in the Post Office. This notice will probably operate chiefly in respect to telegraphists, of whom there are a considerable number in the corps of the Royal Engineers.

BOOKS AND CATALOGUES RECEIVED.—We have received from the Commissioners of the Colony of Victoria a copy of their handbook, giving a detailed account of the resources of that colony.—From Messrs. Marshall and Co. we have received a copy of the specification of their "improved high-pressure self-contained fixed steam engine."—Mr. Bunstead sends us his illustrated catalogue of high-speed "silent" engines.—Messrs. Willem Smit and Co., of Slikkerveer, Holland, send us their illustrated catalogue of dynamos and arc lamps.

EARTHQUAKES.—An earthquake shock occurred in Central Europe on Monday last, and was distinctly felt as far west as Strasburg. According to a Reuter's telegram a severe and prolonged earthquake occurred in Cashmere on the night of October 19th. It was succeeded by a fall of "numerous and brilliant meteors, which continued until morning." This is clearly a case in which the *post hoc, propter hoc* argument should not rashly be applied; but it is not surprising to learn that the native mind thinks otherwise, and great alarm prevails.

ANOTHER TELPHERAGE SYSTEM.—Mr. Van De Poele, whose name is well known in America in connection with electromotors and railways, has recently elaborated the details of a telpherage system. From the published accounts it would appear, however, that this system would be more correctly described as an overhead electrical railway. Mr. De Poele provides substantial iron standards, which are erected side by side in pairs, and carry two parallel insulated hangers upon which stout copper cables are supported. Upon these the wheels of the motor will run, the cars hanging below in the usual manner.

THE EDISON COMPANY.—The Edison Company of New York has just published its latest list of work done. The circular shows a total of 181,463 lights in isolated plants and 149,900 in central stations, making in all 331,363 lamps actually placed. The returns cover ten months, from Oct. 1, 1885, to Aug. 1, 1886, and exhibit the following percentages of increases:—Isolated plants, 35 per cent.; lamps in same, 36 per cent.; central station plants, 132 per cent.; lamps in same, 126 per cent.; isolated plants, increase 182; isolated lamps, increase 48,588; central station plant, increase 33; central station lamps, increase 83,600.

ANOTHER CITY INSTALLATION.—Messrs. Wheatley Kirk, Price, and Goulty, the well-known auctioneers, have recently fitted their offices in Queen Victoria-street with electric light. Steam power being already in use upon the premises for working the passengers' lift and for other purposes, it was found possible to make use of the boiler already fixed. A small vertical engine drives a Crompton dynamo, giving 25 amperes and 90 volts. The machine is employed to charge 36 cells of the "Consolidated" type, and these light nineteen 20 candle-power 72-volt lamps. The installation has now been running for several weeks, and has given great satisfaction. We understand that the installation was fitted up by Mr. F. W. Suter.

AN IMPORTANT DISCOVERY.—We understand that a discovery of some importance has been made at the Munich Public Electrical Laboratory. A new alloy of nickel, to be called "nickeline," has been found to possess a specific resistance considerably higher than that of German silver, together with a still smaller temperature coefficient. Some little doubt rests at present upon the accuracy of this statement, as the figures given by the authority from which we quote are not of an intelligible character. If the information is correct the Munich Public Laboratory, of whose constitution an account will be found in our issue of the 27th August last, will have fully justified its existence.

ELECTRICITY AS A DETECTIVE.—Electric fire and burglar alarms, although not yet so extensively adopted as they well might be, are, nevertheless, articles frequently inquired for in the trade. Messrs. Northam and Co., of Sheffield, inform us, however, that they recently had an inquiry for burglar alarms, which were to be fitted in a low-class lodging-house in Sheffield, for the purpose not of keeping burglars out, but to prevent the thieves within from dropping sheets and blankets out of the windows to confederates beneath. We have no doubt that the proprietor will find that electricity will do him good service in this respect, and we shall not be surprised if some enterprising firm takes up this idea and issues a circular to the lodging-houses of Seven Dials and Ratcliff-highway.

TELEPHONY.—The Northern District Telephone Company is still extending its already extensive system of trunk wires. Last week a new line connecting the Durham Exchange with those at Sunderland and the Tyneside was completed with great success by this enterprising company, which intends shortly to continue its wires to Blyth and Bishop Auckland Durham is now brought into communication with Middlesborough, Stockton, Darlington, East and West Hartlepool, Sunderland, and the Tyneside towns, and when Blyth is connected also a new field for telephone enterprise will be opened to the company, as both Durham and Blyth are thickly surrounded by collieries, and these require ready communication

Digitized by Google

with their head offices, which the company will be able to give them.

POST OFFICE TELEGRAPHS.—The Post Office has issued a new edition of their book of diagrams of telegraph and telephone circuits. The number of plates has been considerably increased, and the shape of the book has been altered to small 8vo., rendering it more handy for reference than in its previous oblong form. The diagrams are excellently engraved, and even in the most complicated circuits the connections may be traced with great facility. The explanations are printed as a rule upon the pages opposite to the diagrams to which they refer, and plenty of space is left for private notes. The Post Office system is frequently made the object of depreciatory remark in the daily press, but beyond all doubt it is the finest and most efficient system of telegraphs that exists in any part of the world.

GREAT GRIMSBY.—The first installation of the electric light in this town has just been made at the factory of the Great Northern Ice Company by Messrs. Swete and Main, under the personal supervision of the company's chief engineer, Mr. E. H. Tompkins. The installation is on the incandescent principle, and consists of 25 Swan lamps of 16 candle-power, each being fitted with a cut-out and switch. The dynamo is one made by the late firm of Oppermann Brothers, and is driven direct from a 6 horse-power horizontal steam engine, which is also used for driving a set of ammonia pumps, against a pressure of 180lb. on the square inch, the engine running at 100 revolutions per minute. The installation is a great success, and is interesting as being, we believe, the first utilisation of the electric light in an artificial ice factory.

THE BRIGHTON ELECTRIC RAILWAY.—The severe storm which raged upon our sonthern and western coasts on Friday and Saturday last did considerable injury to the electric railway upon the beach at Brighton. We are, however, very glad to be enabled to state that the reports which appeared in some of the daily papers, to the effect that the railway had been almost entirely swept away, were very much exaggerated. The most serious damage is confined to a length of about 150 yards, and here the destruction is, indeed, practically complete. The shingle was washed from under the sleepers, and the rails were then torn and twisted in a most remarkable manner. We are sure that our readers will sympathise with Mr. Volk's misfortune, but it is fully anticipated that the little line will be again in working order within a few days.

A CHALLENGE.—The *New York World* says :—"There has always been sharp rivalry between the several electric light companies, but the war waged between the American, of this city, and the Thomson-Houston, of Boston, has been conducted with unusual ferocity. It has now reached a point at which the New Yorker boldly challenges the Bostonian to a test of the respective merits of the two systems. As the forfeits are to go to the Charleston sufferers we are disposed to urge the Thomson-Houston and all other companies to promptly 'put up or shut up.' The American company, which issues the challenge, is the one which General Stone and the Lighthouse Board have selected to light the torch of Liberty. Mr. Goff, the president of the company, on being informed that his proposition to supply the apparatus had been accepted, made a gift of it to the Government."

AN AMERICAN OPINION.—The New York *Electrical Review* has the following paragraph, which enables us to see "how it strikes a contemporary :"—"A gentleman well known in scientific circles lately returned from Europe, in speaking of the relative progress of electric lighting in England and the United States, expresses the opinion that while not much has been done on a large scale in the way of installations for general distribution of electric current in the cities and towns of England, still the growth is an extremely healthy one. The number of installations in private residences is extremely large. Especially successful are numerous storage battery plants, the motive power for the dynamo being usually a gas engine. It is a matter of regret that more attention has not been given in this country to domestic incandescent installations."

THE LIGHTING OF BROOKLYN.—According to the Brooklyn *Union*, that city is lighted by 825 electric lamps and 11,137 gas lamps. The former cost $182.50 each per annum, and the average cost of the gas lamps is $21.50. When electricity was introduced it was on the basis of one electric light taking the place of 7½ gas lamps. In reality each electric light replaces about 4⅓ gas lamps. Had the substitution of electric lamps for gas been effected on a basis of 1 to 7½, the former would even then have cost $17,520 more than the gas lamps ; but as it is, the city pays $76,280 more for the electric lights than the displaced gas lamps would cost. Brooklyn's appropriation for street lighting this year is $360,000, whereas the city has incurred obligations amounting to $390,000. If all the gas lamps were replaced by electric lights the city would have to pay $633,600 for its street illuminations.

A TOUR OF INSPECTION.—During the past summer Prof. Plympton, who is one of the members of the Brooklyn Underground Wire Commission, visited Europe for the purpose of studying the underground wire systems of this country and the Continent. In his report to the commissioners the professor intimates that he has practically had his journey for nothing. The only underground systems which he succeeded in discovering were those of Paris, Bordeaux, Antwerp, Berlin, and Newcastle-upon-Tyne. The London Post Office service, which comprises an underground system of very respectable dimensions, should certainly have attracted his attention ; but from its omission we suppose that the professor's inquiries extended only, or chiefly, to electric light and telephone wires. The report speaks in somewhat contemptuous terms of the position of the European countries in the matter, and contains the following passage :—"To the subtle and critical questions raised by these conditions [that is, the conditions of underground electric communication in general], foreign experts are absolutely dumb. They may be thinking unutterable things, or they may be making in secret indescribable experiments ; but they have reached no results, and they regard Americans engaged in that line sometimes with awe as superior beings, sometimes with amazement as persons who rush in where superior beings fear to tread." With all due courtesy to the learned professor, we must ask his permission flatly to disclaim the idea that English electricians look upon their American *confrères* either upon the one hand as fools or upon the other as preternaturally gifted beings. Without entering into any barren controversy, we may briefly call attention to the fact that the necessity for burying the wires has become urgent in America at an earlier date than it has in this country, not merely from the more general use of the telephone, but also from the fact that the use of street pole lines was at first tolerated in the States, whereas all our overhead lines in cities are also over house. As matters stand, we can well afford to wait a while in order by-and-bye to profit by the invaluable experiments which are now being undertaken in the United States.

A VOLTAMETER VOLTMETER.—A voltmeter based upon the electrolysis of water has recently been devised. It is scarcely a commercial article, but as the instrument is inexpensive and

Digitized by Google

easily made, it may sometimes find a place in the laboratory of the electrical amateur. The following description of the construction and use of the instrument will probably be intelligible, but we shall leave to the aforesaid amateur the interesting and instructive task of determining for himself the method of calibrating the instrument. Two glass tubes, each, say, 16 millimetres diameter and 50 centimetres in length, are held by brass clamps which are attached to a wooden rod. Tube A is closed at the upper end by a stopcock, or a short piece of vulcanite tubing which can be squeezed tight by a screw-clamp will serve equally well. The lower end is closed by a well-fitting cork, which projects, say, an inch beyond the tube. Through this cork passes a pair of platinised (or carbon) electrodes. The cork has also a wide hole bored first half way through from the upper side, and then outwards horizontally, so as to form a lateral communication with the tube itself. A short piece of glass tubing is fixed in the lateral opening, and over this passes one end of an india rubber tube, say 2ft. in length, the other end of which is slipped over the lower end of tube B. This last tube is open at both ends. The stopcock on A being open, acidified water is poured into B until its level stands about midway in each tube. Tube A being provided with a scale graduated in centimetres, the apparatus is complete. The method of use is as follows: The stopcock remaining open, tube B is raised by sliding the clamp up the rod until the level of the water reaches nearly to the top of the scale on A. The stopcock is now closed, and the electrodes are connected to the points whose difference of potential is required. After the current has been passing for a few minutes—the time being carefully noted—the height of B is again adjusted until the liquids are at the same level in the two tubes. We can then find from the scale reading the number of cubic centimetres of liberated gas at atmospheric pressure. If care is taken always to use diluted acid of the same strength, the resistance between the electrodes can be determined once for all.

Spanish Telegraph Statistics.—In April last we gave some particulars of the working of the Spanish telegraph service during the first six months of 1885. The official statistics for the second half of the year have now been published, and show a satisfactory, though moderate, improvement. The number of new stations opened to the public during the six months was 30, of which 29 belonged to the railway companies and one to the State, as compared with an aggregate of 15 in the first six months. Only one station was closed. The increase of wire was 167 kilometres as compared with 108 in the first half of the year. The number of stations belonging to the State was 533, those of the railway companies open to the public 359, municipal 15, private 1, and semaphoric 6. As regards the number of despatches, the return shows a total of 1,332,394 messages in the interior, of which 1,075,866 were private telegrams, as compared with 1,245,326 and 982,291 respectively in the first six months. The foreign telegrams numbered 342,202, as against 362,765. The item included in the Budget for the telegraph service was £120,437, and the revenue accruing to the State for the six months under review was £138,893. There was therefore a profit. The revenue for the first six months was £101,000 only. It is interesting to note that of the 902 interruptions, of more than six hours' duration each, 630 were owing to bad weather, 120 were from decay, 119 were from causes unknown, and 32 were intentional breakages. Since writing the above we have received the Madrid papers of Saturday last, and observe that some dissatisfaction exists among Bourse speculators with respect to the delivery of foreign telegrams. Bitter complaints are heard in some quarters about the efficiency of the service. It will be observed in the statistics given above that although the number of messages circulating in the interior showed a satisfactory increase, the foreign telegrams for the half year showed a falling off, and it is urged that this falling off is likely to become much more marked unless the authorities take measures to improve the service. It is alleged that messages despatched from Paris or London at three o'clock in the afternoon are not delivered in Madrid until eight or nine o'clock in the evening, if not later. Errors in transmissions are also complained of.

A New Method of Making Incandescent Filaments.—The Wollaston process of obtaining fine platinum wire consists, as is well known, in enclosing the wire, before the drawing process, within a thicker wire or tube, and after the drawing process, dissolving the silver off by nitric acid. We understand that Mr. Robert Dick, of Glasgow, has invented a somewhat analogous process in order to obtain fine and dense carbon filaments for his incandescent lamps. Mr. Dick has tried a variety of materials, such as silk, cotton, paper, &c., but finds the fibres of the kitool plant specially adapted to his purpose. (What kind of a vegetable is the kitool?) In using these fibres he draws them through fine steel draw plates or dies with sharp cutting edges to a uniform size. The fibres so prepared are then enclosed in a fine copper tube, the fibre being much longer than the copper at this stage, to allow of the tube being drawn over the fibre. These tubes are then drawn down, which reduces their diameter and compresses the material within them to the desired density. The compressed tubes, with the filaments thus formed in them, are then cut into suitable lengths and bent or shaped approximately to the desired form the carbons are intended to retain in the lamps, which admits of their being rolled into spirals or other shapes, in which state they are carbonised within the tubes under pressure by heating them to bright redness in a plumbago crucible in the ordinary way. After this carbonisation of the filaments, the copper tube or other metallic coating is removed from the greater part of their length, or wholly removed by immersion in nitric acid, or by electrolysis. Part of the metallic coating may, however, be left at the ends to serve as convenient means of connecting the filaments to the conducting wires of the lamp. The employment of the metallic tube serves the purposes of compressing the material forming the filament placed within it, and of maintaining the pressure and shape during the carbonising process. The advantages, according to Mr. Dick, obtained by this compression of the carbon-forming material during its formation and carbonisation are many: First, it strengthens the filament mechanically; second, it enables the carbon to give a high specific amount of luminosity per unit of energy expended on it in the lamp, thus rendering the carbon filament a very durable and economical medium in incandescent lamps for electric lighting.

The Cowles Electrical Furnace.—Prof. Mabey has recently stated that in experimenting with the Cowles electrical furnace it has been found that its efficiency could be largely increased, and the rather rapid formation of graphite prevented, to a certain extent, if the charcoal were coated with lime previous to using it. It was also found that the quantity of product formed was increased when the electrodes were allowed to enter the mixture of ore and carbon in an inclined position, at an angle of about 30° from the horizontal plane. A continuous reduction is more easily effected when the electrodes are capable of being drawn apart so as to gradually expose fresh portions of ore to the action of the current. The Professor continued:—"In the discussion that followed a paper read by Dr. Mehmer, of Berlin, Dr. Martius was inclined to the belief that the metallic aluminum was of no greater value

Digitized by Google

for ornamental purposes than zinc, and that its alloys possessed no properties relating to corrosion, strength, &c., that were worthy of mention. These assertions can best be answered by referring to the actual properties of these metals which are established beyond doubt. But the opinion expressed by Dr. Werner Siemens that, so far as practical results are concerned, this electrical furnace is identical with that constructed by his brother, Sir William Siemens, is of more importance. The continuous working of an electrical furnace requires as nearly as possible a constant resistance between the electrodes Assuming that a dynamo machine was carrying the energy from 300 horse-power and distributing it in an arc a few inches in length, and that suddenly the arc was broken by the introduction of fresh material, the effect upon the dynamo can be imagined. Dr. Siemens thought that the reduction of aluminum depended upon the presence of copper, and he expressed doubts as to whether reduction would result in its absence. Reference was made to the statement that aluminum bronze had been made in a crucible furnace by fusing together copper, carbon, and corundum. We have tried the latter experiment at the highest temperature we could produce in a crucible furnace without the slighest reduction of aluminum. Nevertheless, it may be true that traces of aluminum can be introduced into copper by this method. The assertion of Dr. Siemens that aluminum could not be reduced without copper is erroneous. We have repeatedly taken mixtures of metallic aluminum and carbon from the furnace in large quantities. The question by another chemist as to whether any analysis of the products had been made followed a remark by Dr. Martius that they did not need to be informed by Americans concerning aluminum or its alloys."

A New Peroxide Battery.—Mr. I. L. Roberts contributes a paper to the New York *Electrical World*, in the course of which he propounds certain views as to the relation between chemical action and electricity, which although scarcely new are perhaps worth recalling. He says :—" It is probable that when coal is consumed in oxygen or a metal is burned in chlorine or fluorine, the action is electric; or, in other words, all chemical action first produces a current of electricity. But as we do not know how to attach binding posts to such elements, the current is not made manifest to our senses. As the currents thus made are entirely short-circuited on themselves, they produce only the phenomena of heat, as does the current in an ordinary battery when short-circuited on itself. As soon as we are able to get some way of conducting away the current from simple chemical union, then we will reach the ideal method of producing electricity. The ideal battery is one which will not deteriorate on open circuit, and will be constant on closed circuit. Both these qualities have been attained, but not in the same cell. Chromic acid as a depolariser is constant enough, while sal-ammoniac, as a single fluid, will not destroy on open circuit to an injurious extent. I think I may venture to say that the nearest approach to the ideal battery that has come before the public is one recently invented by myself and known as my Roberts peroxide battery. The main feature in this battery is the peroxide of lead which is used as a depolariser. It has been known in electro-chemistry for some time that peroxide of lead is one of the most powerful depolarisers, as used, for instance, in the secondary battery. But no commercial use has been made of it in primary batteries; because, first, it was a powder and difficult to apply to the purpose; and, secondly, it was too costly to put into competition with peroxide of manganese, which, though not so good, was cheap. It was the writer's fortune to discover how to make it cheap enough and solid enough to far outstrip manganese dioxide as a depolariser. It is made by adding to red lead permanganate of potash in a powdered form and well mixing them. To this there is added any acid which will decompose the permanganate, such as sulphuric, or preferably hydrochloric acid. This will unite with the alkali and liberate the permanganic acid, which is the most powerful oxidiser known to chemists. This will immediately unite with the red oxide of lead, Pb_2O_3, and produce PbO_2. The whole mass, if properly made, is in a semi-liquid form, and if poured into a mould containing a carbon, it will set in a few seconds. The mould can be opened, and the whole removed and dried, when it will be porous like a carbon and will be a conductor of electricity."

Electric Lighting in the Black Forest.—The (New York) *Electrical World* has the following:—To find the luxuries of a London drawing room on the side of some rugged mountain which our forefathers could have viewed with nothing but aversion, writes a correspondent, no longer causes surprise to any one. But there is a certain sense of anomaly in meeting in some remote region with a form of lighting which has been actually rejected in the city of London as too expensive an indulgence. To climb up thousands of feet by means of a railway which has obviously the hardest work to get along, and to penetrate into the heart of a vast assemblage of granite hills such as the Black Forest, and then to find a village street lined with these lofty posts which have scarcely yet become familiar to the capitals of Europe, and to drive in a flood of artificial moonlight, strikes one at the first moment as a little strange. Obviously, however, electric lighting is specially adapted for mountain districts. Rushing streams and tumbling cataracts supply working power in the most economic form, and reduce the expense of the new light to little more than the cost of the original apparatus. It seems to be an accepted view now that when gas or fuel is used to set in motion the dynamo machines which produce the electric current, about the same amount of combustible material is consumed as would give a corresponding, or at least a sufficient, light by means of gas. The preliminary expense of the electric work is so much to be added, and the total cost is thus raised far above that of gas; but when it is merely a question of diverting a fraction of a torrent, or levying a trifling contribution on a waterfall, the motive power is obtained for nothing, and the only permanent expense consists in the renewal of carbon pencils or other lamp apparatus, the wear and tear of machinery, and the expense of superintendence. At Triberg, near the summit of the Black Forest Railway—a place which boasts the best waterfall in South Germany—water is, of course, plentiful, and advantage has been taken of the fact. The principal streets of the village, which must be nearly half a mile long, are well lighted by nine arc lights, or Siemens lamps. The expense of the installation is said to have been 40,000 marks, or £2,000, and the standing expenses are inappreciable. One or two private establishments have also set up electric lights of their own. A bier-halle and a watch manufactory are lighted by incandescent light, and the Lion Hotel has a Siemens lamp in the speise-saal. The installation of this lamp cost 800 marks, or £40, and the only continuing expense consists in a few pfennig per night for renewal of carbons and a small rent for house room paid to a neighbouring manufactory in which the necessary water wheel and dynamo are placed. Another Triberg hotel, not to be outdone, promises shortly the incandescent light throughout its suite of public rooms; and this form of light is already introduced at Tarasp, on the Lower Engadine, and at the new hotel at the head of the Malojah Pass

THE IMMISCH ELECTRO-MOTOR.

It will be within the recollection of many of our readers that at the International Inventions Exhibition of 1885 the firm of Immisch and Co. were awarded a silver medal in the class of electro-motors. Since that date, however, so little has been heard of the Immisch motor that it might almost have been supposed that a promising career had, unhappily, been blighted in the bud by some untoward misfortune. As a matter of fact this is, however, by no means the case. Messrs. Immisch have been occupied during the past twelve months in the experimental development of some very novel features in motor construction, and have been enabled to pursue the evolution of this particular type of machine through several important stages. Warned by the disastrous experience of others in a bygone era in the matter of dynamo-electric machinery, they wisely determined to withdraw to a large extent from the open market until the time had arrived when it should appear that, so far as they were themselves concerned, the experimental epoch was fairly over. As no details of the construction of either the earlier or the later types of this motor have as yet been made public, save in the form of Patent Office enigmas, our readers will no doubt be interested if we avail ourselves of the opportunity which a recent visit to the works of Messrs. Immisch has afforded us to lay before them a detailed account of the design and construction of these machines.

Before, however, we enter upon this task we must devote a few lines to the new premises to which the firm has quite recently migrated. The factory, in Maldon-crescent, Kentish Town, forms part of a very large and substantial building, and is thoroughly well adapted for electrical engineering work. It consists of four floors, each 95ft. by 38ft., and in addition there is a large flat upon the roof, which is used for the storage of accumulators. The machinery is driven by a 30 horse-power (nominal) Marshall engine, semi-fixed type, with boiler underneath. The engine is fitted with a Hartnell governor, and runs at 80 revolutions, driving on to a main counter shaft running at 150 revolutions, from which power is distributed by shafting throughout the first and second floors. The third and fourth floors, which comprise the brass-finishing, the winding lathes, and other comparatively light machinery, receive power from a six horse-power motor, which is supplied with current from a dynamo upon the ground floor. This arrangement is giving the most perfect satisfaction, and we understand that Messrs. Immisch intend shortly to put in a large dynamo, which will enable them to drive the machinery in the remaining shops by electro-motors, thus doing away with a considerable amount of shafting and belting.

We are also informed that a large motor is about to be supplied for driving the whole of the machinery in an adjoining factory, for which current will be furnished from the above-mentioned dynamo. Our space will not permit us to give a detailed account of the whole of the plant which has been laid down; but some idea of the substantial and permanent character of the operations contemplated will be gathered if we mention some of the more important machines which attracted our attention. On the ground floor is a planing machine weighing sixteen tons, and capable of working over a space 12ft. in length, 5ft. 6in. in width, and 4ft. 6in. in height. At the time of our visit this machine was planing out the armature space in the field-magnets of two dynamos intended for charging accumulators in parallel. These dynamos, we may mention in passing, will be 20-unit machines, with double commutators upon either side of the field-magnets. They are each intended to supply four circuits with 20 volts and 250 amperes; or, of course, these circuits may be coupled up in any other way as required. The advantage of this arrangement, enabling accumulators to be charged in parallel, is obvious.

The engineers' shop on the first floor contains some very fine machinery of modern construction. Among others we noticed a massive lathe made principally for turning fields after the planing machine has done its part of the work, and also a large double-table shaping machine, with 16½in. stroke embodying several recent improvements. This shop contains slotting, drilling, milling, and planing machines, together with a dozen lathes of various kinds. The brass finishers' shop contains seventeen machines of smaller size, which are driven by a 6 h.-p. series-wound electro-motor, as already mentioned We were informed that it is intended shortly to duplicate this plant (for which plenty of space is available), and that it was anticipated that the same motor would still be able to do the whole work with ease. This motor is illustrated in the accompanying figure. The dimensions of its bed are 2ft. 3in. by 1ft. 4½in., and the machine stands only 11in. high; it weighs about 350lb., and takes a current of 51·5 amperes at 100 volts when doing full work, showing an efficiency of conversion of 85 per cent.

The floor above is perhaps the most interesting to an electrician; here the armature cores are built up and the coils are wound. This latter process is carried out in a lathe, notwithstanding that the armatures are of the drum type. The connections, though of a somewhat complex character, are much simplified in practice by means of a particularly ingenious system of arranging the brass tags with which the ends of the various coils are labelled. The intricate character of this work will be better appreciated after a glance at the diagrams which we are about to describe, especially when it is understood that while these figures relate to an armature of only 6 coils at the most, yet in practice armatures of 48 and 96 coils are frequently wound, and one with as many as 144 coils is now in hand.

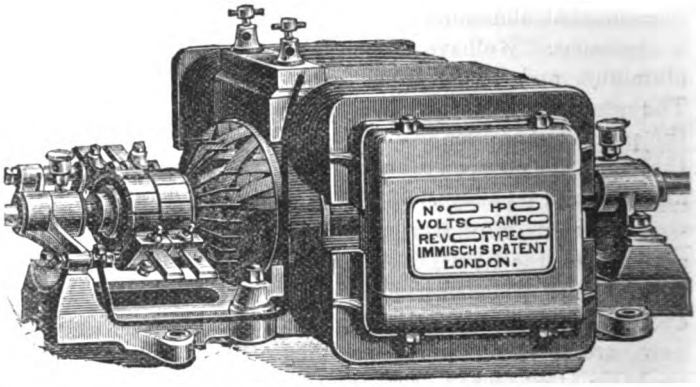

FIG. 1.—The Immisch Motor.

The main feature which is claimed for the Immisch motor, and which, so far as our inspection goes, would seem to be fully confirmed, is that of an entire absence of lead. From this follows a very nearly complete immunity from sparking, and the capability of reversible running by a mere reversal of the connections of either armature or field. It is further claimed that by means of the devices which we shall presently explain the uniformity and symmetry of the magnetic field are secured without resort to any wasteful method of compensation. These qualities undoubtedly render the motor particularly well suited for use with variable loads, as for instance with tramcar work, where not only is the load subject to continuous variation, but the direction of rotation has frequently to be reversed. Under these conditions it is not uncommon for motors, otherwise excellent, to give much trouble at the brushes.

The earliest motors constructed by this firm—now some four or five years ago—embodied an idea which did not, however, aim at securing a symmetrical field, but, on the contrary, sacrificed something in this direction in order to obtain increased efficiency by the avoidance of "dead points." In the present machines this latter advantage is still retained, in addition to the features already referred to; it will therefore be the most simple, and probably the most interesting method if we approach the present construction by means of a brief historical sketch tracing the evolution of the several ideas which are embodied in the latest type.

It is evident that if a motor have n poles in the field, and either $n+1$ or $n-1$ coils upon the armature, and if the coils be successively cut out of circuit at the time when the magnetic field due to this particular coil coincides in direction with that of the final resultant field then there can be no absolute dead point. This first idea was embodied in a somewhat crude

Digitized by Google

form in a motor whose construction is seen at a glance in Fig. 2. But apart from other faults it is palpably evident that the strains upon the armature shaft are in this case very unevenly balanced, and in fact there resulted so severe a bending strain upon the shaft as to render the construction quite impracticable. The next step was to alter the form of the armature to that of a drum with Pacinotti teeth, to retain the three armature coils, but to wind them in two subdivisions placed at right angles to one another, and to reduce the pole pieces on the field to two only. The strains upon the armature shaft are now equal and opposite at all points, and a machine of this construction ran perfectly smoothly. With the object of avoiding a backward pull upon the Pacinotti teeth it was, however, found necessary to cut away the pole

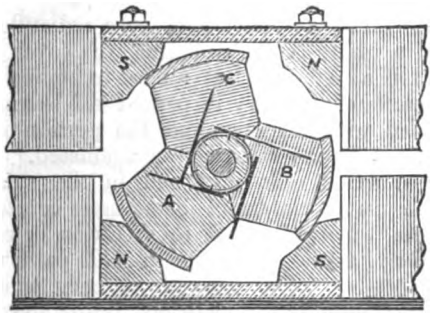

FIG. 2.

piece of the field upon the side from which the coils were retreating, as indicated in Fig. 4 (to which we shall have presently to make further reference). A three horse-power motor constructed after this manner was shown at the Inventions Exhibition last year, and gave an average efficiency of 75 per cent. Obviously, however, this construction involves the serious defect of requiring a rotation in one direction only. The magnets are also very costly to make in wrought iron. Malleable castings were tried for some time with good effect, but further improvements have enabled this construction of the field to be discarded.

Before, however, we describe the next advance, it is necessary to say something more about the principle involved in cutting out the coil, which is passing through the position at right angles to the position of the field. This device in one of several forms is common to all the motors which have been constructed by the firm. Its extreme value in preserving the symmetry of the field will be readily appreciated when we consider that the magnetic axis of the *armature* field itself always passes through this particular coil, so that its magnetic moment with regard to the actual resultant field is very small, while at right angles to this position it is a maximum, and hence its disturbing effect upon the resultant field would be also a maximum if it were left in circuit. The coil which occupies this position is deprived of its injurious influence either by open circuiting or short-circuiting. Each method has its particular advantages, but the latter is now most frequently adopted, because it lends itself to ring or cylinder as well as to drum-wound armatures. No injurious heating effect results from the short-circuiting so long as the field poles are properly proportioned. The same identical construction has been successfully applied to a dynamo, and a machine so made is now running at the Liverpool Exhibition. If the circuit be broken under full load no trace of sparking is observable. It is, however, necessary that the brushes be very accurately set when the construction is adopted for a dynamo, although such care is not necessary in the case of a motor. This leads us to describe the arrangement of the brushes and the commutators for either motors or dynamos, and then by the aid of the diagrams of the winding it will be seen how the cutting out of the coils is effected.

Owing to the symmetrical and unvarying character of the resultant field it will easily be understood that with brushes of suitable construction it is possible to fix their position once for all, and to send out the motor with the brushes screwed down in their final position. For this purpose, in order that the point of contact may not be affected by wear, "normal" instead of tangential brush-contacts are employed, as has also been done by Mr. Holroyd Smith.

The commutator is illustrated in Fig. 3. It will be seen that it consists of two similar halves separately insulated, and each containing as many sections as there are circuits through the armature, and one of these halves is displaced through an angular distance equal to half the space of one section with respect to the other. There are then four brushes, two side by side bearing upon either half of the commutator. Its mode of action will be best understood from the diagrammatic view in Fig. 4.

This figure shows the connections of a drum-wound arma-

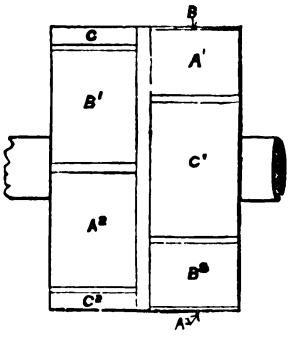

FIG. 3.

ture, having three pairs of coils, the wires being so connected that each coil is joined in series with the coil at right angles. The brushes on each half of the commutator are now connected in parallel, and in the position shown in the figure coil *a* has just been cut out, and will remain so until the armature has advanced one twelfth of a revolution. It will be seen that this double coil occupies the position *in and at right angles to* the axis of the resultant magnetic field. There are in all four connections between the coils marked A and the commutator; but upon inspection it will be found that they are all clear of the brushes. Upon the

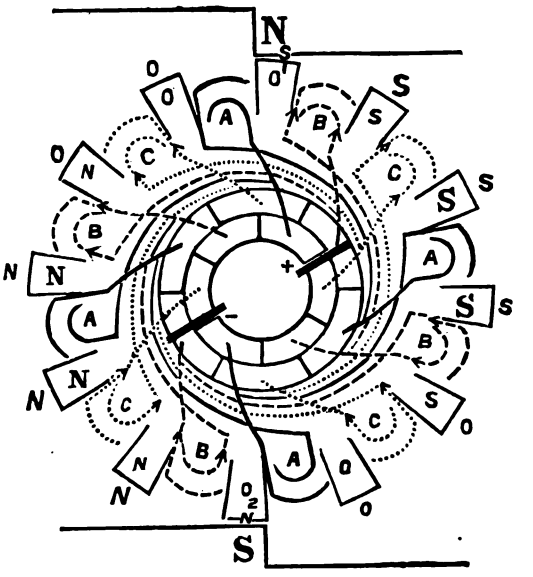

FIG. 4.—A, just cut out.

other hand, starting at the positive brushes, it will be seen that there are two paths open, one through coils B and the other through coils C. In tracing these connections, when a line terminates at the circumference it will be understood that it is to be picked up again at the extremity of the same diameter of the figure.

But this construction is open to one very obvious and equally serious objection. In cutting out the part of coil A which we wish to get rid of, we at the same moment deprive ourselves of the other half of the same circuit, which being situated

Digitized by Google

in the magnetic axis of the field is in the very position to do most work with least deformation of the resultant field. It might seem upon a cursory inspection, and we confess that it did so seem to us, that this difficulty might be avoided by a comparatively simple alteration in the coupling of the coils. But on further examination it will, we think, be admitted that no available solution of the problem can be found, and the construction has accordingly been abandoned, while the same general principle is still retained in the improved types. The armature here figured was the one for which the silver medal was awarded last year.

(To be continued.)

NEW FORM OF STANDARDS OF E.M.F.

BY ALEX. MUIRHEAD.

Fig. 1 illustrates the mode of constructing Clark cells that has been adopted hitherto. *Zn* is a rod of pure zinc sup-

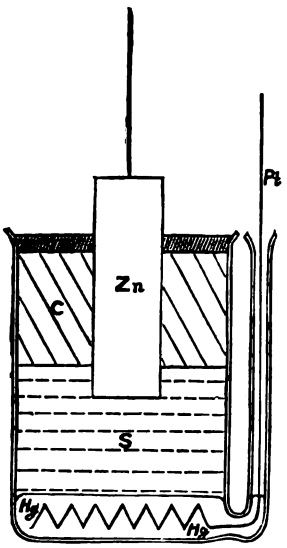

FIG. 1.

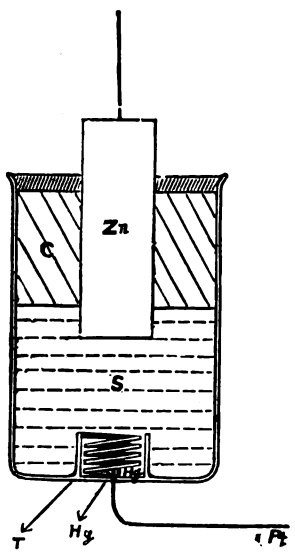

FIG. 2.

ported by means of a cork, C, in a glass cell or vessel; at the bottom of the cell is a layer of pure redistilled mercury, *Hg*,

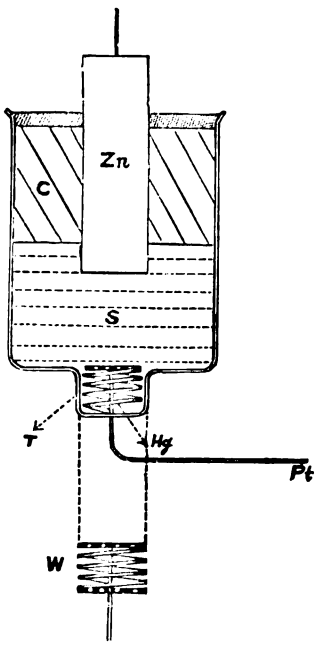

FIG. 3.

with which connection is made by means of a platinum wire, *Pt*, either hermetically sealed into the glass cell or passed down a small tube attached to the side of the cell, as in Fig. 1; between the mercury and the zinc electrodes is a paste, S, composed of mercurous sulphate (protosulphate) and saturated solution of zinc sulphate. The usual forms of the Clark cell, especially when newly set up, are unsuitable for transport; the mercury, being free, is apt to leave the platinum wire contact *Pt*, when the cell is inverted or upset, and to fall through the paste into contact with the zinc rod, thereby either short-circuiting the cell altogether or destroying the value of its electromotive force. To remedy this defect the cell is constructed as follows:—

The wire *Pt*, which may be of platinum or platinum-iridium, is coiled up in such a manner as to form a cylindrical-shaped cage, terminating at both ends in a flat or slightly-curved closely-wound spiral. This cage of platinum is fitted inside a tubular projection, T, made to the cell itself, as in Figs. 2 and 3. In filling the spiral, a quantity of pure redistilled mercury is placed in a glass cell, sufficient to cover the cage, and heated for a few minutes almost to boiling point; on cooling, the excess of mercury is poured off, leaving the cage completely filled with mercury, and the portion of the platinum wire *Pt* inside the cell well amalgamated. It is found that Clark's standard cells improved in the manner above described have the advantage of being more constant in electromotive force when subjected to vibration or rough treatment than those made according to old patterns, besides being more portable. The mass of mercury, when confined in chambers constructed of platinum in the above manner, adheres firmly to the platinum connection, and does not separate readily from it.

For most practical purposes Dr. Muirhead says that these cells form sufficiently reliable standards of electromotive force even when set up without the mass of pure mercury in contact

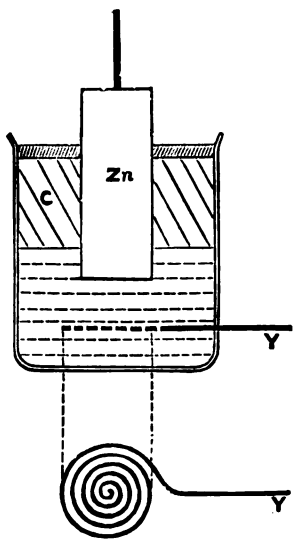

FIG. 4.

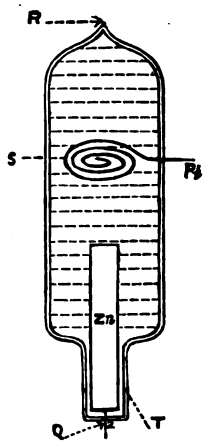

FIG. 5.

with the amalgamated platinum wire connection *Pt*. The platinum *Pt* alone answers well enough provided it is properly amalgamated with pure mercury. That is to say, standard cells with merely a surface of pure amalgamated platinum as the positive electrode, pure zinc as the negative electrode, and a mixture of pure mercurous sulphate with saturated solution of pure zinc sulphate as electrolyte, agree closely enough in electromotive force with each other for all ordinary electrical measurements.

When this mode of constructing the platinum electrode is adopted the best results have been obtained with the platinum wire wound closely into a flat or slightly curved spiral, the amalgamation being effected either by boiling it in pure mercury or by dipping it red hot into pure mercury. When platinum foil is employed, the amalgamation is more permanent if the surface be roughened or the foil corrugated or grooved. In Fig. 4 Y is a flat closely-wound spiral of platinum wire which has been coated or amalgamated with pure mercury by either of the methods above described; the continuation of the wire, *Pt* is sealed into the glass cell, forming the outer connec-

Digitized by Google

tion. *Zn* is a rod of pure zinc supported by a cork, C, The horizontal dotted lines which have the same meaning in all the figures of the drawing represent the electrolyte used in these cells, viz., a paste composed of pure mercurous sulphate and saturated solution of pure zinc sulphate.

Fig. 5 illustrates another mode of setting up standard cells according to this invention—one which is more expensive, but more durable, than those previously shown. Instead of supporting the zinc electrode by means of a cork, C (as in Figs. 1 and 2), a platinum wire connection, Q, is fused into the zinc rod *Zn*, and sealed into the glass tube T at 2, the junction of the platinum and the zinc being protected from the electrolyte of the combination and at the same time firmly secured to the tube by shellac or other suitable cement. S is the electro-negative plate, a flat spiral of platinum wire similar to Y of Fig. 4.

The cell is hermetically sealed up at R after the introduction of the electrolytic paste of pure zinc and mercurous sulphates.

The following is a comparison of several cells of the new form supplied recently to the Eastern Telegraph Company. The comparison was made against three standards belonging to Mr. Herbert Taylor, and the readings are on the Thomson and Varley slide:—

In Fig. 6 we illustrate a very compact and useful form of this cell. The four terminals belong to two entirely distinct

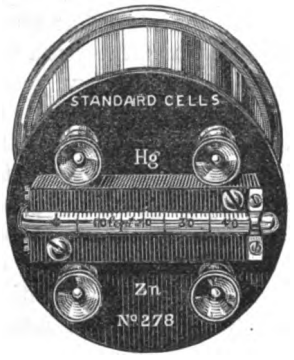

FIG. 6.

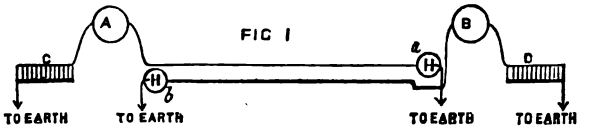
cells, the advantage being that the two cells may be used as a check one upon the other. A thermometer stands within the box, and the stem being bent at right angles lies in a groove across the top of the case, so that the temperature at the time of the reading is known.

AN "EMERGENCY SIGNAL" FOR RAILWAY TRAINS.

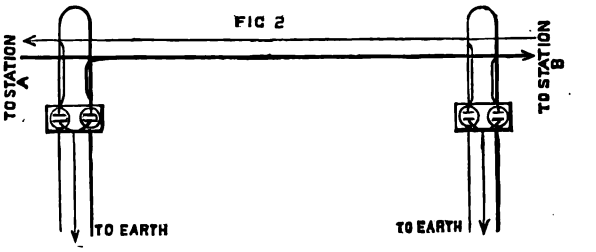
BY W. RICE AND W. SYKES.

This device is intended to give greater protection to the travelling public by establishing on the railways a series of signalling points from which the officials at the stations to the left and right can be informed of any accident or unusual obstruction. By this means the traffic of the line can immediately be stopped, and when assistance is required (as in the case of a serious collision or breakdown) such assistance can be sent with the least possible delay.

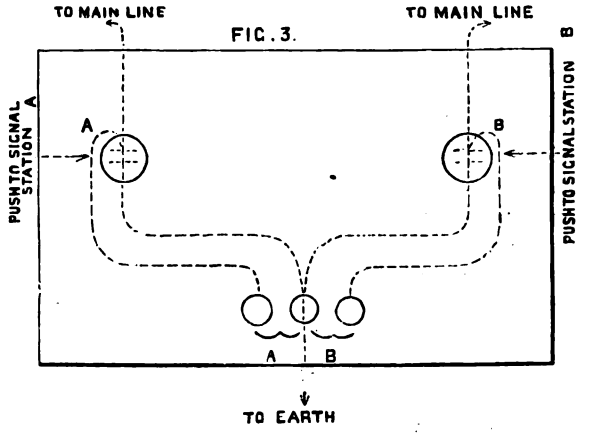
The essential portion of the apparatus is illustrated below. Let A and B (Fig. 1) represent electric alarm bells at the two railway stations or ordinary signal boxes. One pole of the motor of bell A has permanent earth connection through a battery, *c*; the other is attached to a line which terminates in a push, *a*, at station B, this push when used giving earth connection and ringing bell at A. In a similar manner the bell B is connected to earth through the battery *d*, and also to a line which terminates in a push, *b*, at station A. As thus connected, the lines serve for the ordinary signals between the two stations, each signalman ringing the distant bell by the battery to which it is connected at its own station.



But it will also be seen that with this arrangement either bell may be rung from *any intermediate point* by merely making earth connection and completing a circuit. Thus, if the guard of a train on any part of the line from A to B wishes in an emergency to signal to A, he can immediately do so by a temporary connection between the main line and the earth.



The main object of the system, however, is to establish a series of *permanent signalling stations*, from whence the guard or other persons can at once communicate with the station to the left or right. This is accomplished by fixing to the telegraph poles or other supports a series of double pushes, with short lines leading therefrom to the main lines and also to the earth, as shown in Fig. 2. The nominal position of the push of course leaves the circuit open, but the moment it is pressed earth connection is established and the signal is given.



This system may be made still more efficient by the adoption of the telephone. In this case the ordinary arrangement of the telephone company should be used at the stations, and the guard of each train furnished with a portable telephone, which he could at once connect at any of the signalling stations by means of binding screws to be fixed for that purpose.

Fig. 3 is an enlarged view, showing the telephone connections.

THEORY IN THE WORKSHOP.

Of all the schemes propounded in recent years for the spread of theoretical and technical knowledge among the artisan classes none commends itself to our judgment so strongly as that which was tried by a leading firm of electrical engineers in the provinces last winter. It consisted of a course of Lectures delivered on the spot to the artisans and workpeople employed at the works, and students who were learning the business. The lecturer set out with a conviction, evidently shared by those who had called in his services, that the right direction for technical training is to bring home to the craftsman the scientific principles involved in daily work which passes under his hands. In other words, the firm, desiring that their servants should acquire some theoretical knowledge of the special business in which they were engaged, took the practical step of obtaining oral instruction for them, illustrated by experimental and practical applications drawn from their own workshop. There was no cramming, no examination at the end of the course, and we do not hear of any prizes. This is as it should be. The plan is not exactly new; it was adopted, if we remember rightly, by the postal telegraph authorities in respect to their operators soon after the acquisition of the telegraphs by the State; but as a solution of our technical shortcomings this is not the one which has found most favour in public estimation. Nevertheless, in the long run it will be found the one of most practical utility; and we congratulate the firm referred to on their liberality, enlightenment, and boldness in setting so good an example.

We hope that the experiment may be persevered in, and may find plenty of imitators elsewhere. It is not known to us whether the firm in question are contented with the results in this particular instance, and we do not particularly care to learn. We are satisfied that the principle is a sound one, and that even if it failed—which we do not for a moment assume—its failure would be due more to the method of applying it than to the principle itself. In some respects, we frankly confess that the Lectures chosen were not exactly what we should have supposed most needed for the object in view. They erred on the side of being too scientific. At least this is what we should suspect unless the craftsmen and apprentices addressed on this occasion were exceptionally well educated beforehand, and less in need of elementary instruction than men of their class usually are. Of one thing we are sure that the Lectures, the transcript of which has just been published in book form, are far away over the heads of average artisans, even of such as are daily employed in callings which have scientific principles underlying them. It is, we fear, too commonly supposed that this is an unavoidable necessity, and that to impart scientific knowledge the pupils must always rise to the level of the teacher, and the teacher never stoop to that of his pupils. The remarks we are about to offer are dictated by a lively sense of the untruth of this popular error, and a desire that any future lectures framed with a similar object may steer clear of the faults to which we venture to draw attention.

First, we make bold to warn all intending employers of Lecturers against such as contemplate publishing their discourses. Let us not be misunderstood. So far from meaning that these particular Lectures were not worth publishing, we assert that they are extremely valuable; anything from the pen of the distinguished author of them was sure to be so. But it does not follow that his are the sort of Lectures working men could have listened to with entire profit; and, on the other hand, it does unquestionably follow, when a Lecturer intends his Lectures for publication, he will have his final audience in his mind quite as much as, and probably more, than the simple folk whom he originally addressed. On this point some remarks in the present number of the *Quarterly Review*, which have caused a great sensation in the literary world, are not inappropriate. A few years ago, says the reviewer, a man who contributed articles to a current periodical, or who delivered a course of lectures, had as a rule the good sense to know that when they had fulfilled the purpose for which they were originally intended the world had no more concern with them, and he would as soon have thought of inflicting them in the shape of a volume, on the public, as he would have thought of issuing an edition of his private letters to his friends. So says the caustic reviewer, and he adds that nowadays every person who has figured in either of the capacities of journalist or lecturer thinks he is entitled to force himself into notice in the character of an author. Now this is not at all to be laid to the charge of our Lecturer. What, however, he may be accused of is the converse of this, namely, that being pre-eminently an author he has allowed himself to be forced into the position of a Lecturer—or, more accurately, has assumed the *rôle* of a popular lecturer with the view of publishing a volume of scientific essays.

Nothing could warrant the publishing of any course of truly popular lectures save as models of what such lectures ought to be. The more serviceable they were on delivery, the less, as a rule, are they fitted for general edification afterwards. Models in many ways, the Lectures in question, which we have read with much enjoyment, certainly are; but not of what Lectures to working men ought to be. They begin well, and for a few pages the fact is kept well in mind that the audience knows less than

Digitized by Google

the lecturer. But soon he is off at full gallop to regions all his own, the very landmarks of which are unfamiliar and unintelligible to his hearers. His struggles between popularity and scientific accuracy are often quite amusing. At one moment he is simply stating the elementary fact that magnetism is something like sweethearting—not that the lecturer employed any illustration half so intelligible—unlike poles attracting each other; and within the next five minutes he is "strictly defining" the modes of measuring forces adopted in scientific work—the standard of mass, and the standard of length, according to the French *units* of measurement. *Dynes*, *megadynes*, *grammes*, *centimetres* and *unit poles* speedily follow, interlarded with such rudimentary truths as that if we magnetise a knitting needle we shall find magnetic poles at the ends. Nor is the necessity for the French units proved with any convincing force to a British workman's mind. The objection to the English pound, namely, that it differs at different parts of the earth, and is quite different on the earth to what "it would be on the moon," applies equally to the gramme; and as a pound avoirdupois has some meaning for a practical engineer, whereas the 453·59th part of a pound has none, he naturally declines to follow his teacher, or gives up the attempt in despair. We are not recommending that scientific accuracy, like political economy, be banished to the planets, but we are decidedly of opinion that in addressing an unscientific audience, the fact that an English pound would be short weight if carried to the moon, and all similar abstractions, might be advantageously relegated to that luminary. We respectfully, and without offensive intention, commend these observations to all persons desirous of introducing theory into the workshop.

CORRESPONDENCE.

USE OF THE TANGENT SCALE IN A GALVANOMETER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On account of the correspondence which has recently taken place in this and other journals regarding the use of the tangent scale in a galvanometer, when the plane of the coil makes an angle with the direction of the force in the magnetic field, the following extract from Sir William Thomson's patent No. 4617, of 1883, and the accompanying remarks, may clear up some of the points that have been raised:—

"In using this instrument I sometimes cause the zero to be at one end of the scale, so that when the potential is at the prescribed definite amount, the pointer is at the centre mark of the scale of tangents. The deflections are thus more easily observed on account of the large size of the divisions."

The extract is quite explicit as to taking the zero at one end of the scale, and it is abundantly evident from the text of the patent and from the illustrative drawings that the scale referred to is a tangent scale. The essential feature in this use of the tangent scale is that the strength of the current is proportional to the difference between the tangents of the angle corresponding to zero, and that corresponding to the deflection due to the current.

The total length of the scale, as shown in the patent already referred to, and used in this laboratory for over two years, is 120°. Lately, however, the length of this scale has, with considerable advantage, been increased to 140·8°, thus giving twice the sensibility obtainable with the 120° scale.

As regards Prof. Carey Foster's letter to *Nature*, of October 7th, 1886, a tangent galvanometer arranged to use the tangent scale in this manner is essentially adapted to measure currents which flow through its own coil in one direction only, but in these instruments, as designed by Sir William Thomson, the necessary accuracy is secured by the following procedure. The index (which has a range of about 95° on each side the middle point of the tangent scale) is caused to point to a mark exactly 90° from the middle point of the scale, and the relative positions of the coil and the scale are then adjusted, so that when the index points to the 90° mark the strongest current which can be safely sent through the coil produces no sensible deflection.—Yours, &c, J. RENNIE.

Physical Laboratory, University, Glasgow,
October 16th, 1886.

THE ELECTRIC LOCOMOTIVE AND POWER COMPANY (LIMITED).

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Although I hope I may yet be spared the necessity of causing retardation of electric traction work anywhere along the line, the prospectus of the Electric Locomotive and Power Company (Limited) compels me not to remain quiescent.

The *advantages* claimed for Mr Elieson's patent by many press notices are fully described in my patent of the 31st January, 1883, and numbered 539 and 539*.

Mr. Elieson's patent is dated nearly a year and a half later than mine, viz., 6th June, 1884, and numbered 8654. I, however, do not wish the electrical world to think that I give the motor a movement of running round a table, as I should know very well that the *additional* power required for that purpose would be pure and unnecessary loss. (Enough to make all the difference probably in many cases of the possibility of competing with other methods of traction.)

I have had to give formal notice through my solicitors to the Electric Locomotive and Power Company (Limited), that Mr. Elieson's patent infringes mine. The electric field is large enough for us all—one man develops one point, one another.—Yours, &c., RADCLIFFE WARD.

10A, Great Queen-street, Westminster, S.W.,
20th October, 1886.

THE THURY DYNAMO.

Amongst the electric light installations in towns, those of Bellegarde-on-Valserine (Ain) and of the Roche-sur-Fordu (Haute-Savoie) have been reported as good examples of this class of work. The dynamos employed are of the Thury type, constructed by Messrs. Meuron and Cuénod, and are illustrated herewith. Figs. 1 and 2 show two schematic views of the

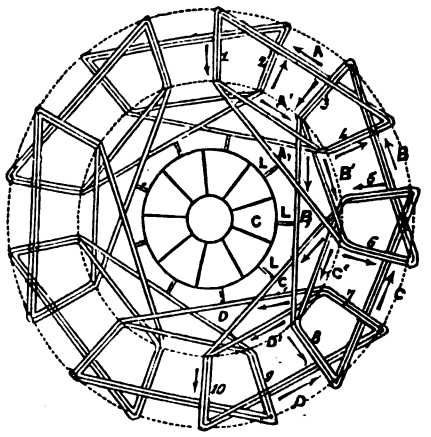

FIG. 1.

winding. The field-magnets are arranged as in Fig. 3, and consist of six electro-magnets *A A*, with massive pole pieces *pp*. The magnets are so wound as to develop alternately poles *U* and *S*. The hexagonal frame of field-magnets is fixed to the base plates B, by means of bronze supports E E on the iron base B. The armature is composed of two iron discs, K K (Fig. 4), riveted into the wood I I, upon which is wound the iron wire M, the layers of which are insulated from each other by sheets of paper. Upon the framework thus

Digitized by Google

made the conducting wire is wound. The method of winding is shown in Figs. 1 and 2. The figures are so clear as to need little description. The figure being diagrammatic the number of turns in each coil, 1, 2, 3, is so much larger than is shown

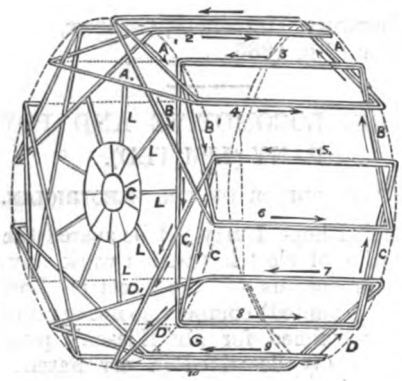

FIG. 2.

that the spaces *a*, *b*, *c*, *d*, &c. are filled with wire. The winding can be traced from *a* to *a*, *b* to *b*, throughout. The collector or commutator *c* is connected to the armature coils by the

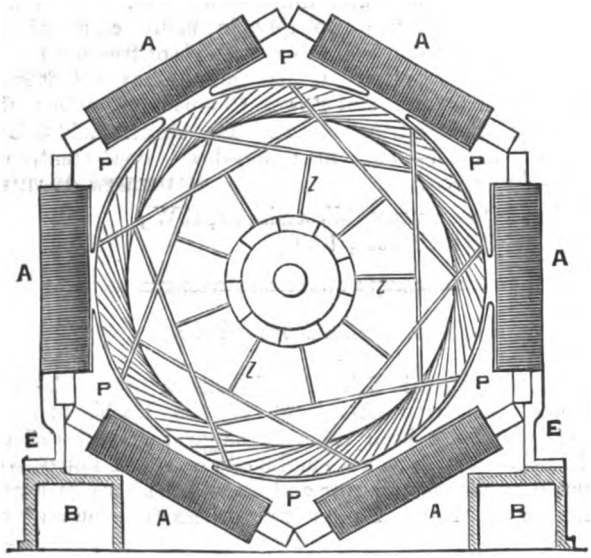

FIG. 3.

nine plates *l l*, and is similar to that of the ordinary Gramme. Its periphery is in contact with six brushes corresponding to the six poles of the field-magnets. These brushes

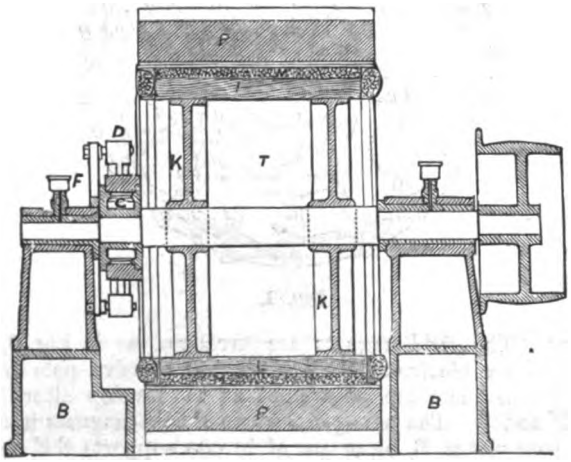

FIG. 4.

have often to be regulated separately. They are mounted on a common stud F, capable of being turned as required. This enables them to be shifted altogether without their relative angular position being varied. This disposition of the brushes renders their regulation easy, and permits of the reversing of the current in the exterior circuit when the machine is not self-excited. The brushes can be used in couples or not as required. This machine is constructed in four types of 100 volts, absorbing in ordinary work 20, 30, 60, and 100 horse-power respectively, and revolving at 600, 450, 350, and 250 revolutions, giving respectively 150, 225, 450, and 750 amperes, with an internal resistance of 0 034, 0·02, 0·009, and 0·004 ohm. The ten larger types supply respectively 600 and 1,000 sixteen candle-power normal incandescent lamps. The special characteristics claimed for this machine are—(1), the method of winding, which is said to involve the minimum waste of wire; (2), the low speed; and (3), the small internal resistance.

FURTHER NOTES ON THE FORMULÆ OF THE ELECTRO-MAGNET AND EQUATIONS OF THE DYNAMO.*

BY PROF. SILVANUS P. THOMPSON, D.SC., B.A.

1. *Frölich's simplified Formula of the Electromagnet.*

Since my former communication to the Physical Society was made, a further work on the theory of the dynamo by Dr. Frölich has appeared.† In this work he carries the simplification of the formulæ of magnet and of dynamo one stage further by introducing considerations somewhat closely connected with those which entered into my own work of 1883-4.

The form adopted by me in 1883 for the Lamont-Frölich formula was

$$H = \frac{G\kappa Si}{1+\sigma Si};$$

where H is the resulting average intensity of the magnetic field (in which the armature rotates), κ the initial value of the magnetic permeability, G a co-efficient depending upon such purely geometrical quantities as the form and size of core, pole-pieces, and coils, S the number of windings of the magnetising coil, and σ the "saturation-coefficient." This can be transformed at once to Frölich's form by writing $M = G\kappa/\sigma$; $k = \sigma$; $x = Si$. In 1884 I pointed out‡ the nature of this saturation-constant and its importance in the resulting equations of the dynamo. It is the reciprocal of that number of ampere-turns which, to mark its importance, I ventured to term "diacritical," namely *that number of ampere-turns which will reduce the instantaneous value of the magnetic permeability to half its initial value*, or which, in the formula used, will give to the magnet exactly *half its maximum magnetism*. I further pointed out in my lectures on the dynamo that year, that, if the number of windings of the coil S is given, there will be a "diacritical" current, namely a particular value of current which will exactly half-saturate the magnet. Dr. Frölich has independently made use of this conception, and has applied it to the formula of the electro-magnet. The argument is his, but I retain the notation I have used.

Writing $(Si)'$ for the diacritical number of ampere turns, we have (as I showed in 1884) $(Si)' = 1/\sigma$.

Taking the expression

$$H = \frac{G\kappa Si}{1+\sigma Si} = \frac{G\kappa}{\sigma} \cdot \frac{Si}{\frac{1}{\sigma}+Si},$$

and writing $Y = \frac{G\kappa}{\sigma}$, we have $H = Y \frac{Si}{Si+(Si)'}$

where Y is obviously the limiting maximum value of H when the excitement is infinitely great. If S is given, then i' is the diacritical current, and the expression becomes

$$H = Y \frac{i}{i+i'},$$

which is true for every electromagnet excited by a single

* Communicated to the *Phil. Mag.*, September, 1886, by the Physical Society; read June 26th, 1886.

Digitized by Google

current. Two observations made on any electromagnet will determine the two constants Y and i'. Further, if r be the resistance of the magnetising coil, since $ir = e$ (the potential requisite to send the current through the coil), we may obviously write the equation

$$H = Y\frac{e}{e+e'};$$

where e' is the diacritical difference of potential, namely, that difference of potential which, applied to the coil of resistance r and of S convolutions, will half saturate the core.

The extreme convenience of this form of the law of the electromagnet must be at once apparent, since it enables the equation of a given magnet to be instantly adapted to the case of any given current or potential, and is equally applicable to express either the intensity of the field or the magnetic moment of the magnet. To put the matter in a more general way, let ψ represent current, or potential, or ampere-turns, and let ψ' be the diacritical value of the same for the given magnet; let ϕ be the intensity of the field, or the strength of the pole, or the magnetic moment, or the integral of the magnetic induction, and Φ its maximum value; then

$$\phi = \Phi\frac{\psi}{\psi+\psi'}.$$

This being the general equation of the electromagnet, it remains to be shown how excessively simple become the equations of the various kinds of dynamo.

2. *Equations of the Series-wound Dynamo.*

If A is the "equivalent area" of the coils of the armature, and H the average strength of the field in which it turns, the number of lines of force cut in each quadrant is AH; hence the average electromotive force at the speed n is

$$E = 4nAH. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

But $H = Y\frac{i}{i+i'}$, and, writing B = 4 A Y, and remembering that, if ΣR be the sum of the resistances in the circuit, $E/\Sigma R = i$ (by Ohm's law), we get

$$i = \frac{nB}{\Sigma R} - i'.$$

But Y being the maximum value of H, it is obvious that nB is the maximum value that E could possibly have (at that speed) even if the magnets were separately excited to saturation. Hence nB/ΣR is the maximum value that i could have if the magnets were thus separately saturated and the armature, driven at speed n, were in a circuit the total resistance of which was equal to ΣR. Adopting Frölich's notation here, we will write as $\bar{i}$ this current; and as it is important to distinguish the current generated under such conditions, I propose to call it the "maximal current."* The equation of the series dynamo now becomes

$$i = \bar{i} - i'; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

or, multiplying each term by ΣR,

$$E = \bar{E} - E', \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where $\bar{E}$ is the "maximal" value of E at that speed with saturated magnets. And again, writing e for the difference of potentials at the terminals of the machine, since e, multiplied by the external resistance $R = i$ under all circumstances, we have

$$e = \bar{e} - e' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

It appears, then, that in the case of the series-wound dynamo, each of the single electrical quantities is equal to the difference between the "maximal" value which that quantity could have at that speed if the field-magnet were separately saturated and the "diacritical" value of the same quantity. This important result was announced by Frölich in 1885.

* The *maximal* current must not be confused with the *maximum* current. The latter would be obtained by rotating the armature in the saturated field at a very high speed in a circuit of resistance so small that the current did just not fuse the conductors. The *maximal* current is that obtained at speed n in circuit of resistance ΣR when the magnets are separately excited to saturation.

It may be remarked that, since we may write

$$H = Y\frac{E}{E+E'},$$

we may deduce from (1) the result

$$E = nB - E',$$

and from this derive equation (3).

It may be noted, in passing, that B is the electromotive forces that would be generated in the armature at speed = 1 if the field-magnets were separately excited to absolute saturation. It is the maximal value of E at unit speed.

3. *Expressions for the "Dead Turns."*

It is known that in every dynamo the current (with a given resistance) is not proportional to the speed, but is proportional to the speed less a certain number of revolutions per second. This latter number is known familiarly as the "dead turns." It is also known that (with given resistance) there is a certain speed below which the dynamo does not excite itself. This least speed of excitement (with given resistance) is the same as the "dead turns." It is called by some the "critical" speed; though that name is preferably reserved for the speed that is critical for self-regulation, and which is (unlike the least speed of excitation) independent of the resistance.

We can find an expression for the dead turns as follows:—

Taking the expression for the current,

$$i = \frac{nB}{\Sigma R} - i',$$

equate it to zero; the current of the machine (series-wound) being *nil* when n is reduced sufficiently to n' (= the dead turns). Then $i' = \frac{n'B}{\Sigma R}$, and

$$n' = \frac{i'\Sigma R}{B} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

It appears, then, that the dead turns are proportional to the diacritical current and to the resistance; and inversely proportional to A and Y, the factors of B. It will be noted that $i'\Sigma R = E'$, the diacritical electromotive force.

Again, we have found $E = nB - E'$; and as $E' = n'B$, it follows that

$$E = (n - n')B. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

This result is interesting in itself, and might have been used as a starting-point for the equations of the dynamo, inasmuch as it is readily found hy experiment as a fundamental relation between speed and electromotive force. Following the analogy and the nomenclature adopted, we may regard n' (the dead turns) as the diacritical speed. In other words, it is that speed at which, with magnets separately excited to saturation, the induced electromotive force will be diacritical, and will, with the given resistances ΣR, give the diacritical current. This equation (6) gives by far the best method of determining the important constant B. Two experiments to observe a pair of values of E and n will suffice to determine both n' and B.

4. *Equations of the Shunt Dynamo.*

Here we use r_s and i_s for the resistance and current of the shunt-coil, and r_a and i_a for those of the armature. We may then calculate the potential at terminals as follows. Writing $\mathfrak{R}$ for the resistance of the whole system of machine and its circuits, as measured from brush to brush*,

$$E = e + r_a i_a = e\frac{r_a}{\mathfrak{R}} = 4nAH,$$

$$H = Y\frac{e}{e+e'},$$

$$e\frac{r_a}{\mathfrak{R}} = nB\frac{e}{e+e'};$$

whence

$$e = \frac{nB\mathfrak{R}}{r_a} - e'. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

* The author's "Dynamoelectric Machinery," second edition, p. 298.

Digitized by Google

But $\frac{nB\mathfrak{A}}{r_a}$ is the same thing as the "maximal" value of e which the machine would give, if the magnets were separately saturated, when working at the speed n through resistances as given. It may therefore be written as $\bar{e}$.

Whence, finally, $$e = \bar{e} - e' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

From which we get at once also for the shunt current,

$$i_s = \bar{i}_s - i_s' ; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and for the main-circuit current,

$$i = \bar{i} - i' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

5. *General Equation of the Self-Exciting Dynamo.*

Let ψ be any one of the currents or potentials of the dynamo, $\bar{\psi}$ its "maximal" value—that is to say, the value it has when the magnet is separately saturated—and ψ' its "diacritical value."

$$\bar{\psi} = f(n, A, Y, [R]) ;$$

and, by the very nature of the case, whatever the form of the function f,

$$\psi = f(n, A, H, [R]) ;$$

and

$$H = Y \frac{\psi}{\psi + \psi'} ;$$

whence

$$\psi = \bar{\psi} \frac{\psi}{\psi + \psi'} ;$$

and, finally,

$$\psi = \bar{\psi} - \psi' ; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

which is the general equation of the self-exciting dynamo.

It may here be pointed out that the two terms on the right-hand side of this equation—the "maximal" and "diacritical" values of the quantity on the left—possess certain properties. In a given dynamo the "diacritical" term is a constant, whilst the "maximal" term is a variable which increases with the speed of driving. The maximal term when representing a current varies also with changes of resistance, in an inverse way, but differently in shunt dynamos from series dynamos; when it represents an electromotive force it does not vary with changes of resistance. A year ago Dr. Frölich sought to divide the equation of the dynamo into two parts—an armature part and a field-magnet part. This does not quite correspond to the case. The "diacritical" term appertains to field-magnet primarily; but since the number of ampere-turns of current that will produce a half-saturated magnetic field depends also on the quantity and quality of the iron in the machine, it is impossible to regard it as independent of the iron masses of the armature. The "maximal" term is proportional both to A, the total effective area of the armature-coils, and to Y, the maximum value of the magnetic field. The "diacritical" term for currents is lowered by increase in the number of magnetising coils, and for potentials is raised by increase in the resistance of the magnetising coils. The "maximal" term is not altered by altering the magnetising coils, but increases with an increase in the number of coils of the armature, and, for currents, decreases with increasing resistance. If the iron parts of a dynamo be given of a certain form, size, and quality, then it may in general be said that ψ' depends only on the windings (and, for currents, on the resistance) of the field-magnet, and $\bar{\psi}$ depends only on the windings of the armature (and, for currents, on its resistance) and not upon the windings of the field-magnet, or on their resistance except (and this only for currents) so far as their resistance contributes to the resistance of the whole circuit through which the current generated in the armature flows.

6. *Conditions of Self-regulation for Compound-wound Dynamos.*

In this case we write the formula of the electromagnet in terms of the ampere-turns; Si_a for the excitation due to the coils in the armature part of the circuit, Zi_s for that due to the shunt, and ϕ' as the diacritical number of ampere-turns. Then, writing

$$E = 4nAH ;$$

$$e = E - (r_a + r_m) i_a ;$$

$$H = Y \frac{Zi_s + Si_a}{Zi_s + Si_a + \phi'} = Y \frac{Zi_s + Si_a}{\bar{\phi}}, \text{ by equation (11) } ante ;$$

$$B = 4AY ;$$

we have

$$e\phi' = i_s Z(nB - e) + i_a\{S(nB - e) - (r_a + r_m)\bar{\phi}\} \quad . \quad . \quad (12)$$

The condition sought is to be such as to make e constant. Now ϕ' is a constant, so is i_s if e is, and n may be made constant at any value we please. Hence, as i_a is a variable, the condition of constancy can only be attained by giving the dynamo such a speed n_1 that the coefficient of i_a shall be zero, or that

$$S(n_1 B - e) = (r_a + r_m)\bar{\phi} \quad . \quad . \quad . \quad . \quad (13)$$

But $\bar{\phi}$, the maximal number of ampere turns, is not itself a constant, since it contains as one of the three terms in its sum the quantity Si_a. Hence we gather that absolute self-regulation is physically impossible; and it approaches to perfection as $Zi_s + \phi'$ are great as compared with Si_a. In other words, there must be so much iron in the machine that the diacritical excitement is very great, and it must have a small armature resistance; otherwise S (and Si_a) cannot be small as compared with Z (and Zi_s). This is known already to electric engineers. Assuming that the dynamo is well designed in these respects, $\bar{\phi}$ will be very nearly constant, and the equation of condition may be accepted as adequately true. This leaves equation (12) in the form

$$e\phi' = i_s Z(n_1 B - e),$$

$$\frac{e\phi'}{i_s Z} = n_1 B - e,$$

$$\frac{r}{Z}\phi' = n_1 B - e.$$

Putting in this value of $n_1 B - e$ into equation (13), we have

$$\frac{r_s}{Z}\phi' = \frac{r_a + r_m}{S}\bar{\phi} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

Now ϕ' may be written either as Si_a' or as Zi_s', and $\bar{\phi}$ may be written either as $S\bar{i}_a$ or as $Z\bar{i}_s$. Choosing the second form in the first case and the first form in the second case, we may obtain

$$r_s i_s' = (r_a + r_m)\bar{i}_a ;$$

or finally,

$$e_s' = \bar{e}_{a+m} ; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (15)$$

or the diacritical value of the potential at terminals for the shunt-wound part of the circuit must be equal to the maximal value of the potential at terminals for the armature and series-wound part. The equation (14) also gives

$$\frac{Z}{S} = \frac{r_s}{r_a + r_m} \cdot \frac{\phi'}{\bar{\phi}}, \quad . \quad . \quad . \quad . \quad . \quad (16)$$

which is more correct than the formula usually given hitherto for the ratio of the shunt and series windings, and which assumes absence of saturation terms.

The simplicity of these results, no less than that of the processes by which they are derived, lends additional value to the new formula of Dr. Frölich, whose work deserves to be more widely known and recognised than it now is.

SOUTH KENSINGTON EXAMINATIONS.

(Continued from page 269.)

HONOURS EXAMINATION.

Full marks can only be got by answering all the questions; but good answers to some of the questions are likely to gain more marks than hasty attempts to answer all of them. The value attached to each question is the same.

41. Given a sufficient length of telegraph cable consisting of a single thick copper wire uniformly covered with a cylindrical coating of insulating material, describe and explain measurements and experiments that would enable you to determine the specific inductive capacity of the insulator.

A.—Let a be the radius of the wire and l its length, and let b be the radius of insulating covering, and k its specific inductive capacity.

Then the capacity of the given length of cable will be

$$\frac{k\,l}{2\log_e \frac{b}{a}}$$

Digitized by Google

A proof of this would not be required from a candidate at the examination, but it will be useful to give it here.

The current in the wire may be considered as an infinite straight current, so that the lines of force are perpendicular to the wire, and therefore the tubes of force are wedges whose sections are proportional to the distance from the axis, and thus where V is the potential inside the insulator, and A is a constant, we have

$$\frac{dV}{dr} = -\frac{A}{r}$$

r being measured perpendicular to the wire.

Therefore $$V = -A \log r + B$$

Now, V must have a constant value V_0 at the surface of the wire, and must vanish at the surface of the insulating material, so that writing $r=a$, and $r=b$, respectively, in the above equation, we get

$$V_0 = -A \log a + B$$
$$0 = -A \log b + B$$

which gives $$A = \frac{V_0}{\log \frac{b}{a}}$$

and therefore if σ be the surface density on the wire

$$\sigma = -\frac{k}{4\pi}\left(\frac{dV}{dr}\right)_{r=a} = \frac{kA}{4\pi a} = \frac{kV_0}{4\pi a \log \frac{b}{a}}$$

Multiplying by $2\pi a l$, the area of the surface of the wire of length l, we find that the whole quantity of electricity on that length is $$\frac{k l V_0}{2 \log \frac{b}{a}}$$

and the capacity is $$\frac{k l}{2 \log \frac{b}{a}}$$

The quantities to be measured are therefore—

(1). The length l, which may be obtained by direct comparison with an accurate scale.

(2). The radius of the wire, and that of the insulating covering, which may be done conveniently by means of a micrometer-screw wire gauge.

(3). The capacity of the given length of cable, which may be determined by comparison with a condenser of known capacity. The method selected should of course be described in detail.

42. The specific inductive capacity of the dielectric of any condenser being known, state and explain how you could determine experimentally the specific resistance of the dielectric.

A.—Charge the condenser, and connect its two surfaces with the electrodes of an electrometer. Let S be the capacity of the condenser, Q the charge on either surface at the time t, R the resistance of the dielectric, C the current in it at the time t, and E the difference of potential indicated by the electrometer at the time t.

The rate of fall of potential will be found after some time to become constant, showing that there is a steady current through the dielectric. When this occurs let the values E_1 and E_2 of E, at the times t_1 and t_2 respectively, be observed.

Now we have

$$Q = SE = SCR = -SR\frac{dQ}{dt}.$$

Therefore, if Q_1 be the value of Q at the time t_1

$$Q = Q_1 e^{-\frac{t-t_1}{SR}}$$

And therefore, if E_1 be the value of E at the time t_1

$$E = E_1 e^{-\frac{t-t_1}{SR}}$$

So that $$E_2 = E_1 e^{-\frac{t_2-t_1}{SR}},$$

Which gives $$R = \frac{t_2-t_1}{S \log \frac{E_1}{E_2}}$$

If the specific inductive capacity of the dielectric be known the value of S can be found by calculation from the dimensions of the condenser, if the latter be of simple form; otherwise by an experimental determination of the capacity of the condenser with air as a dielectric, which is a much easier observation than that of the value of S directly, since with air as a dielectric there is no electric absorption.

The value of R being known, the specific resistance can be calculated from the dimensions of the dielectric.

43. Explain fully the theory of "Wheatstone's Bridge." Describe the form of Wheatstone's Bridge with which measurements are made by adjusting a movable contact upon a graduated wire, showing what precautions and corrections are required, and how these can be made.

A.—In the Wheatstone bridge method of comparing the resistances of two conductors, four conductors, A B, B O, O C, C A, are connected, as shown in Fig. 1. The points A and O are also connected through a galvanometer, G, and a key, H, and the points B and C are connected through a key, K, and a battery, M.

In making an experiment, say, to compare the resistances of the conductors B A and A C, the battery circuit is first completed through the key K, and then the galvanometer circuit through the key H, and the resistances of the conductors B O and O C are adjusted until no deflection occurs on completing the galvanometer circuit. The resistance of B A will then be in the same ratio to that of A C, as the resistance of B O is to that of O C.

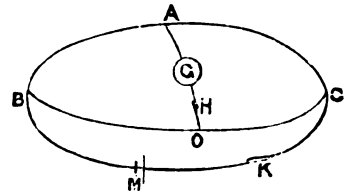

FIG. 1.

In Fig. 1 we have a system of six conductors connecting four points, three conductors meeting at each point. We might investigate the relations between the resistances of the conductors directly from Fig. 1, but the investigation will perhaps seem clearer if we draw the diagram again in its simplest form as shown in Fig. 2.

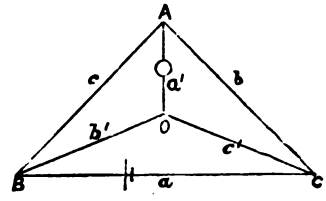

FIG. 2.

Let A, B, C, O represent the potentials of the points A, B, C, O, respectively.

Let the resistance of A B be represented by c
" " B C " a
" " C A " b
" " O A " a'
" " O B " b'
" " O C " c'

In order that there may be no current in A O the potentials at A and O must be equal. If the resistances of the conductors be so arranged that this is the case, A O may be removed without altering the distribution of currents in the conductors, and therefore without changing the potentials A, B, C, O. Considering, then, the conductors B A, A C, connecting the points B C, we see that the current through B A must be equal to the current through A C. Let x be the strength of this current. Then we have

$$B - A = cx$$
$$A - C = bx,$$
$$B - C = (b+c)x.$$

Therefore $$\frac{B-A}{B-C} = \frac{c}{b+c}$$
$$\frac{A-C}{B-C} = \frac{b}{b+c},$$

which give $$A = \frac{Bb+Cc}{b+c}.$$

By similar reasoning $$O = \frac{Bc'+Cb'}{b'+c'}.$$

In order, therefore, that there may be no current through A O due to a battery in B C, we must have

$$\frac{Bb+Cc}{b+c} = \frac{Bc'+Cb'}{b'+c'},$$

which reduces to $$bb' = cc'$$

or $$b : c :: c' : b'$$

which is the relation previously stated. In the form of Wheat-

Digitized by Google

stone bridge with a sliding contact, the conductor B O C consists of a graduated wire of uniform thickness, so that the resistances of any two portions of it are in the ratio of their lengths. The point of contact O is made to slide along B O C until a balance is obtained, when the ratio c'/b' is read off, and therefore the ratio b/c is known.

A convenient form of a Wheatstone bridge of this construction is shown in Fig. 3, in which E F is the wire on which the sliding contact moves, and E A, A B, B C, C D, D F are thick strips of copper whose resistance is inappreciable, and which are used for making the necessary connections.

FIG. 3.

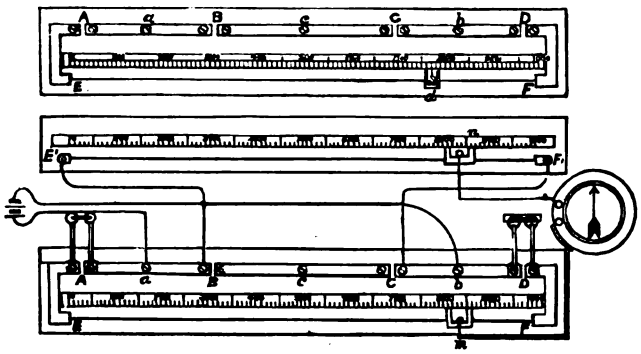

FIG. 4.

In order to compare two resistances R_1 and R_2, R_1 is inserted at B, and R_2 at C, and the gaps A and D are closed by means of thick copper strips whose resistances are inappreciable. The ends of the battery circuit (which must contain a key) are connected to the binding-screws a and b, and the wires leading from the galvanometer are connected, one to the binding-screw c, and the other to the slider d. The key in the galvanometer circuit may either form part of the slider or the contact of the slider may be continuous, and the key may be distinct from it.

The slider is then adjusted until a balance is obtained and its position is read off from the scale. If x be the distance of the sliding contact from E, and y be its distance from F, we shall then have

$$\frac{R_1}{R_2}=\frac{x}{y}.$$

The method in this form is open to the objection that a small error in reading the position of the slider generally introduces a comparatively large error into the result, and it is not easy to determine the position of the slider with great exactness. The first points, then, on which we have to fix our attention are to arrange our apparatus so that the galvanometer deflection may be as great as possible, and so that the error in determining the position of the slider may have the smallest possible influence on the result.

It may be shown that in a given system the greatest galvanometer deflection will be obtained when of the two resistances, that of the battery and that of the galvanometer, the greater resistance is made to join the two greatest to the two least of the four other resistances.

The battery must, however, never be introduced into the sliding contact, as the passage of a strong current would injure the surface of the wire at the point of contact with the slider.

In order that a given error in reading the position of the slider may introduce as small an error as possible into the result we must select a resistance R_2 with which to compare R_1, such that R_2 is as nearly as possible equal to R_1, for the resulting error will be least when the resistances to be compared are equal, and consequently the slider bisects the wire E F.

For let $x+z$ be the true value of x, and consequentiy $y-z$ the true value of y, $x+y$ being the length of the wire, and therefore constant.

Let R_1+a be the true value of R_1.

Then
$$R_1+a=R_2\frac{x}{y}\left\{1+\frac{z(x+y)}{xy}\right\}$$
$$=R_1\left\{1+\frac{z(x+y)}{xy}\right\}$$

Therefore
$$a=R_1\frac{z(x+y)}{xy}$$

For this to be a minimum $x\,y$ must be a maximum, and therefore, since $x+y$ is constant, $x=y$, or the slider must be at the middle point of the wire.

Again, the resistance of the wire E F will generally be small compared with the resistance R_1 and R_2, and therefore most of the current will flow through E F, and very little through R_1 and R_2. If, therefore, we replace the copper strips in the gaps A and D by resistance coils, we may increase the slope of potential along the wire and therefore greatly increase the delicacy with which the position of the slider can be adjusted.

In order to obtain the best arrangement, R_1 should first be determined approximately by the method already described, and the coils inserted at A and D should have resistances r_1 and r_2 respectively, as nearly as possible in the same ratio as that of R_1 and R_2.

Let a be the resistance of unit length of the wire E F. Then when a balance is obtained we shall have

$$\frac{R_1}{R_2}=\frac{r_1+ax}{r_2+ay}$$

The resistances of the thick copper strips may be neglected without much loss in accuracy, but it is of great importance that the contacts should be good, and where special accuracy is required it is better to replace the binding screws by bent pieces of thick copper, soldered to the copper strips and dipping into mercury cups.

To eliminate possible small errors due to thermo-electric couples at the junctions of different metals, a commutator should be inserted in the battery circuit, and the true position of the slider taken as the mean between the two readings obtained with currents in opposite directions.

In order to prevent variation in resistance due to change in temperature, the coils and the resistance to be determined should be placed in water baths, so that their temperatures can be ascertained, and in the case of the coils used for comparison a correction applied if the temperature observed differs from that at which they are correct.

An error may also be introduced by the unequal wearing away of the wire E F by the friction of the slider, or by accidental damage to the wire, and therefore the wire should be calibrated immediately before making important observations.

The calibration, and, at the same time the determination of the value of a, may conveniently be carried out by a method due to Prof. G. Carey Foster, and described by him in a paper in the *Journal* of the Society of Telegraph-Engineers for 1872.

Let a second graduated wire E′ F′ be connected with the bridge as shown in Fig. 4.

The gaps A and B are closed, the one by a short thick wire of practically insensible resistance, the other by a known resistance of an amount equal to that of a short length of the wire E F. This known resistance forms a gauge with which the resistances of successive portions of the wire E F may be compared.

Suppose the gauge to be at D, then the slider m is placed at or near the right hand end of E F, and the second slider n is adjusted so that there is no deflection.

The gauge and the thick copper connector are now interchanged, and the balance is restored by moving m. Then clearly the distance through which m is moved gives the length of the wire E F, whose resistance is equal to the difference between the resistance, of the gauge and connector, or, if the latter be neglected, to the resistance of the gauge. The gauge and connector may now be again interchanged, and the balance restored by moving n; and by continuing the process until m reaches the other end of the wire E F, a series of measurements will be obtained from which a table may be drawn up showing the true reading corresponding to any given observed reading E $m=x$, either by interpolation, or more conveniently by plotting the results of the measurements in the form of a curve. German silver is commonly used for the wire E F, as its specific resistance is high and does not vary greatly with the temperature.

In making measurements with the Wheatstone bridge care should always be taken to complete the battery circuit before completing the galvanometer circuit, as otherwise even when a balance is obtained, there will be a "kick" of the galvanometer needle due to the momentary self-induction current. When the resistance coils are properly wound they do not contribute to this, but there will always be some self-induction in the rest of the circuit, so the precaution mentioned above should never be neglected.

CITY AND GUILDS OF LONDON INSTITUTE EXAMINATION PAPERS.

ELECTROTECHNICS.—COURSE A.

1. Describe the process of making, adjusting, and testing a condenser.

2. Describe the condenser method of measuring the resistance of a battery, and prove the formula used.

3. Prove the equation employed when testing resistances by the Wheatstone bridge, and describe with sketches some form of "wire" bridge. What are the advantages and disadvantages of the latter in comparison with the forms in which resistance boxes are exclusively used?

4. Describe the construction of the Wimshurst influence machine.

Digitized by Google

How does the presence of the Leyden jars affect the discharge? What is the function of the diagonal conductors?

5. Give an account of the experimental way of measuring the magnetic moment of a magnet.

6. Sixty accumulators, each having an E.M.F. of 2·05 volts and an internal resistance of ·004 ohm, are employed to light 90 glow lamps. Each lamp requires 0·64 ampere of current. The effective resistance of the leads is 0·226 ohm. Find what percentage of the whole work done by the battery is utilised in the lamps, and what potential difference is employed to run them.

7. Give the definitions of "unit magnetic pole," "unit intensity of magnetic field," "one dyne," "the absolute unit of strength of current," "one ohm," "one farad."

8. Find the resistance of a copper telegraph wire 83 mils. in diameter and 54 miles long, having given that the specific resistance of copper at 0°C. is 1·57 microhm. What is the resistance of this wire at 35°C. if the temperature coefficient be ·0038?

9. Describe the Latimer Clark standard cell, and the precautions to be observed in making and using it. How can the Daniell cell be converted into a standard cell?

10. Describe the "sine" method of relatively calibrating a galvanometer; why cannot it be used for deflections beyond a certain limit. How would you convert your *relative* calibration into an *absolute* one?

ON ELECTROLYSIS.

BY PROF. OLIVER J. LODGE, D.SC.

(Continued from page 398.)

Theory of Kohlrausch.—The fundamental assumptions underlying the beautiful theory of Kohlrausch are the same as those adopted by Wiedemann. He considers electrolytic conduction performed by dissociated atoms, each of which carries the same numerical charge of electricity, one set positive the other set negative. He follows Quincke in considering their motion due and proportional to the slope of potential $\frac{dV}{dx}$; and he accounts for migration by unequal speed of travel. But—and this is the special Kohlrausch idea—every ion is supposed to have a specific velocity, in a given fluid, when urged by a given slope of potential; a velocity wholly independent of all other circumstances. Moreover, all very dilute solutions are found to behave similarly, so that an ion's rate of travel is nearly independent of the nature of the dissolved substance so long as there is not sufficient of it to interfere with the general aqueous nature of the liquid. Kohlrausch has further shown how to calculate this specific ionic velocity in absolute measure, from conductivity, concentration, and migration data. And the following table, taken from Clerk Maxwell's "Elementary Electricity," embodies some of his results.

Specific Velocity of different Ions in centimetres per second when urged in a very watery solution (i.e., *one whose viscosity differs very little from water, no matter what acid or salt is being electrolysed in it) when urged by an E.M.F. of one volt per centimetre: according to Kohlrausch.*

Cations:	H	K	Am	Na	Li	Ba	Sr
	·0029	·00051	·00049	·00032	·00020	·00033	·00030
			Ca	Mg			
			·00025	·00022			
Anions:	I	Br	Cl	F	N_2O_3	Cl_2O_3	$C_2H_3O_2$
	·00058	·00056	·00053	·00031	·00050	·00038	·00023

It is only with much misgiving that I venture to criticise so admirable a theory supported by close agreement with experiment; but it seems less dangerous to hesitate unduly over a true theory, than to accept too hastily a false one. In the expectation that the objections I urge against the entire and comprehensive truth of this doctrine of specific atomic velocity will be speedily met and shattered I proceed to state them. In the first place I proceed to draw a radical distinction between the *sum* of the velocities of opposite ions and their individual velocities. Even if we admit provisionally that the sum of anion and cation velocities can be calculated from conductivity data, I demur at the partitioning of this velocity u into two unequal portions and affixing a definite velocity to either ion. The only data existing for such apportionment of u, into nu and $(1-n)u$, are the migration data of Hittorf; and I have shown at some length that all the observed facts may be otherwise explained, I even venture to think, *must* be otherwise (or to some extent otherwise) explained. But, passing over this point, there are doubts about the sufficiency of our present data for u itself. The Kohlrausch theory considers the dissolved salt as the sole electrolyte; it neglects the conductivity of the water.* Let us therefore start *ne novo* and independently.

Attempt at Calculation of absolute Ionic Velocity.—Let n equal the number of dissociated molecules *of the substance undergoing decomposition* in a liquid, per unit length. Let q equal the total charge (reckoning + and − together numerically), and m the mass of each molecule; and let u be the relative velocity of opposite ions with respect to each other, under the influence of a propelling force $\frac{dV}{dx}$.

Consider an element $dxdydz$. The number of active molecules in its face is n^2dydz, the number leaving it per second is $n^2dydz \cdot nu = n^3udydz$. The quantity of electricity thus conveyed is qn^3udydz per second, and the corresponding amount of travelling matter is mn^3udydz per second, so that the electrochemical equivalent of the substance is $\epsilon = m/q$. By Ohm's law the strength of current is $k\frac{dV}{dx}dydz$, where k is specific conductivity of the solution; hence, since the current is also the quantity conveyed per second,

$$k\frac{dV}{dx}dydz = qn^3udydz,$$

or

$$u = \frac{k\frac{dV}{dx}}{qn^3} = \frac{\epsilon k}{mn^3}\cdot\frac{dV}{dx}.$$

But mn^3 is the number of grammes of the electrolysed or dissociated substance in a unit cube, and this we may write $N\mu$, where N stands for the number of monad gramme-equivalents of the really electrolysed substance per c.c., and μ is its molecular weight compared with hydrogen. Moreover $\frac{\epsilon}{\mu}$ is simply the electrochemical equivalent of hydrogen, *i.e.*, a constant, say η; so

$$u = \frac{k}{N}\cdot\eta\frac{dV}{dx}.$$

We see, then, that for a given slope of potential u varies only with $\frac{k}{N}$ or, as Kohlrausch would put it, with conductivity ÷ concentration, which latter he has proved within certain limits to be nearly constant for many salt solutions.*

But the question now arises, is N really simple concentration? What is the substance really undergoing electrolysis? Kohlrausch considers that in weak saline or acid solutions it is the dissolved salt or acid only, and he appears to consider that every molecule of this is effective; hence he would say N is at once determined by knowing how much stuff has been dissolved per litre. Take, for example: A 5 per cent. solution of ammonic chloride contains about ·001 gramme equivalent of the salt per c.c. (*i.e.*, say 53 grammes per litre); and it has a conductivity about 9×10^{-6} that of mercury at 0°, or say 10^{-10} absolute units. The E.C.E. of hydrogen is 10^{-4}; so then we can easily calculate the sum of the ionic velocities for the AmCl molecule in such a solution, *on the hypothesis that it is the sole effective compound present, and that the whole of it is effective*—

$$u = \frac{10^{-10}}{10^{-3}}\cdot 10^{-4}\frac{dV}{dx} = 10^{-11}\frac{dV}{dx}.$$

Let the slope of potential be one volt per centimetre, *i.e.*, let $\frac{dV}{dx} = 10^8$, then $u = ·001$; and this agrees exactly with Kohlrausch's value; only he apportions it ·00049 to Am, and ·00053 to Cl, upon Hittorfian grounds, instead of half to each. Ignoring this last mere migration question, what is there hypothetical about the arithmetical problem? Plainly the nature of the substance conveying the current; *i.e.*, the value of N.

If what I have said under the head "migration" has any weight, the current is really conveyed partly by the dissolved substance and partly by the solvent, in the proportion of λ to $1-\lambda$. Let us reconsider the above investigation from this point of view. Very little change need be made; we shall have n_1^3 and n_2^3 for the number of dissociated molecules of the two substances per c.c., and u_1 and u_2 for their respective ionic velocities. The ratio in which the two substances conduct the current will be $n_1^3u_1$; $n_2^3u_2$; and corresponding to n_1^3 and n_2^3, there will be N_1 and N_2 to represent the amount of dissociated substance present, reckoned in gramme-equivalents per cubic centimetre of solution; but q remains of the same value as before and equal to $\frac{N_1}{\eta n_1^3}$ or $\frac{N_2}{\eta n_2^3}$.

So the equation between two expressions for intensty of current becomes

$$k\frac{dV}{dx} = q\,(n_1^3u_1 + n_2^3u_2) = \frac{q}{\lambda}n_1^3u_1;$$

or

$$u_1 = \frac{\lambda k}{N_1}\cdot\eta\frac{dV}{dx},$$

and

$$u_2 = \frac{(1-\lambda)k}{N_2}\cdot\eta\frac{dV}{dx}.$$

The value of λ is determined by migration experiments, in the way already explained, and k of course is known; but, since there exists no known means of ascertaining the value of N_1 and N_2, there remains complete uncertainty as to the values of u_1 and u_2; all that one can determine, from conduction and migration data combined, are the values of N_1u_1 and

* In the January (1886) number of *Wiedemann's Annalen*, Prof. Kohlrausch gives a long account of his present standpoint. In sec. 20 he discusses this question of the conductivity of water, and sees reason for modifying his original view, and for admitting that in very dilute solutions water does share in the electrolysis. He mentions, what I did not know, that part-conduction by water had been suggested by Prof. Clausius as accounting for migration; but Prof. Kohlrausch himself adheres to his old Hittorfian view of it.

* Kohlrausch's latest statements make k/N (understanding N in his sense *pro tem.*) a linear function $\sqrt[3]{N}$, *i.e.*, of the distance between molecules; but the plotted lines showing this are after all very curved, and all that the facts really amount to is, I think, that

$$k = a + bN + cN^2 + \&c.$$

where a being the conductivity of pure water, may be taken as zero. The N here interpreted in Kohlrausch's sense, as representing the amount of dissolved salt, I call henceforth N′.

Digitized by Google

of N_2u_2. On Kohlrausch's hypothesis, taking the suffix 1 as applicable to dissolved salt, λ is supposed to be 1 and u_2 accordingly 0; moreover, since *every* molecule of the salt is supposed by him to be dissociated sufficiently to take part in the conduction, N_1 is considered known from concentration data, *i.e.*, from the percentage of salt contained in the water, and thus u_1 is calculable. Permitting ourselves to doubt all this, we come to the conclusion that we do not yet know the absolute velocity of any ion, and cannot know it without further information regarding the dissociation ratio (that is, N_1/N', or N_2/N') of each substance present. On the unlikely supposition that this criticism be in any sense accepted, what is the meaning of the striking agreement between Kohlrausch's theory and experiment? His view leads to the equation

$$k\eta\frac{dV}{dx}=N'u,$$

where N′ is the total number of monad gramme-equivalents *of the dissolved substance* in a cubic centimetre of solution. Our view, on the other hand, leads to the equation

$$k\eta\frac{dV}{dx}=N_1u_1+N_2u_2,$$

where N_1+N_2 represents the (unknown) amount of *actually conducting substance* per c.c. of solution.

Now it seems by experiment that k/N' is an approximate constant,* at any rate for weak solutions; so we must suppose the fact to mean that $N_1u_1+N_2u_2$ is, within limits, nearly proportional to N′.

It is in no way surprising that the dissociation of both substances should proceed *pari passu* with, and be initially proportional to, the quantity of stuff added to the water; but there remains a further question, which, if I am able to discuss it, shall be considered elsewhere.

Theory of von Helmholtz.—Finally we come to the wide-reaching theory of Helmholtz.

The root idea of this theory is that each kind of matter has a specific attraction for electricity, some kinds for positive, other kinds for negative; that, accordingly, work must be done to separate an atom from its electrical charge, or to remove electricity from an atom of high specific attraction and give it to another lower in the scale. Further, that chemical affinity is mainly due to the electrical attraction of oppositely charged atoms, and that when such atoms combine into a compound molecule they do not discharge into each other, but retain their charge.

Apply this principle to a Daniell cell.

During the action of the cell a certain amount of positive electricity has to leave (deposited) Cu, a substance which attracts it feebly, and enter into union with (dissolved) Zn, a substance which attracts it much; hence is derived the energy or E.M.F. of the cell.

Apply the same principle to a water voltameter. During the passage of a current the charges are torn from hydrogen and oxygen atoms and given to the electrodes, which, if they are platinum, have no special attraction for either electricity; hence arises the E.M.F. of polarisation, or the work needed to decompose the liquid. Work is done, according to this theory, not in tearing the atoms asunder, but in tearing their electric charges from them. If the ions are allowed to enter into combination with some available radicles, in such a way as to retain their charges, polarisation E.M.F. is much reduced. So long as the atoms have not given up their charges they cling to the electrodes and cannot be removed mechanically, say by exhaustion or the like; but if once their charges are given up and molecules of the single substance formed, it makes but little difference to polarisation whether that substance be allowed to dissolve in the liquid or be made to bubble up from it. But it is to be understood, I believe, that in estimating E.M.F., or effective energy of a cell per unit electricity conveyed, Helmholtz would take into account the energy of all secondary, as well as of all primary actions, "minor attractions of solvents" as well as affinities of iron.

Helmholtz points out that the interior of an electrolyte cannot stand the slightest electrostatic strain, and hence, in so far as a voltameter behaves as a condenser, it does so by reason of actions going on within the films or boundaries separating the liquid from the electrodes. From observations made with his air-free cell Helmholtz estimates the thickness of these quasi-dielectic films as 10^{-8} centimetre—the customary molecular magnitude.

It seems to me that Helmholtz accepts the possibility that ordinary electrostatic laws may be applied to the interactions of atoms and their charges, and to the attractions of atoms by the electrodes across this thin molecular film. And he points out that the reason so feeble an E.M.F. is sufficient to effect decomposition is just because of the extreme thinness of the film—the slope of potential dV/dx being by no means insignificant.

Helmholtz shows that the analogue between the pre-decomposition state of a voltameter and a condenser of constant capacity is accurately sustained by his air-free cell, charge being proportional to potential down to $\frac{1}{1000}$ volt or perhaps lower; and this fact he considers to prove that by far the greater part of the force binding atoms together, and probably the whole of it, is electrical; for "if any chemical force bound ions together, requiring work to overcome it, an inferior limit ought to exist to such E.M.F.'s as are able to attract ions to the electrodes and charge them as condensers. No indication of any such limit has yet been discovered."

But while he thus considers it proved that the mightiest chemical forces are really electrical, he by no means denies the existence of others. Atoms cling to electricity, and charged atoms cling to one another, but uncharged atoms may cling somewhat, and this may be the distinction between "typical compounds" and "molecular aggregates." This distinction had been forced upon me also independently, and so I quote it with full agreement. All electrolytes belong to the "typical compound" class, and it is by means of the charges in these atoms that they are so easily decomposable, notwithstanding their strong affinities. But combination can occur between elements of very weak affinity, which only with difficulty can be got to unite; and yet, once combined, they seem to cling with the most surprising tenacity. These bodies, I should suppose, are molecular aggregates held together by purely "chemical," *i.e.*, material or non-electrical, forces; and the reason of their apparent tenacity is, I would suggest, merely that they afford no handle to lay hold of. They are quite unsusceptible to electrical influence, unless it be in the violent and perhaps thermal form of the electric spark. If I instance such bodies as cyanogen and ammonia it is only to indicate more suggestively what I mean.

I do not feel sure whether Helmholtz would lend his name to the suggestion just made, for he hedges a little about these molecular modes of combination, and says: "But the fact that even elementary substances with few exceptions have molecules composed of two atoms makes it probable that even in these cases electric neutralisation is produced by combination of two atoms each fully charged, not by neutralisation of every single unity of affinity." I venture with great deference to suggest, as an objection to this view, the fact that charged (say hydrogen) atoms are unable to unite with each other, though they attack everything else with vigour, but that so soon as they are allowed to give up their charges to an electrode they at once unite and become molecules of gas.

I need not stay to do more than remark that the notion of an attraction between matter and electricity is made by Helmholtz to explain a great many other things—"contact E.M.F.," "thermo-electricity," "frictional electricity," and, in fact, all electrostatics and most of current electricity. These things appear in a great many of his writings, first in his great Memoir of 1847, but they are conveniently summarised in his Faraday Lecture of 1881, from which I have just now been quoting.

It is scarcely decent to obtrude my own opinion on so fundamental a subject as this, but I may be permitted to say that if one does grant such an attraction, and if one further conceives positive and negative electricity as the two constituents of ether, not only chemical affinity but specific inductive capacity and refractive index, together with the Fresnel-Fizeau connection between ether and matter, can be readily conceived, and, so to speak, accounted for; and the attraction of gravitation does not lag far in the background. Seven years ago I spent some time endeavouring to set out all these things in a systematic and pretentious form, but I came to the conclusion that the task was beyond my strength. The special things which Helmholtz more particularly explains by his theory—viz., contact E.M.F., thermo-electricity, and frictional electricity—did not suggest themselves to me in such a direct connection with it; nor do they now.

The theory of Helmholtz insensibly impels one to try to apply ordinary electrostatic considerations to the interactions of atoms and to the effect of electrodes upon them. It suggests, in fact, a theory of chemistry; in the form of a sort of supplementary kinetic theory of gases with electrified atoms. But the liquid state, which (more than ever by recent researches*) seems essential to chemical action, has difficulties of its own to be overcome before the behaviour of electrified atoms can be properly treated.

It may be noted that whereas the actual force of attraction between two atoms at a distance like 10^{-9} is not great, being something like 10^{-4} dyne, the acceleration produced by it in the small mass of an atom is terrific, being nearly a trillion times that produced in ordinary bodies by the earth. To show that mechanical forces are insignificant compared with electric ones between charged atoms, Helmholtz reminds us that their electric attraction at any distance exceeds their gravitative attraction at the same distance nearly a hexillion times.†

* See, however, a previous footnote.

* Those of Mr. Dixon and others on combustion and on gaseous combination or explosion. As Prof. Armstrong has pointed out, they seem to suggest a necessity for the presence of a dissociated typical compound, *i.e.*, for electrically charged atoms (see above), in every reaction. Should this turn out to be a fact, it will be one of profound chemical and physical interest.

† This is not exactly Helmholtz's way of putting it (Faraday Lecture, 1881), but it comes to the same thing; and it is perhaps as well to notice that there is nothing uncertain about the calculation; the least accurately known datum in it is the gavitation constant, or the earth's mean density. The general expression for the ratio between the electric attraction of two radicles in an electrolytic compound and their gravitative attraction, at any given distance, is

$$\frac{V^2}{4\gamma\mu_1\mu_2\eta^2};$$

where V is the velocity of light, η the electro-chemical equivalent of hydrogen, γ is the gravitation constant, $g\mathrm{R}^2/\mathrm{E}$, or $\frac{3g}{8\rho\times10^9}$ while μ_1 and μ_2 are the combining equivalents of the radicles in the compound compared with hydrogen; or $\mu_1+\mu_2$ is the compound's ordinary "molecular weight" divided by its "atomicity"; *e.g.* for water, $\mu_1\mu_2=8$; for copper sulphate, 80; for silver nitrate, 6696.

The numerical value of the above ratio is

$$\frac{10^{36}}{3\mu_1\mu_2}$$

(To be continued.)

CAOUTCHOUC FROM A EUROPEAN HERB.—According to the *Bulletin de la Société Chimique de Paris*, a plant belonging to the lettuce tribe, scientifically known as *Soachus Oleraceus*, and quite common on the wayside and among dry rubbish heaps in France, has been found to yield a very good quality of caoutchouc. The plants are steeped in carbon bisulphide, and afterwards boiled in alcohol and caustic potash. About 4·3 per cent. of the weight is thus obtained as caoutchouc.

COMPANIES' MEETINGS & REPORTS.

Direct Spanish Telegraph Company (Limited).

An extraordinary general meeting of this Company was held at Winchester House, 50, Old Broad-street, London, on 19th inst., under the presidency of Sir James Anderson, to consider the confirmation of the resolutions passed at the extraordinary meeting on the 30th ult. for reducing the capital of the Company.

The MANAGER (Mr. Ch. Gerhardi) read the notice calling the meeting.

The CHAIRMAN in opening the proceedings announced that Mr. Bannatyne had intimated his intention of taking legal proceedings against the proposed scheme being put into execution. He also regretted to say that he had received other protests, representing in all thirty-seven shares, while, on the other hand, in favour of the proceeding they had proxies from ninety shareholders. At the last meeting Mr. Baker was the only proprietor who, in the opinion of the Board, presented any specific arguments against the Directors' action, or any specific arguments which the Board could answer. Mr. Baker had a right to be seriously considered, because he was a man who naturally understood the class of business before them, and he must have had many examples to put before them. The Directors therefore had naturally very carefully considered everything which that gentleman had said, especially after the meeting. Mr. Baker said, Why not wait for ten years, and then the preference shareholders will get the whole of the arrears, and begin with a 10 per cent. dividend after ten years? In his (the Chairman's) opinion that view had influenced some of the shareholders, and it was plainly seen that it had some weight. But a little consideration would show the shareholders that at the end of 10 years the preference shareholders would get no arrears at all. All the arrears of the £5,000 lying by would go naturally to recoup the capital lost, so that if the capital remained intact, as it now was, at the end of 10 years the preference shareholders would get 7 per cent. only and no arrears whatever, and the ordinary shareholders of course would get nothing, but would have to look forward to something like 40 years before they could get anything unless the debentures were paid off with the arrears. If that were done the preference shareholders would begin to get some of their arrears. But still the ordinary shareholders could look forward to nothing. That was the position they were now in. Would they go on for 10 years and get nothing at all till that time, or would they now take 2 per cent. less than they would get then and begin to get a dividend now of £2. 10s. per share of arrears paid down? That was the position they were in. The Directors had no possible object in doing anything but making the Company a living concern; and it could not benefit them or anyone belonging to them to do anything other than endeavour to make the Company a live instead of a dead horse. Another shareholder at the last meeting, after the proceedings were over, made a suggestion which the Directors had not failed to consider. He saw that it was before them again that morning by the broker who had got the protesting 37 shares. The suggestion was, Why not, after the shareholders get, say 5 per cent., divide anything above that between the preference and the ordinary shareholders? That point had not escaped the Directors, but it had to be remembered that in all these 13 years the ordinary shareholders, who found the bulk of the capital for the Company, had received only 19s. 11d. per share dividend, and as for their getting above 5 per cent. in the time to come, that would all depend on what was going to happen in 10 years with the existing cable. If the existing cable remained intact, and they were going to have an improving revenue, then they might talk of dividing what might accrue above 5 per cent. between the preference and the ordinary shareholders. They did not, however, know what would happen to the cable in 10 years. They had allowed for the yearly £5,000 reserve, but there was nothing whatever for war risks or contingencies other than very ordinary contingencies for repairs, so that it might easily happen in 10 years that the preference shareholders even would not get 7 per cent., while of course the ordinary shareholders would get nothing. The Directors had no object whatever except to make the Company a paying concern, and there was no reason for anybody to say otherwise. Unless the Directors had the shareholders' support, it would be naturally very difficult to carry it through, and the law might say that they should not do so. That, however, would be proved. Mr. Bannatyne might get his object in opposing them, whatever that object might be, but if it was to get more than the Directors' scheme offered, he thought the chances of that were very remote. He concluded by moving the following resolution:—"That the two resolutions passed as special resolutions at the extraordinary general meeting of the Company held on the 30th September last be, and the same are hereby, confirmed."

Mr. ETLINGER seconded the motion.

Mr. COCHRAN said that the statement of the Chairman was not sufficiently clear to satisfy him. He had understood, before coming to that meeting, that the Chairman was going to make a statement which would convince all reasonable men that the proposal made by Mr. Baker at the last meeting would not work, and that the preference shareholders would not get their 10 per cent. He wished that the Chairman would state the premises on which he had arrived at that conclusion.

The CHAIRMAN, in reply, said that Mr. Baker's objection to the Board's scheme was based on the proposition that it would be more advantageous to the preference shareholders to wait ten years and then receive £10 per share for arrears of interest and 10 per cent. dividend afterwards, rather than accept the Board's scheme of £2. 10s. per share for arrears of interest at the end of this year, and 10 per cent. dividend from that date upon the reduced capital. This proposition, however, assumed the position of affairs to be quite different from the actual position, which was as follows:—At the end of ten years the lost capital would be recouped, and that money would remain in hand as an asset representing the abandoned cable; but there would be no funds wherewith to pay any arrears whatever of preference dividend, and when the payment of the preference dividend was resumed after the ten years it would be at the rate of about 7 per cent., and not 10, unless the income of the Company were materially to improve. Assuming the accuracy of the financial statement already made of an average net revenue of £12,750 a year, there would be reserve for renewal of cables of £5,000, and interest to pay on debentures amounting to £3,720. That would leave £4,030. It therefore followed that the present preference capital of £60,000 could only receive a bare 7 per cent. dividend. The question arose as to the use to be made of the £60,000 accumulated at the end of ten years. If a new cable were laid it would be necessary to make provision for its maintenance, say, £2,000 put to the reserve. That would reduce the £4,030 and leave for the preference shareholders only £2,030, or about 3½ per cent. dividend. If it should be found possible to do without a new cable, then the £60,000 could probably be best employed in redeeming the Company's debentures (which paid for the existing new cable of 1884). Interest to the extent of £3,600 would be saved, which, added to the £4,030, would leave £7,630 for the preference shareholders, or sufficient to pay them the 10 per cent. dividend and £1,630 towards arrears of interest. That assumed that they laid no other cable, that the cable in existence now remained intact, and required no outlay of the capital now lying by—assumed, in fact, what was improbable, and what no one knowing anything of such a matter would conceive. The total arrears in the year, say, 1898, would be £75,000 (arrears to pay off) and it would take forty-six years before all the arrears would be paid. It was, therefore, only in the year 1944 that all the arrears would be paid, and not in 1898, as Mr. Baker suggested. With these facts before them it was for the shareholders to decide whether they would support the Directors in their endeavour to restore the Company to the position of a dividend-paying concern, or allow it to drag on in its present non-dividend-paying state.

Mr. BANNATYNE said that notwithstanding all that the Chairman had stated, his (the speaker's) conviction was, if anything, stronger than ever that as regards the preference shareholders the scheme proposed by the Directors was illegal, unfair, and unjust. He intended, however, as far as that meeting was concerned, merely to vote against the confirmation of the resolution. Sir James Anderson had made an allusion as to what his (the speaker's) object might be. It was simply to prevent a great injustice being done to the preference shareholders. He differed altogether from the Chairman's statement that there was no other way of improving the position of the Company. Why did not the Board have a conference with both the leading preference and ordinary shareholders?

The CHAIRMAN: Have you any plan?

Mr. BANNATYNE: Yes.

The CHAIRMAN: Will you favour us with it?

Mr. BANNATYNE said that he was not bound to do so. Let the resolutions be withdrawn first, and then let the shareholders be called together to consider the best plan.

The CHAIRMAN said that Mr. Bannatyne had talked about legality and justice; but where was the justice or the legality of Mr. Bannatyne in forming another company when he was chairman of that Company? And where was his sense of justice in speaking in the tone he had of the Directors' plan? Mr. Bannatyne had some other object.

Mr. BANNATYNE repeated that he had not.

Mr. LOWE: It is to smash up the company, as I said at the last meeting.

The CHAIRMAN, continuing, said that it was for the Court to decide whether what the Board proposed was illegal. It was open to Mr. Bannatyne, while Chairman, to propose any plan for making the company a going concern; but he had not done so. In answer to a shareholder, the Chairman added that the concessions held by the Company did not give them a monopoly. The proxies were not sent out at the expense of the Company.

The SHAREHOLDER, who said he was trustee for a widow lady, afterwards proceeded to express objection to the Directors' proposal, contending that it was unfair to cut down the preference and ordinary shares alike, and that greater consideration should be shown to the preference shareholders.

Mr. COCHRAN said he felt bound to vote against the resolution, as the statement of the Chairman did not appear to him as at all conclusive. If they approved of the scheme proposed it seemed to him that they would be open then to the same difficulties as had been referred to, for the risks and all the other accidents to which the cable was exposed would equally affect them and would equally cut away the revenue from which their dividend had to be paid. He thought in any case that the shareholders would have acted more in their own interests if they had adopted the suggestion made at the last meeting to adjourn that meeting with the view to holding a conference. He did not want to attack the Board, but Sir James Anderson was a Director of the Eastern and of the Globe Companies, both of which were largely interested in the shares of the Direct Spanish Company. If the business went on in the ordinary way the ordinary shareholders would, he contended, get nothing; but by the altered circumstances proposed they would participate largely in the revenue. Moreover, it was the ordinary shareholders' money that was lost, the preference capital having been raised to buy the cable which was now working and earning money.

The CHAIRMAN observed that he had answered that point at the last meeting, and Mr. Cochran was not stating the matter properly.

Mr. COCHRAN said he had seen the resolution for raising the preference capital, and it asked for powers to buy the cable in question (which cost £45,000), and for other purposes.

The CHAIRMAN: For other purposes.

Mr. COCHRAN maintained that the principal object was to buy the cable.

The CHAIRMAN, in reply, said that Mr. Cochran seemed to forget that

Digitized by Google

the preferred and the ordinary shareholders were partners in a business which had lost so much of its capital. That was the basis the Directors were going on; and as he understood the law, there must be a *pro rata* suffering on the part of the proprietors in wiping off the lost capital, or in doing something to reinstate it. Mr. Cochran had repealed his attack because he (the Chairman) was a Director of the Eastern and the Globe Companies, but the former had all ordinary and the latter all preference shares. He was an anxious Director of both those companies, as he was of this Company, which he desired to be made a living concern. That was the sole desire of the Directors, and if the shareholders did not let them carry it out they must remain as they were, unless some other acceptable proposal could be made.

The motion was then put, and carried by 14 against 5.

The CHAIRMAN, in answer to Mr. Burt, said that the Directors would gladly receive and consider Mr. Bannatyne's plan.

Mr. BURT said it was very easy to find fault with other people's plans, but difficult to suggest others. If Mr. Bannatyne at the eleventh hour would put before the Directors a scheme which he considered more just and legal, the Directors would give their careful consideration to it, and, if necessary, invite the shareholders' acceptance of it. It was not too late yet, because the Directors' scheme was not carried. He did not think the shareholders would attach too much importance to what was complained of in one scheme if no suggestion for improving it were made.

Mr. BANNATYNE said that the the first intimation he had of the Directors' plan was three days before the meeting, on his return to town.

The CHAIRMAN: It is a fortnight since then.

A SHAREHOLDER: Three weeks.

Mr. BANNATYNE: Call it three. Continuing, he said he was not bound to consider another scheme in opposition to that of the Directors, but he was perfectly willing to do so with any of the shareholders or Directors. He could not be expected to bring forward a plan without sufficient time to consider the matter and prepare a plan, because it was of great difficulty, as he was quite aware.

The CHAIRMAN: You were here for 11 or 12 years. Mr. Baker gave us a plan in five minutes. If you have any plan for consideration we will pause and call another meeting after this; but we have our legal adviser who says within what lines we must go, and we have Articles of Association, and everything has been taken into consideration. If there is nothing but vague talk there is no use trying to argue it.

Mr. COCHRAN said he wished to propose a vote of thanks to the Chairman and Directors. He had criticised them, but he was satisfied that they were in a very difficult position. He thought it would not be in good taste on the part of Mr. Bannatyne, unless he had something substantial to propose, to land the Company and the unfortunate shareholders in law costs. He would therefore take the liberty of suggesting to Mr. Bannatyne, unless he had something to propose that could be carried out legally, that it would be wise to pause.

The resolution was seconded and carried.

On the motion of Mr. COCHRAN, seconded by Mr. WALTER PUCKLE, a resolution was passed unanimously "That unless a tangible and practical scheme can be formulated in substitution of that of the Directors, the shareholders deprecate an appeal to law, as being expensive and useless."

The proceedings then terminated.

Eastern Extension Australasia and China Telegraph Company.

Report and accounts of the Directors for the half year ended 30th June last, to be submitted to the shareholders at the twenty-sixth ordinary general meeting, to be held on the 27th October, at Winchester House, 50, Old Broad-street, E.C., at 2 o'clock.

The gross receipts, inclusive of Government subsidies, have amounted during that period to £224,843. 0s. 1d., against £259,476. 9s. for the corresponding half year of 1885. The working and other expenses, including £31,361. 5s. 9d. for cost of repairs to cables and expenses of ships, absorb £81,775. 7s. 1d., against £74,418. 6s. 9d. for the corresponding half year of 1885, leaving a balance of £143.067. 13s. From this is deducted £3,992. 7s. 7d, for income-tax, and £41,595 for interest on debentures and contributions to sinking funds, leaving £97,480. 5s. 8d. as the net profit for the half year, against £140,358. 6s. 11d. for the corresponding period of 1885. One quarterly interim dividend of 1¼ per cent., amounting to £31, 250, has been paid during the half year, and another of like amount will be distributed on the 15th instant. In consequence of the diminution of revenue, which is attributable to the causes referred to at the last general meeting, and which unfortunately still prevail, your Directors do not feel justified in paying a bonus for the past half year, and have therefore decided to carry forward the balance of £34,980. 5s. 8d. to the next account. In accordance with the provisions of the trust deed, dated 10th May, 1879, 251 Five per Cent. Australian Government Subsidy Debentures were drawn on the the 12th April last, for payment at par on the 1st July. The numbers of the drawn debentures are given in the Directors' report. The renewal of the Penang-Singapore (original) cable, referred to in the last report, was successfully completed on the 5th June last, and a considerable portion of the old line has been recovered. The cost of the operation will be dealt with in the accounts for the current half year. There have been numerous repairs to the Company's cables during the past half year, but no serious interruptions occurred during that period. Unfortunately, since the close of the half year, both the Madras-Penang and Rangoon-Penang cables have been simultaneously broken, which totally interrupted the communication between India and this Company's system for 13 days, and resulted in considerable loss of traffic. Notwithstanding the prevalence of the South West monsoon, the Company's maintenance steamers have been successful in repairing both sections. All the Company's cables are now in good working order. The land line between Port Darwin and Adelaide, belonging to the South Australian Government, has, as usual, been well maintained during the half year under review.

NOTES.

TELEGRAPH CABLE REPAIRED.—The Post Office announces that telegraphic communication with the Scilly Islands is now restored.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 22nd inst. amounted to £3,616.

CABLE TO MADAGASCAR.—The Portuguese Government has authorised the French cable to Madagascar being landed at Mozambique, which will therefore be one of the stations of the new line.

MUIRHEAD'S NEW FORM OF STANDARDS OF E.M.F.—Dr. Muirhead informs us that his new standard cells can be obtained from Messrs. Muirhead and Co., Cowley-street, Westminster, S.W.

ENFIELD.—During the coming winter it is intended to run the Enfield Small Arms Factory all night, by aid of the electric light. The plant for this purpose was purchased some months ago, but it has not as yet been erected.

EASTERN TELEGRAPH COMPANY.—This company announce the payment by interest warrants on 1st November next, of interest for the half year ending 31st October, 1886, on their Four per Cent. Mortgage Debenture Stock.

SICILY.—The electric light is making some progress in Sicily. A distillery at Messina was lately supplied with an Edison plant, and the success of this installation appears to have stimulated quite an active inquiry in the district.

CONTINUOUS CURRENT TRANSFORMERS.—We have received from Messrs. Paris and Scott, of Norwich, a circular containing an account of their combined motor and dynamo for effecting the conversion of high tension into low tension currents.

STREET LIGHTING AT DOMFRONT.—The streets of Domfront are now illuminated by 52 Edison incandescent lamps of 16 candle-power. The dynamo is driven from a turbine on the River Varenne, at a distance of 1,500 metres from the village.

SHIP LIGHTING.—The "Prince of Wales," the latest addition to the London and North-Western Company's fleet, made her trial trip on the 26th inst. The vessel has been fitted throughout with electric light by Messrs. King, Brown and Co., of Leith.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended October 22nd were £2,975, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE CROMPTON POCKET-BOOK.—We have received from Messrs. Crompton and Co. a copy of their "Price List and Useful Formulæ," which contains a large amount of valuable information for the practical electrician in a concise and readily available form.

RAPID PASSAGE OF THE SUEZ CANAL.—The ss. "Salazie," belonging to the Messageries Maritimes Company, by the aid of her electric lights, has just made the passage of the Suez Canal in sixteen hours, this being the shortest time on record. She passed twenty-two stationary vessels *en route*.

THE ACCIDENT AT THE PARIS GRAND HOTEL.—This accident, to which we referred last week on the basis of a somewhat incoherent account from the correspondent of a daily journal, turns out to have been a boiler explosion, and therefore has no real connection with the electric light.

THE DIRECT SPANISH.—The case of Bannatyne *v.* The Direct Spanish Telegraph Company, concerning the question which has recently been put before the company for a reduction of capital, as reported in our issues of October 1 and 22, is to be heard to-day (Friday), before Vice-Chancellor Bacon.

ITALY.—A project has been set on foot in the columns of our Milanese contemporary, *L'Elettricità*, for the establishment of an Italian Society of Electricians. It is contemplated also to provide a library, a technical school, and a public laboratory. We hope that the scheme will meet with the success which it deserves.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—This company notify that the coupon on their Five per Cent. Manilla Debentures (1880 issue), due on November 1st proximo, will be payable on and after that date on presentation at the Consolidated Bank, Threadneedle-street, E.C.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At a meeting of the directors of this company, held on Wednesday last, it was decided to place £7,000 to reserve, and to recommend a dividend of 8s. per share on account of arrears of dividend on the First Preference shares to the shareholders at the approaching meeting.

PERSONAL.—Mr. H. Kingsford, late electrician on board the steamship "Mackay-Bennett," and who a short time since accepted the position of engineer and electrician of the Central and South American Cable Company's system, has been very successful in repairing two of that company's cables, one repair having been effected in thirty-six hours.

HONOURS TO AN ELECTRICIAN.—The Senate of the Royal University of Ireland has bestowed their highest scientific degree of Doctor of Science upon Prof. John Perry, F.R.S. Prof. Perry is an old graduate of the Dublin University, and this recognition of his undoubted claims to high scientific distinction is as creditable to the magnates of the Senate House as it must be gratifying to the Professor himself.

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY. This company notify that the twenty-third distribution on the certificates issued under the trust deed of March 12, 1875, will be made on and after November 1, 1886. The distribution which arises from dividends on the shares held by the trustees will be at the rate of 9d. per £5 certificate, payable two clear days after presentation of Coupon No. 23 at Messrs. Barclay, Bevan, and Co.'s bank.

CABLE JOINTS.—In view of the importance of ensuring thoroughly good joints in electric light cables, Messrs. Walter T. Glover and Co., of Salford, have arranged to supply cables of various sizes jointed together before they are insulated, and in this way securing perfect joints, having equal quality of insulation with the rest of the cable, without bulkiness or possibility of leakage. Thus a cable is made of, say, $\frac{19}{10}$ths, $\frac{19}{14}$ths, $\frac{19}{18}$ths, all jointed in the core before being insulated.

FATAL ACCIDENT TO AN ELECTRICIAN.—The *Globe* states that a sad accident occurred on Saturday evening on the River Dart. While a party of London electricians were on board a steamer off Sharpham Point some of the men are stated to have commenced "skylarking." Alfred Tite, of Westminster, fell off the bow of the steamer, struck his head against the paddle wheels, and was drowned. The body was recovered. Tite leaves a widow and seven children.

NEW FRENCH ELECTRICAL COMPANY.—A new company, under what must surely be an old name resuscitated—La Compagnie Electrique—has just been floated in Paris, with a nominal capital of £60,000. The *Bulletin Internationale de l'Electricité* learns from a reliable source that the company will occupy itself chiefly with installations for the transmission of

Digitized by Google

power. It is even said that they will be prepared to place upon the market plant capable of realising results superior to those of M. Marcel Deprez.

THE GERMAN TELEGRAPHS.—It is stated that the German Telegraph Administration are making a trial of an autograph recording instrument, by which the handwriting or drawings may be transmitted in fac simile. We do not know whether any really new principle is involved in this apparatus, but if it follows the lines of any one of the ingenious instruments which have already been devised for autographic transmission, it will probably fail in practice, as these have always done hitherto, from want of sufficient rapidity of action.

EAGLES.—According to the *New York Herald*, an incident which recently occurred at New-Haven, Connecticut, tends to throw grave doubt upon the ancient belief that an eagle can look at the sun without winking. It seems that a very fine specimen of this noble bird was recently captured alive in the streets of New Haven, having damaged himself by a collision with an electric light tower. This certainly tends to show that the bird was dazzled by the light; but possibly he suffered from myopia, or will the citizens claim that the incident merely proves that their tower lights exceed the sun in brilliancy?

FINSBURY TECHNICAL COLLEGE.—The last of the course of free popular Saturday evening lectures at Finsbury Technical College, Leonard-street, City-road, was given by Prof. Silvanus P. Thompson, D.Sc., on "Magnets and Electro-magnets." The chair was taken by the Lord Mayor, who was supported by Sir P. Magnus, Alderman S. Knill, Mr. E.C. Robins, Mr. Beck, M.A., Mr. J. Bigwood, Mr. Jennings (Master of the Drapers' Company), and others. The lecture was naturally of a non-technical character, and was illustrated with numerous experiments, which were followed with great interest by the audience.

CHINESE TELEGRAPH LINES.—The *Globe* recently contained the following paragraph:—"The Chinese Government have contracted with Messrs. Telge and Co. for the construction of a telegraph line from Tai-nan to Tai-pei. Messrs. Jardine, Matheson and Co. have obtained a contract for laying a cable from Amoy to Hoo-mee (Formosa), the cost of which is estimated at $210,000. It is expected that both of these lines will be completed before the end of this year." We have reason to believe that these contracts have received the sanction of the Governor of Formosa, but have yet to be confirmed by the Imperial authorities at Pekin.

INDIA.—The *Indian Engineer* of October 2nd commences a series of articles under the title of "Electric Light for India." The first paper is very well written and aims at enforcing the special advantages of the electric light in tropical climates, and endeavours to disabuse the Anglo-Indian mind of the prevalent idea that electric lighting has still to emerge from the experimental stage. The various details of an installation are then briefly described, the apparatus of Messrs. Siemens Brothers being more particularly referred to. We hope that this series of articles will answer their intended purpose, and give a decided impetus to electric lighting in our Indian Empire.

"HEAT INDICATING PAINT."—*L'Ingenieur Electricien* is perfectly correct in stating that it is no new discovery that the salt consisting of the double iodide of mercury and copper changes colour upon heating, and our contemporary may or may not be right in assuming that a "heat-indicating" paint recently brought out by Mr. Henry Crookes, of Westminster, is composed of this particular substance; but the journal in question is certainly wrong (and this is why we refer to the matter) in confounding the inventor of this paint with Mr. William Crookes, F.R.S, the discoverer of "radiant matter," of the metal thallium, and the indefatigable worker at chemical "fractionations."

COCOA PALMS AS LIGHTNING CONDUCTORS.—In a recent article the *Ceylon Observer* refers to the power of the cocoa nut palm to conduct lightning. Sir Emerson Tennent long ago pointed out that this tree acts as a conductor in protecting houses from lightning, and in one instance 500 palms were struck in a single plantation during a succession of thunder storms, in April, 1859. But the trees themselves suffer terribly in the process, for however slightly they may be touched by the electric fluid, they die. Sometimes only the edges of the branches are singed, at others a few leaves turned brown alone show where the tree was touched; yet, however slightly the apparent effect, in course of time the tree withers gradually and dies.

THE "VOLTA."—On Saturday last at the instance of Major-General Fred. Brine, a further trial of the capabilities of the electric launch, the "Volta," was made on the lower reaches of the Thames, in the presence of General Lord Chelmsford and other officers of both branches of the service. Those present included General Pritchard, General Sir R. Pollock, General Sir H. de Bathe, Admiral Sir Erasmus Ommaney, Admiral Curme, Captain Palliser, and Captain Murphy. The trip was from Westminster Bridge to Greenwich Hospital, where the party were entertained by Admiral Brandeth. A start was made at sixteen minutes to two, and the hospital was reached within eight minutes of the hour, a speed averaging something over six miles and a half per hour.

THE PARIS EXHIBITION OF 1889.—The *Journal Officiel* contains the following list of names of those who will form the committee of electro-technics for the International Exhibition of 1889:—MM. Ed. Becquerel, Alf. Cornu, Marcel Deprez, Maurice Lévy, Lippmann, Maurice Lœwy, Mascart, le Colonel Perrier, membres de l'Institut; Armengaud, membre du Conseil Municipal de Paris; Baille, Bartet, Bergon, Blavier, Caël, Carpentier, Chatard, Fontaine, Fribourg, Hospitalier, Huet, Joubert, Jousselin, Lemonnier, Ménier, Mercadier, de Méritens, Napoli, Gaston Planté, Postal-Viney, Potier, Raynaud, Richard, Ed. de Rothschild, Sartiaux, Sciama, le Colonel Sebert, Violle, Vivarez. The appointment of secretary to the committee has not yet been made.

A BIG MOTOR.—For some time past the technical press has contained more or less authentic paragraphs as to the construction at the Rhode Island Locomotive Works of an electric motor intended to develop no less than 670 horse-power. As these statements have recently become more circumstantial we give them for what they may be worth. The machine, which is said to be now actually completed, has been built from the designs of Messrs. E. M. Bentley and W. G. Knight. It is intended for use upon the proposed underground railway at New York. The engine runs upon six wheels of 68in. diameter, and is provided with electric head-lights, bells, and vacuum breaks, worked automatically by electricity. Every carriage in the train will also be fitted with an electric brake, and will be lighted throughout by incandescent lamps.

EQUIVALENCE OF CHEMICAL ENERGY AND CURRENT ENERGY.—H. Jahn, in the *Ann. Phys. Chem.*, gives an account of some experiments in which he proves Helmholtz's relation between the secondary heat of a galvanic element and its temperature coefficient. The elements examined were silver in silver nitrate, with lead in lead nitrate, and copper in copper nitrate respectively. The solutions had a strength of $(M')_2(NO_3)_2 + 100H_2O$. The chemical heat of the cell is obtained from the formula $Q = W - aJ(\Delta Jg)t$, where W is the

Digitized by Google

heat evolved in cell, a the heat equivalent of unit of work, J the current intensity in amperes, $\Delta - Jg$ the potential difference of poles, and t the duration of the experiment. The values obtained from this formula agree closely with those obtained from thermo-chemical data. The chemical heat less the current heat gives the secondary heat, which is compared with that obtained by calculation from Helmholtz's relation. The following are the results :—

Element.		E. M.F.	Chemical heat.	Current heat.	Secondary heat.	
					found.	calc.
$Ag_2, Ag_2(NO_3)_2$	$Pb(NO_3)_2, Pb$	0·932	50·87	42·98	7·95	7·89
$Ag_2, Ag_2(NO_3)_2$	$Cu(NO_3)_2, Cu$	0·458	30·04	21·12	8·92	8·92

ENGINE TRIAL.—One of the most satisfactory engine trials ever carried out took place on Wednesday last at the Colonial and Indian Exhibition. Messrs. Davey, Paxman and Co. placed at the disposal of Mr. W. E. Rich, C.E. (late partner with Messrs. Easton and Anderson, of Erith, Kent, who have carried out so successfully the trials of engines for the Royal Agricultural Society of England), and Prof. A. B. W. Kennedy, University College, Gower-street, W.C., for carrying out a perfectly fair and impartial trial of one of their engines and boilers at the above Exhibition in order that it might be known to consumers what duty would be performed, and the amount of coal and water used by an engine and boiler after having been in work for three years. The engine in question is of the semi-fixed compound type, having cylinders 12¼in. and 20in. diameter respectively, by 24in. stroke. The result of 5 hours and 42 minutes' trial was exceptionally good, and Messrs. Davey, Paxman and Co. are to be congratulated upon the figures which were obtained. As the trial took place too late to allow us to have illustrations made for this week's issue, we refrain from discussing the figures, but have merely given the event as a matter of history.

A NEW COULOMB-METER.—M. Jacquemier has devised a coulomb-meter based upon the following principles :—An ampere-meter, which may be of any known construction so long as the deflections are proportionate throughout the scale, is connected with a train of clock-work. A wheel which makes one turn per minute carries a detent. At every revolution the latter closes with a second train of wheels, by means of which the index is moved upon the scale where the coulombs are read. The moment when the two trains gear together is that at which the detent upon the first wheel is passing zero point upon the scale of the ampere-meter; the disengagement, upon the other hand, is effected when the detent arrives at the needle of the ampere-meter, wherever it may be upon the scale. Thus the distance traversed by the needle of the coulomb-meter at every revolution—that is, once every minute—is proportionate to the current indicated by the needle of the ampere-meter. If the ampere-meter is not constructed to give proportionate deviations, M. Jacquemier employs a suitable can, mounted upon the same axle, to carry the detent. From this description it will be seen that the method is not accurate when the current strength undergoes any rapid fluctuations.

A BARBER'S VIEWS ON ELECTRIC LIGHTING.—A New York barber has recently expressed the opinion that when the electric light becomes universal, baldness will be comparatively unknown. Middle aged gentlemen who find their hair getting "thin at the top," will do well to ponder the observations of this authority. He says :—"You will notice that there are no classes of men more frequently bald than retail salesmen, bookkeepers, and office clerks in certain lines of business. Why should baldness affect them more than others? Because they habitually stand or sit nearly every evening under gas-lights. The artificial heat dries out the hair, makes it brittle and unhealthy, and finally kills it at the root. If you will pass your hand through your hair after you have been standing under a gas-light for a few moments you will see at once how it is. Although you may not have noticed the heat on your head, your hair, if you've got any, will be hot to the roots. You'll be surprised to observe, too, at what a distance from the light the hair will absorb the heat, and there is nothing so bad for the hair as getting it dry. I have an idea, too, that after the electric light has been in universal use for a generation or two, baldness will be as scarce as it was before gas-lights and nightwork got common together."

AMERICAN VIEWS ON ENGLISH ELECTRICIANS.—We quoted last week a somewhat unflattering opinion upon the electricians of this country which had been expressed by an American professor. We have therefore additional pleasure in quoting the following paragraph from a New York contemporary journal :—"There are many signs that the revival of electric lighting in England has begun, in spite of the tremendous obstacles that are placed in the way of those who desire to engage in the business. The fact that the industry is as a whole in good shape to-day bears no small testimony to the bulldog tenacity and genuine 'grit' of our British cousins. The men who have held on through the days of trial deserve our sympathy and praise, and it is only to be hoped that new and reasonable legislation will soon be given them as aid and stimulus in the arduous work still before them. The fact is, English electricians and companies have done their best in the only fields that remained open to them, that of isolated arc and incandescent lighting in works or residences, and that of special lighting on ship board. If now the unfair legislation against electric light enterprises of the larger kind is removed, or even if the English gas companies undergo conversion, as the American gas companies are doing, we shall see central stations in every part of the country."

GALVANIC POLARISATION.—From the abstracts of papers in the *Journal* of the Chemical Society we take the following :—Determinations have recently been made by Herr H. Jahn of the electromotive force of polarisation of solutions of various salts. The apparatus used consisted of a tuning-fork contact breaker, by which the solutions were alternately polarised by a battery of three Bunsens, and circuited through a tangent galvanometer, the latter being compared with a Clark's cell. The polarisation cell was placed in melting ice. The values obtained were compared with the E.M.F's produced by elements formed of different pairs of the salts experimented with, thus : $p_{ZnSO_4} - p_{CuSO_4} = E$; the results compared very favourably. From these values, the secondary heat evolution, as distinct from that due to resistance, is determined from the equation $W_s = aJpt - Q$, where W_s = secondary heat, a = heat equivalent of unit of work, J = strength of current, p = polarisation E.M.F., and Q = heat of combination. The results agree closely with those obtained by Favre by direct experiment. It is remarkable that they are all multiples of the same number; thus copper, zinc, and cadmium salts = 2 × 10 cal.; lead salts = 3 × 10 cal.; silver salts and sulphuric acid = 4 × 10 cal. Lastly, the polarisation E.M.F.'s of the same salts for a temperature of 34° were determined. For zinc or copper salts, the polarisation E.M.F.'s are in much the same relation as at 0°, hence the E.M.F. of a Daniell element must, in accordance with Helmholtz's laws, be independent of temperature.—*Ann. Phys. Chem.*

ELECTRIC LIGHT AT ANVERS.—At Anvers, Belgium, there are several large factory buildings which are let out in separate shops to the working lapidaries, who form such an extensive colony in this district. Both light and motive power are

Digitized by Google

usually included in the rent of the shops, but as a rule the lapidaries very seldom work by artificial light, even in the shortest days of winter, as the men have a strong (and reasonable) prejudice to working in an atmosphere heated and contaminated by gas. This statement represents a fact which can readily be verified by inquiry on the spot. A notable opportunity is here afforded for the introduction of electric light. The first extensive installation of this character in Anvers has just been completed, and we have received a very detailed account of the arrangements, which will probably be of interest to many of our readers. This installation, which has been put in on behalf of M. Leytens, consists of 100 Victoria incandescent lamps of 16 candles; the dynamo is of the Gulcher type, but has undergone modification at the hands of M. Dufait, engineer, at Charleroi. The machine gives 125 amperes at 70 volts, and runs at 500 turns a minute. Hedges' fusible cut-outs are provided upon one of the mains, and a magnetic cut-out constructed by M. Dratz upon the other. A "De Hummel" voltmeter is connected with the terminals of the machine. All the conductors are placed in wooden grooves, which are provided with covers. The lamps are suspended from the ceilings, and provided with shades and reflectors to concentrate the light upon the working benches. The workmen themselves express entire satisfaction with the light, and in other factories they are already agitating for its introduction.

THE BRUSSELS EXHIBITION OF TELEPHONY.—We have already informed our readers that in the early weeks of 1887 it is intended to hold in Brussels an International Exhibition of Telephony upon an extensive scale. The arrangements in connection with the undertaking are being carried out by the Société Belge des Ingenieurs et des Industries, with whom the Belgian Society of Electricians has recently been amalgamated. We have received from the secretary of the society a letter requesting us to make known the objects of the Exhibition, which are set forth in an enclosed circular as follows:—"This Exhibition is intended to display all the apparatus and processes hitherto devised for the transmission of the human voice to a distance, and the application of these methods down to the latest date. Its character will be both scientific and practical. The exhibits will therefore comprise telephones, microphones, radiophones, and phonographs; switch-boards and other appliances connected with telephone exchanges; 'toll' stations; conductors and insulators, and all 'outdoor' appliances. Further, special consideration will be given to anti-inductive systems, to the use of cables containing large numbers of lines, to long-distance telephony and apparatus connected therewith, and to systems of simultaneous telegraphy and telephony. In addition to actual apparatus, plans, diagrams, or models will be received. A series of experiments and of competitive trials will be undertaken and conferences will be held. No charge will be made for space. Applications must be sent in before 1st December. The Exhibition will remain open for five weeks. Any one desiring to contribute to the discussions, or to make any suggestion with regard to the experimental work, is requested to communicate with M. H. Aerts, the president of the committee of conferences and exhibits."

THE ELECTRIC LIGHT IN MADRID.—The Madrid paper *El Dia* of the 24th inst. states that a meeting of the Madrid Mercantile Club was to be held on Monday last to consider the proposal for the installation of the electric light which was drawn up by the committee appointed for that purpose. The proposal in question limits the installation of the new light to an area embracing the most important thoroughfares of the city—viz., the whole of the Puerta del Sol, part of the Carrera de San Jeronimo, and the following streets: Carretas, Montera, Arenal Postas, and portions of Alealá, Cármen, Preciados, and Calle Mayor. It is estimated that in order to light the establishments in the district named, 16,300 sixteen candle-power lamps will be required. The cost of the installation is estimated at 500,000 pesetas, say £20,000, that sum to include machinery and electrical appliances. It is calculated that the annual cost of the light, including material, staff, offices, taxes, depreciation, &c., will amount to 170,827 pesetas, say £6,835. Subject to the due ratification of the project, it is proposed to incorporate an electric light company, with a capital of 500,000 pesetas, divided into 2,000 shares of 250 pesetas (£10) each. The committee estimate that the saving to those who use the light will be at the outset forty per cent. and considerably more after a few years. The cost of gas is placed at slightly over 5 centimes per burner per hour, while the cost of the proposed electric light will not be more than 3 centimes, and probably as low as two centimes after the first five years. As an illustration, it is affirmed that the cost of gas in an establishment with 12 lights burning five hours per day is 92 pesetas 60 centimes (say £3. 14s. 9d.) a month, whereas an equal number of electric lamps, burning the same length of time, will only cost 54 pesetas (say £2. 3s. 4d.), and will at the same time yield a better light.

THE LATEST ACCUMULATOR.—The "invention" of secondary batteries proceeds merrily. The very latest type of which we have been able to obtain information up to the hour of going to press is due to the labours of M. Montaud. The preparation of the plates is thus described:—"The electrodes are placed in a bath containing a saturated solution of an alkali, and which also contains an excess of litharge. The current being passed through the bath, one of the plates is peroxidised and the other becomes coated with spongy lead. The latter plate is afterwards submitted to strong mechanical pressure. The chemical action in the baths is very rapid." M. Montaud employs very thin plates having a large superficial area. The principal advantages which are claimed for this battery, and which we shall be very glad to find substantiated in practice, are the following:—(1) Rapidity of charge; (2) high efficiency; (3) output large in comparison with total weight. The authority from which we quote makes a fourth claim on behalf of the cells, to the effect that the battery is of small weight in comparison with its total output. It may be that our logical faculty is small in comparison with the considerable output of mental effort which we have made to understand exactly what is here meant; but up to the present we have been unable to determine the precise distinction between claim (3) and claim (4). The capacity is given in terms of the "square metre of useful surface" as 50 ampere hours, and in terms of weight as 9·1 ampere hours per kilogramme of "useful" lead. The normal charging current per kilogramme of "useful" lead is two amperes, but this may be doubled without injury. The normal current of discharge in the same units is 4·5 amperes, and this quantity may be increased without inconvenience to 20 or 25 amperes. We can only again express our desire to find these figures realised in practice.

H.M.S. "LAWRENCE."—On Saturday last the official trial of the electric lighting installation on board H.M.S. "Lawrence," took place at Gilbrook Yard, Birkenhead. The "Lawrence" is a despatch boat, built by the firm of Messrs. Laird Brothers, of Birkenhead, for the Indian Government, and is luxuriously fitted up for the use of the Vicroy and suite. The installation consists of two Goolden-Trotter A dynamos, giving 8,800 watts each at 400 revolutions, coupled direct to a pair of Willans three-cylinder compound tandem engines.

Digitized by Google

There are 125 Edison-Swan 20 candle-power lamps at 80 volts, which are placed in "Trotter dioptric shades" throughout the ship. The fittings are of the Admiralty pattern, except in the saloon and chief cabin, where they are of a more ornamental character, and are electro-plated. A yard-arm reflector is also provided, and fitted with eight 50 candle-power lamps for use when the vessel is coaling. The dynamos are placed in a room on deck, an arrangement which will allow of ample ventilation, presenting a favourable contrast in this respect to the usual position of dynamos on board ship. The entire work of the installation was carried out without dockyard assistance by the firm of Goolden and Trotter within five weeks from the commencement. At the trials on Saturday Mr. Jopp, the Director of Stores, was present on behalf of the India Office, Mr. Hudson being the inspecting officer in the unavoidable absence of Sir Edward J. Reed, M.P., K.C.B. Mr. John Laird and Mr. Henry Laird were also present. The dynamos ran extremely well, were perfectly cool, and quite sparkless at the commutators at some fifty revolutions under the contract speed. The lamps also were the subject of some remark, for, while giving a light of fully 20 candles at 80 volts, when the speed was reduced and the voltmeter indicated 50 volts, the light appeared to be nearly 15 candles, and the ship was still well lighted. At the close of the inspection Mr. Jopp tendered his thanks to the contractors, and Mr. R. A. Scott, their superintendent, and expressed his gratification at the manner in which the work had been done. Some of those present ventured to express the opinion that the "Lawrence" was better lighted than any other ship at present in Her Majesty's service. Messrs. Goolden and Trotter have also finished the installation of the troopship "Dalhousie," and we understand that the official trial takes place this week.

THE EFFICIENCY OF ARC LIGHTING.—Mr. John Wallace, C.E., contributes to the *Indian Engineer* an able paper upon "Petroleum," in the course of which he makes a comparative estimate of the amount of light obtainable by different methods from the incandescence of carbon. He refers to the arc light as follows:—The incandescence of carbon in the electric lamp is worth referring to, just to show what are the possibilities of lighting by means of highly-heated carbon particles. For the purposes of comparison, we shall refer only to the carbon used in an arc lamp, and to the power, reduced to heat units, required to produce the electric current, which renders it incandescent. And in the same manner we shall treat the carbon used in gas lighting, and the heat, in units, employed to render it incandescent. The steam power used to produce through a dynamo one-candle light for one hour in an arc lamp is equal to 907·2 foot pounds, or 1·17 unit. The carbon burnt in the atmosphere is equal to ·151 grain in weight, and converts to ·28 unit, making a total of 1·45 or nearly 1½ heat units. This is exactly the quantity of heat required to raise 1½ pounds of water 1° F. in temperature, and may be taken as the equivalent of one electric candle-light for one hour. The force required to produce one candle-light from coal gas, is that produced by the combustion of 62·5 grains of gas containing 45 grains of carbon and equal to 188 units. The ratio of the two totals of units is as 1 to 129, and the ratio of the consumption of carbon is 1 to 160, so it is evident that if the gas carbon could be burnt with the same economy as that in the arc lamp it would burn with a light of 160 candles instead of only one. Is this possible? Dividing the totals of units, in each case, by their respective weights of carbon, we find that each grain of carbon in the arc is acted on by a force equal to 9·6 units of heat, while each grain of carbon in the gas has only 4·17 units to heat it. In incandescent economy, therefore, gas can never compete with electricity, but, seeing the amount of waste that takes place in the gas burner, there must still be room for much improvement. The combustion of carbon in the arc lamp is effected at a much higher temperature than in the Argand gas burner, and this fact seems to be fully recognised in the Wenham burner, which uses the heat of its waste products to superheat the gas and air going to the flame. By this means the discrepancy between gas and electric lighting has been reduced from $\frac{1}{160}$ to $\frac{1}{100}$. The limit to the further improvement of the Wenham burner, and others of its class, will probably be determined by the heat resisting power of the material used in their construction.

THE JARMAN ELECTRICAL TRAM CAR.—On Monday last Mr. Jarman, of Brixton-road, exhibited a working model of a tramcar driven by primary batteries. The model, which was some 2ft. in length and with the batteries weighed nearly 1½cwt., was shown running very smoothly upon a circular line, which contained several curves of 6ft. radius. Mr. Jarman makes no claim for any improvements or for any special construction of either batteries, motor, or gearing. The primary batteries were only employed as a matter of convenience, any other method of furnishing the required current is equally within the province of this system. The motors may equally be of any known type, those shown were of Mr. Jarman's own construction, but being mere models, it is of course useless to criticise them. The gearing adopted consisted of an ordinary train of spur and mitre wheels having no special feature, but it is proposed to employ hornbeam teeth when working on a larger scale. By this time our readers are possibly at a loss to imagine what can be the points which are to be considered distinctive features in Mr. Jarman's electric tramcar. Not to keep them longer in suspense, we proceed at once, and in few words, to unfold the secret. Two distinct motors of identical construction are mounted side by side, with their armature shafts coupled in one line, and driving each on to the same toothed gearing, the arrangement being in this respect very similar to that adopted by Mr. Reckenzaun for his electrical boats. Mr. Jarman's object is, however, somewhat different. The brushes are connected to a reversing lever placed under the control of the driver, and it is arranged that when one pair of brushes is on the commutator the other is lifted, so that only one motor is in circuit at a time. It is further arranged that one motor drives the car in one direction, and the other in the opposite direction, so that, in the words of the inventor, "each armature has its time to cool down should it become heated." By this means Mr. Jarman overcomes the difficulties which may arise from the overheating of the machine, owing to too prolonged working. Our readers will form their own opinion as to the value of this device, but we may ask them to remember the fact that a tramcar is liable to very numerous stoppages. Whenever a fresh start is made the coils of the motor are necessarily subject for a short time to a current far greater than they can safely bear for any length of time, and this certainly tends to render the question of heating of even greater importance than ordinarily in the case of motors employed for this special purpose. At the same time it must be admitted that if we resort to a device of this character, we practically confess ourselves baffled in the search for a thoroughly satisfactory solution of this particular phase of the problem of the electrical transmission of energy; and our columns have of late borne testimony to the fact that there are still electricians, both in this country and abroad, who would not care as yet to confess themselves beaten in this matter.

THE IMMISCH ELECTROMOTOR.

(Continued from page 490.)

There still remain some points of interest to be noted in connection with the Immisch motor of 1885. If our readers will turn back to the diagram of the armature winding, Fig. 4, page 489, they will notice that the polarity of the Pacinotti teeth has in every case been indicated twice over. We will presently explain the reason for this. By increasing the size of the lettering in the diagram, as we travel away from the neutral points (*o*), an attempt has been made to indicate the relative strengths of the successive poles of the armature field. The lettering does not show the actual or resultant polarity of the teeth when the machine is in action, but it indicates the poles which tend to be formed by the current in the coils of the armature. The letters upon the teeth themselves indicate the poles for that position of the commutator which is shown in the figure, that is when coil A has just been cut out. The outside letters indicate the position of the poles in space when the armature has advanced through an angular distance of about 28°—that is, just under one-twelfth of a revolution. In this position coil A is about to enter the circuit, and coil B is upon the point of being cut out.

It follows from this that the position of the armature field in space is continually shifting to and fro over a space equal to rather less than one-twelfth of a revolution. It is true that the influence of the field-magnets tends, to a certain extent, to steady the *resultant* field, nevertheless fluctuations of this character cannot but have an injurious tendency. We have now completed our catalogue of the defects of the machine which carried off the silver medal last year, and we shall presently endeavour to enable our readers to judge for themselves how far they have been remedied in the type which has been finally adopted.

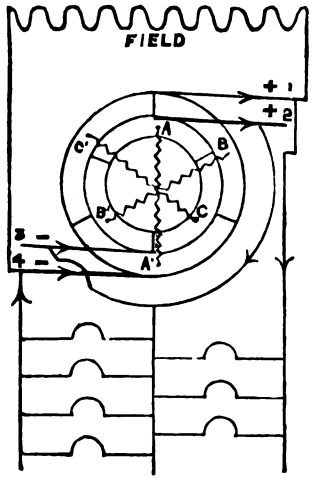

FIG. 5.—Dynamo working on Three-Wire System.

Before, however, we take leave of the results which were obtained in the year 1885, it must be mentioned that meanwhile Messrs. Immisch had been giving attention to the question of dynamo construction as well as that of motors, and had discovered a field for the application both of their bi-sected commutator, and also for the principle of cutting out of circuit that particular coil which tends most to distort the magnetic field; the result being that in the same year, 1885, they constructed a remarkable machine, which, although somewhat resembling the Brush and the Thomson-Houston types in the matter of commutation, has yet, we believe, a perfectly unique claim to distinction, inasmuch as its armature is capable of being run simultaneously upon both circuits of the Edison-Hopkinson three-wire system of distribution. This machine was at work for some five or six months at the Inventions Exhibition, and ran well and without sparking or other difficulty, and this whether the resistances of the two external circuits were or were not in balance.

After what has already been said the construction of the machine will be easily understood from the diagrammatic view in Fig. 5, which shows the connections of the entire circuit. The armature consisted of three coils only, of which one is always cut out by open circuiting—in the figure *c c'* is in this position. The commutator consists of two rings or sections, each with three segments, as already described.

The coils are joined across from a segment of one section to a segment upon the other section, and the two segments are so displaced with regard to one another that their centre lines are 180° distant. By altering the external coupling of the brushes the two coils might be run either in parallel or in series, but for use with the three-wire system the connection is necessarily in series. To join in parallel the + brushes 1 and 2 and the − brushes 3 and 4 would be connected together. To join in series 1 and 4 are left open, and become the terminals of the external pair of mains, and 2 and 3 are connected together, and are then joined in common to the third wire of the network. While we have thus two independent external circuits, the total work is equally distributed among the three coils. The field is shunt-wound, and can either be excited from the whole of the armature or at half the potential from either section. It is, however, clear that, except perhaps upon a very small scale, there are economical objections to the principle of cutting out one-third of the armature wire twice during each revolution (each time over an angular distance of 60°), and before the principle could receive any extensive application it would be necessary considerably to increase the number of coils upon the armature. Theoretically, it is possible to adapt this method to any winding in which the number of coils remains some multiple of three, only it would be necessary at the same time to increase the number of commutator rings. This implies an increase in the number of brushes and very complex connections, so that even with six coils the construction becomes difficult, and beyond that number would probably be found to be impracticable. It is, however, evident, from the performance of the dynamo shown at the Exhibition last year, that if any use can be found for small three-coil machines of this type, the construction is available.

Sufficient has now been said to show that while a substantial advantage is gained from the introduction of the principle of cutting a certain portion of the armature out of action at a certain angular position, yet when this is done by open circuiting a rather heavy price is paid for the privilege. But Messrs. Immisch now claim that in the latest type of their machines, both motors and dynamos, they have succeeded in retaining all the advantages while completely overcoming the objections to the principle, and at the same time both the output and the efficiency of the machines have reached a high figure.

The means by which these results have been attained are sufficiently simple—in conception at least. As already hinted, the coil is now cut out by short-circuiting instead of by open circuiting. The limits of our space will not permit us to enter at great length into a discussion of the reasons why this comparatively simple modification entails such beneficial results. To some extent it is a matter of constructive practicability. For instance, it is no longer necessary, as it was in the previous case, for the motor winding to be of such a character that at the same moment two coils at right angles are cut out of action—only one being actually necessary. An obvious gain results, both as to efficiency and as to output. Secondly, there is no longer such difficulty in increasing the number of coils, thus again reducing the proportionate quantity of wire placed out of action. Thirdly, owing to the re-arrangement of the armature field the brushes are now placed at right angles to the line joining the field poles, and the machine can thus be run in either direction by a simple reversal of the connections of either field or armature. This latter very important feature the Immisch motor shares, however, in common with the Reckenzaun, and some other less known types. Fourthly, and as a consequence of what has gone before, there is no longer any limit to the application of the principle to machines of any required dimensions, whether dynamos or motors. Dynamos of this description have already been constructed with outputs varying between 500 and 10,000 watts. The two 20,000 watt machines for charging accumulators in parallel, and to which we have already referred as being now under

Digitized by Google

construction, are also of this type. Motors giving a brake horse-power of ½ to 12 have been built with entire success. A large machine of this type is now almost complete; it is designed for an output of 40 horse-power, and with an anticipated efficiency of 94 per cent.

We have already given a perspective view of a six horse-power machine in Fig. 1, p. 488. The winding of the armature is diagrammatically shown in Fig. 6; for the sake of clearness only 8 coils are indicated, whereas 48, 96, or even 144 coils are employed in practice. The commutator is of the bisected type already described, and, as will be seen from the figure, the coils are joined to two adjacent segments of the commutator on the two rings, of which one has an angular advance equal to one-half the width of the commutator bar. The two brushes side by side upon the two rings are connected together, so that only one pair is shown in the figure. Tracing the connections in the figure, if we start from one ring of the commutator under the brush, say with the coil marked 1, we cross to the other side of the armature, and thence join the connection leading to coil 6; but if we follow this line backwards to the commutator we arrive at a segment under the same brush from which we started. Similarly coil 5 connects with coil 2, and is

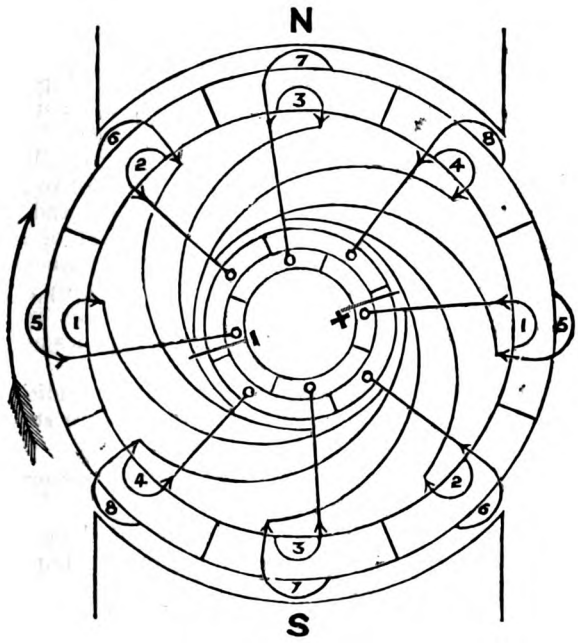

Fig. 6.

short-circuited in the same way by the other brush. It will be observed that the magnetic axis of the armature itself would be situated underneath the coils which are short-circuited. The remaining connections require little comment, the two halves of the circuit can be traced through coils 6, 3, and 4 in series upon the one side, and coils 8, 7, 2 in series upon the other.

It is, however, apparent that, after all, this is only tantamount to the use of an armature of normal type, together with a brush, having a very wide face, so that its period of contact with two adjacent segments of the commutator is abnormally prolonged. It was therefore fully anticipated when the first experiments were made that much trouble might arise from the heating of the coils during the period of short-circuiting, which occurs twice in every revolution. In practice, however, no such effect was ever found to occur so long as the field poles were properly proportioned, and in the case of a motor the brushes may even be shifted some distance to either side of their normal position without producing either sparking or any perceptible increase of heating. But, somewhat singularly, this remark does not apply in the case of a dynamo of similar construction, and the position of the brushes has to be adjusted with some care. So long as this is attended to the machine runs with perfect smoothness; but directly the brushes are displaced, although little or no sparking takes place, yet a considerable and rapid heating of the coils ensues. This feature has, however, little practical importance, for when the position of the brushes has once been determined they can be rigidly fixed, and the dynamo requires no further adjustment whether running on open circuit or with full load. It is hardly necessary to say that the non-heating of the coil proves that during this part of the revolution the algebraical sum of the number of lines of force passing through it is constant. Hence Mr. Albion T. Snell (the electrician to the Immisch Company) explains the discrepancy between the action of dynamos and motors in this respect upon the supposition that the angular distance upon the armature core over which no lines of force either enter or leave the iron is greater in the case of a motor than in that of a dynamo of similar construction. Should this prove to be the case, it tends somewhat to upset previous ideas as to the relative shape of the resultant field in motors and in dynamos, in which the reverse condition has hitherto been supposed to hold; that is to say, the field of a dynamo has been supposed to concentrate within the core of the armature more quickly than that of a motor, whereas these results may find an explanation upon the opposite assumption. It may, however, prove that the experimental results are peculiar to this special construction, and depend upon the fact of the inaction of a portion of the armature. The point is worthy of further study, as it promises to throw some light upon the outstanding questions as to the difference of the reaction in the fields of motors and of dynamos.

Returning to practical matters, Messrs. Immisch are further about to introduce another special feature of great interest, but as the foreign patents are not yet completed we are not at liberty at present to describe the arrangements. It may, however, be stated that the results obtained will enable a single series wound motor under constant E.M.F. to run at nine different speeds under constant load, or to take nine different loads at constant speed, and this by the movement of a single switch, without the introduction of wasteful resistances, and without overstraining the machine. The arrangement was primarily intended for tramcar work, either in connection with accumulators or with dynamos.

The following table gives the result of some tests of the motor to which we have already alluded as being employed for driving machinery at the Immisch Works.

Table I.

Test of an Immisch Motor, weighing 350lb. Resistance, ·55 ohm.

Speed.	Volts.	Amp.	H.P.	E.H.P.	Efficiency.
920	130	31·25	4 42	5·45	·81
980	134	31·5	4·7	5·68	·83
1080	147	31·0	5·2	6·1	·85
1080	147·5	31·5	5·2	6·2	·835
960	137	31·0	4·6	5·7	·805
999	131	31·5	4·8	5·55	·865
1080	148	31·	5·2	6·15	·845
1090	152	31·5	5·25	6·4	·82

These tests were carried out with a Prony brake, having an arm 2ft. $1\frac{7}{32}$in. in length. The weight on the brake being in every case 12lbs. The resistance of the machine being ·55 ohm, the volts lost in the coils will be $·55 \times 31·5 = 17·3$ volts. If, therefore, there were no losses from Foucault currents, mechanical and magnetic friction, &c., the maximum theoretical efficiency would have been

$$\frac{150 - 17·3}{150} = \frac{132·7}{150} = 0·885.$$

The remarkably close accord between this maximum theoretical value and the values actually obtained is a sufficient proof of the general excellence of the design of these machines, and also shows how little is lost by the short-circuiting device.

The following table gives details referring to the several types which have been selected as standards, but we believe that the company undertake to build machines to satisfy any given practical conditions.

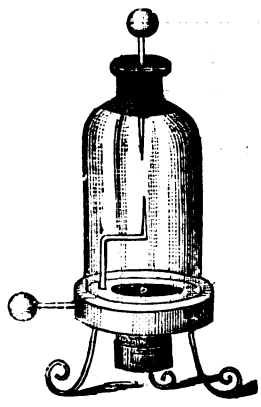
1,600	1·4	3·5					
1,400	1·2	3·0	8·0				
1,200	1·0	2·5	6·8	12·5			
1,000		2·2	5·7	11·25	20		
900		2·0	5·0	10·0	18	27	
800			4·5	9·0	16	24	37
700			4·0	8·0	14	21	32
600				6·8	12	18	27
500				4·5	10	15	22
400					8	12	17
300					6	9	12
200						6	8

The efficiency of conversion averages from 70 per cent. in a 1 h.-p. motor to 90 per cent. in the 20 h.-p.

For the present we shall have to postpone any detailed criticism upon these figures, but there still remain several points of interest in connection with the work of Messrs. Immisch to which we intend to refer at an early date. In conclusion we must add that the whole of the experimental and mathematical work accomplished during the last twelve months has been carried out under the superintendence of Mr. Albion T. Snell, electrician to the company.

EDUCATIONAL APPARATUS.

The accompanying illustration shows a convenient piece of apparatus which has been designed and constructed by Messrs.



King, Mendham and Company, of the Western Electrical Works, Bristol, by means of which the interesting phenomenon of the deposition of dust and smoke by electric action may readily be produced and observed. It consists of a Bell jar, through the top of which is fixed a brass rod carrying a brass ball at its upper extremity and terminating in a point within the jar. Opposite to this is placed another rod, which passes out through the base of the apparatus. Each of these rods is intended to be placed in metallic connection with an electrode of a Wimshurst electrical machine. The Bell jar is mounted on three supports, and beneath the base is a cylindrical box in metal, in which the fume can be produced. Smouldering brown paper is placed in this metal box, and when the smoke has completely filled the jar the machine is started, and the smoke, which at first appears to be greatly agitated, is observed to be quietly vanishing, leaving the jar perfectly empty.

ON DISTRIBUTING ELECTRICITY BY TRANSFORMERS.*

BY CHARLES ZIPERNOWSKY.

After a brief reference to the several attempts that have been made to overcome the difficulties in the way of lighting a considerable area by means of electricity since the subdivision of the electric light has become an accomplished fact, the author points out that a practical system of distributing electric energy over a large area can only be based upon the use of high tension currents for conveying the energy from the generating centres, in combination with some mode of reducing the high tension to the limits of difference of potential which can be made use of without danger or difficulty. This limit is at present about 100 volts. Many methods have been suggested for meeting these conditions.

Thus a counter electromotive force can be introduced into the high tension circuit, as in the case of accumulators, and the terminals of such a device connected with the lamps, &c. The cost is, however, a great defect of the system, and the high tension current which exists at each lamp might lead to fatal consequences.

After referring to the electric transmission of power as another means of overcoming the difficulty, the author discusses the use of induction coils or "transformers" in some detail, tracing their use in the first instance to C. W. Harrison in 1857. Among subsequent workers Jablochkoff, C. T. Bright, Fuller, Varley, Haitzma Enuma, Gaulard and Gibbs are mentioned; and he points out that the want of success was in great part due to the fact that the transformers were connected up in series, an arrangement which is only suitable for use with an invariable number of lamps in any one secondary circuit, or when each transformer supplies only one lamp.

Besides considerations in regard to cost, the conditions to be satisfied by a system of electric distribution are stated as follows:—

(1) Perfect independence of the several consumption devices.

(2) Absolute and relative economy, so that the consumption of energy is in proportion to the number of lamps in use.

(3) All regulation to be concentrated at one central station.

The author then proceeds to describe the method he has devised in conjunction with M. Max Déri, and, with the assistance of M. O. T. Bláthy, to satisfy the above conditions.

This is based on the fact that, with a constant primary tension, the secondary one will vary only in proportion to the internal resistances of the coils; and as the resistance of each coil is less than 1 per cent. of the external resistance, the secondary tension will not vary more than 2 per cent., whatever be the intensity of current supplied to the consuming device. Constancy in the primary tension at the transformer terminals is secured by connecting them in multiple arc with the main line, and the arrangements are such that current and tension are distributed in the primary circuits, much as in a low tension direct supply system, the transformers simply acting as tension-reducing devices.

Instead of the old Ruhmkorff coil pattern of transformer a form is adopted such that the lines of magnetic force circulate entirely in iron, or as nearly so as possible, by which arrangement a considerable economy of magnetising force is effected and other advantages are at the same time gained. Two forms of transformer made on these principles are described, as well as the self-regulation of alternating current machines, which is especially valuable in installations of moderate size.

This system is at present in use in the towns of Gerona in

* Paper taken as read before the British Association at Birmingham.

Digitized by Google

Spain, Lucerne, in Milan, and stations are in course of erection in Turin and Rome. The arrangements for the last named are explained in detail and illustrated by a diagram, and the author concludes by pointing out that, although the last word has not yet been spoken in relation to the distribution of electricity over large areas, the above system is the only one with which he is acquainted that approximates to the fulfilment of an ideal distribution.

ON THE VARIATIONS IN THE VALUES OF SOME STANDARD RESISTANCE COILS.*

The values of the legal ohm standards have been carefully determined for various temperatures. The observations on the coil C.C.L. 100 extending from November, 1884, to January, 1886, are all satisfied by the value ·998770 legal ohm at 12°28 with a temperature coefficient of ·000272 per 1°C., while the values for C.C.L. 201 fall into two series, the one set (November, 1884, to July, 1885) giving a mean value ·998815 legal ohm at 14°15 with a coefficient of ·000259; while the second series gives ·997860 at 10°98 with a temperature coefficient of ·000272 per 1°C. From this it follows that at 12°, during the intervals between the two series of observations the resistance of C.C.L. 101 fell by about ·00015. The low temperature coefficient of series (1) is due to the fact that the high temperature measurements were made some eight months after the low. It is thus necessary to avoid the use of newly-made coils for accurate work, and to test them repeatedly against the standards. Two ten ohm coils were tested. They were made of the same platinum silver wire, ·015 each in diameter. Yet one was found to have a temperature coefficient of ·00289 and the other of ·00312 per 1°C. It is thus of importance to secure accuracy to determine the temperature coefficient of each individual coil used for an important research. Observations on the temperature coefficients of the coils of higher resistance are still in progress.

* Abstract of a paper read before the British Association at Birmingham by R. T. Glazebrook and T. C. Fitzpatrick.

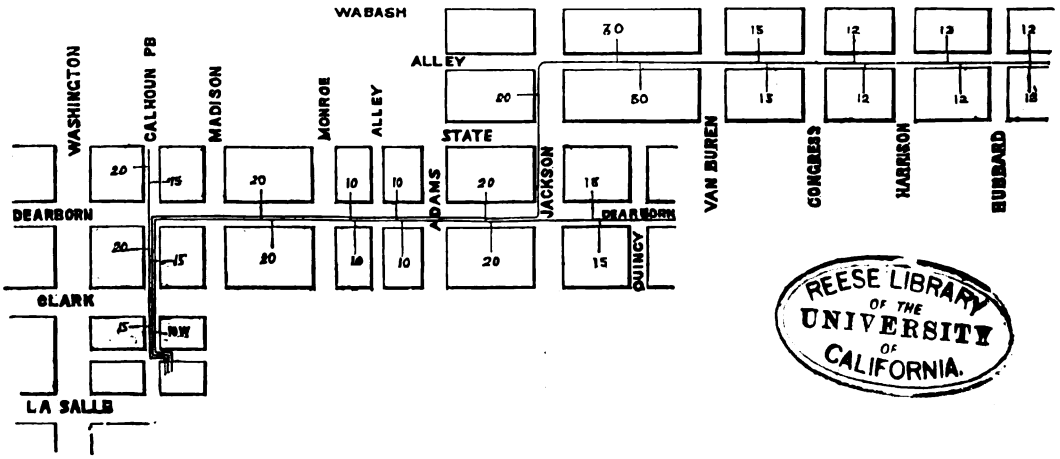
LITERATURE.

Heroes of Science—Physicists. By William Garnett, M.A., D.C.L. [London: Society for Promoting Christian Knowledge.]

Hero worship is, under certain circumstances, commendable, and for all forms of hero worship that paid by intellect to intellect indicates the highest type. The admiration of the animal part of man—to mere brute strength and courage—can hardly be compared with the admiration which is given to intellectual pre-eminence. We are accustomed to restrict the term hero to the victor on the battlefield; but there are other and greater victories than those which lead to the destruction of life. The victories to which we refer are those obtained in attacking Nature's secrets, and wresting them from her grasp, making them for the future subservient to the wants of man. These victors are not understood by the multitude; their work and success only appeal to the few—to those, in fact, who are somewhat familiar with the difficulties to be encountered and overcome in this pursuit of knowledge. Year by year, however, scientific education is spreading, and the number is increasing of those who can appreciate the work of the giant intellects that have in the past stood commandingly out among their fellows as successful labourers in scientific investigations. Prof. Garnett in this work has placed before those who desire it a simple narrative of facts relating to "Heroes of Science" which will conduce to a better appreciation of their services to mankind than has hitherto been the case. Larger books are so filled with details that the prominent discoveries are hidden amongst a mass of irrelevant matter, and fail to make due impression upon the reader. Faraday was like an officer who starts work with a few undersized, immature recruits, and who by energetic work, adds largely to the number, and leaves to his successors a disciplined host of well-developed hardy soldiers. Maxwell takes in hand the disciplined host, and secures for it arms of precision. But enough of generalising, we have to point out what Prof. Garnett has done. His aim is to bring "within reach of every boy and girl material which would otherwise be available only to those who had extensive libraries at their command and much time at their disposal." The "heroes" mentioned are Robert Boyle, Benjamin Franklin, Henry Cavendish, Count Rumford, Thomas Young, Michael Faraday, and James Clerk-Maxwell; and we find, as the author says, "the biographies of a few distinguished men, who by birth were British subjects, and incidental allusions only are made to living philosophers. But, notwithstanding these narrow restrictions, the foundations of the Royal Society of London, of the American Philosophical Society, of the Great Library of Pennsylvania, and of the Royal Institution, are events some account of which comes within the compass of the volume."

It would prove a congenial task were we to dilate at length upon this book; but we think the reader will find it far more pleasant to peruse it for himself. There is not a "hero" mentioned therein but whose work in the realms of scientific investigation will bear the closest study. We may venture to point to the moral which the reading of the life of Cavendish must inculcate. The world asks that the results obtained by original research shall be made as widely known as possible. Can we conceive where electrical science would now stand had Faraday commenced where Cavendish left off, instead of laboriously traversing the same field? Every new fact observed is a step gained, and ought not to be reserved for a moment. While we postpone, time progresses, and if life is allowed to pass while our work is kept back, the work has to be done over again.

UNDERGROUND WIRES AT CHICAGO.



REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.

The accompanying diagram shows the distribution of the wires on the Brooks system, which has just been carried out at Chicago.

The wires are generally taken to opposite blocks for the same splice boxes; but a separate splice box for each block can, if required, be used.

EXHIBITIONS AND ELECTRIC LIGHTING.

The epidemic of Exhibitions which has its seat at South Kensington, and which has broken out with increased severity all over the country this year, is, like most epidemics, useful both for warning and instruction. As to any other useful purpose it may serve we prefer to say as little as possible. These Exhibitions have given immense satisfaction to the community at large, and have afforded a vast amount of innocent enjoyment, with possibly a real though not a very large addition to the general stock of practical knowledge. But from the manufacturer's or tradesman's point of view they leave something to be desired—something which has found expression in more than one quarter already, and something else which is perhaps the more vexing because it cannot be easily or safely put into print. The public sympathy is at present entirely with the Exhibitions, and the wisest thing to do under the circumstances is to humour the public fancy, and make as much out of it in the way of business as is possible. At one time the promoters acted as though they were conferring a favour on every intending exhibitor. In a great measure this idea has been exploded owing to the indisputable evidence of figures, which show that if anything profits by the exhibits it is certainly the Exhibition, and if anybody loses it is certainly the exhibitors. Balance-sheets to the contrary notwithstanding, it is plain that these Exhibitions pay somebody exceeding well, and that the profits might be available for uses to which at present they are not put.

A conspicuous illustration of what we mean is furnished by the electric light, which has played a prominent part in every Exhibition during the last five or six years. At first, acting in the spirit to which we have adverted above, the authorities required the lighting to be done for the value of the advertisement. This is no longer the rule; and where it prevails, it probably results in an inferior article being supplied by persons who have no other claim to public favour than the publicity to be obtained by gratuitous exhibition. Generally, however, the electric light is now paid for at a fair price, several competitors are allowed to light different sections, and the public can form a judgment, if they care to do so, on the relative merits of rival systems. The main advantage to the electric lighting engineers as a body is that visitors to these displays are familiarised with the new illuminant, appreciate its light and comfort, and establish in their own minds a standard of what good lighting on a large scale ought to be. This undoubtedly is a great service to the electric light, which, it may be frankly admitted, owes more to Exhibition craze than to any other influence whatsoever. On the other hand, the electric light may confidently claim to have given as much as it has received. It has undeniably contributed not a little to the success of the Exhibitions wherever they have been held; and it may be doubted whether the most popular among them—the one at South Kensington—would have proved half so attractive in the evening time, and consequently not nearly so profitable as a place of amusement, had it not been for its decorative splendours of illumination, to which the electric light so readily lends itself.

On this account partly, and partly on the utilitarian grounds which these Exhibitions ostensibly serve, we venture again to urge upon the authorities the duty of doing something more for the electric light than they have hitherto done. We have repeatedly suggested that Exhibitions of this kind offer the best of all means for testing accurately the merits of the various electric lighting systems on view. Nothing of the kind has yet been adequately done, and where it has been attempted the results have proved often illusory and sometimes absurd. Where the appliances are merely there for lighting purposes and not as exhibits of course no such tests can or ought to be taken. But if it were known that the show would award prizes to the best exhibits of electric lighting plant as such, there would be no lack of competitors; and if, as might well be the case, the the prizes were valuable, the test would be proportionately severe, and the final awards eagerly coveted. This is a service which the Exhibition authorities might very easily and very properly confer upon the electric lighting industry, but which up till now they have abstained from seriously carrying out. For a comparatively new industry it is just the sort of duty which one might think would be cheerfully taken up by such a body as that which is responsible for the doings at South Kensington. It is a *quasi*-scientific body, and is never tired of preferring its claims to public favour on the ground of services rendered to science, art, and commerce. Here is a great opportunity of establishing its claims by settling in the public interest a disputed question as to cost of the electric light, its illuminating power, its merits as compared with other illuminants, and the relative merits of the several electrical systems now competing for public capital.

It is still literally true that we are without authoritative data on the above-mentioned important practical points; and until we have them, electric lighting, as an industry, can make headway only slowly, and without that confident support of

Digitized by Google

the public which is needful to convert a scientific idea into a working reality. Any Exhibition would serve, provided the judges were well chosen; but none would carry so much weight in public estimation as the voice of South Kensington, and upon none, we make bold to say, does the obligation devolve so naturally. We want South Kensington to do for electric lighting what the Royal Agricultural Society did for the portable steam engine, and what it is now proposing to undertake on behalf of the traction engine—that is to say, to examine with scientific accuracy into the conflicting claims of inventions, and to inform the public as to their cost, efficiency, and relative fitness for special requirements. Undoubtedly this is a task which might be confidently undertaken in the quarter we have named; and as a considerable fund is at its disposal for purposes of the kind here indicated, we trust that action in this direction will not be long delayed. To electric lighting engineers we would say that the lessons of these recent Exhibitions point to the necessity of abstention from exhibits of plant which are not to be tested in a satisfactory manner, and by jurors whose decisions will not be conclusive.

CORRESPONDENCE.

TESTS OF DYNAMOS.

Our contemporary *Industries* commented upon a letter which appeared (and was duly acknowledged) in our columns. The following letter has been sent to the Editor of *Industries*, and a copy was also forwarded to us as likely to prove interesting to those of our readers who have followed the subject.—[Ed. *E.*]

Sir: In your very flattering article on "The Commercial Efficiency of Dynamo Machines" you state that the method was devised by me.

It is entirely due to Mr. H. W. Ravenshaw, to whom it was suggested by Captain Cardew's method of using two dynamos, in which, however, the efficiency of the motor is assumed, or else measured by a mechanical dynamometer.

While the credit of commercial inventions is often absorbed by the firm by whom they are first brought out, I think it is important that purely scientific discoveries should be credited to the actual inventor.

It should be remarked that the tests which you give were carried out more for the purpose of ascertaining the difference between electrical efficiency and commercial efficiency than for determining the actual commercial efficiency of the machine in question. Moreover, the efficiencies were taken, not at the greatest output only, but at various outputs, thus giving the *average* efficiency for different loads.

The result shows that for the size of the machine, namely, a 7½ unit., the difference between the two efficiencies is only 3½ per cent.

The electrical efficiency can be determined in one's arm chair; and for any machine with a given type of dynamo one can determine the commercial efficiency with accuracy sufficient for practical purposes when this difference is known.

I hope shortly to investigate the relative efficiency of a machine when used as a dynamo and as a motor, in order to settle what you describe as a weak point in the method; and this I propose to do by using a machine, whose name had better be withheld, which has an electrical efficiency of 49 per cent., and the commercial efficiency will probably turn out to be 30 per cent. The losses being so great, it is probable that when carefully tested, both as dynamo and as motor, if any practical difference exists, it will be easily detected. The other two machines will be of good efficiency, though of small size.

At the same time I would point out that, as far as the former tests were carried, even in the inferior machines, there was practically no difference in the combined efficiencies as motor and as generator.—Yours, &c.,

Richard P. Trotter.

26th October, 1886.

ON MAGNETIC HYSTERESIS.*

BY PROF. G. FORBES.

Prof. Ewing, in 1885, made a contribution to the science of magnetism which has only lately come into the hands of scientific men, but which is certain to lead to an extension of our powers in dealing with applications, as well as with the theory of magnetism. Lord Rayleigh has already drawn deductions from it in a paper communicated to the *Philosophical Magazine* for August last.

The consequences which I wish to draw from it have reference partly to practical applications, and specially to secondary generators or transformers, and partly to Weber's molecular theory of magnetism.

If a coil of wire carrying an electric current encloses an iron core, whose length is at least 400 times its diameter, or which is of a ring shape, the magnetic induction produced at the middle of the bar, or at any part of the ring, is due altogether to the direct action of the electric current, since there is no free magnetism. In this case the magnetic force is proportional to the electric current.

A curve may be drawn in which abscissæ denote electric current or magnetic force, and ordinates represent magnetic induction. As the magnetic force is increased a curve is traced, but this curve is not retraced as the magnetic force decreases. If the magnetic force reach alternately a positive and a negative maximum a closed curve is traced, and the area of which indicates the work done upon the iron core in a cycle of these operations, just as the area of the curve traced by the steam engine indicator measures the work done by the engine in a complete cycle of the movements of the piston rod.

The nature of this curve shows that we cannot express the magnetic induction in terms of the magnetic force alone. It is also a function of the history of the iron in the immediate past. This phenomenon is called magnetic hysteresis.

A figure (taken from Ewing) shows the increase of magnetic induction from zero to a maximum with increase of magnetic force and the subsequent cycle produced. The arrows indicate the direction in which the curve is traced.

If the iron be subjected during the process of magnetisation to mechanical shocks, these peculiarities disappear and the induction becomes a pure function of the magnetic force. It is generally supposed that the tremors of a dynamo machine prevent the effects of magnetic hysteresis from showing themselves. This may sometimes be the case. It is not always so. In the first model non-commutating dynamo constructed by me the electromotive force did not diminish 10 per cent. after the existing current was reduced to zero. That model consisted of a long cylindrical electro-magnet rotating about its axis, its poles being connected by a soft iron cylinder with closed ends.

In secondary generators hysteresis must play an important part. In this case the magnetising force is due to the sum of the two currents in the primary and secondary coils. Now the maximum value of the current in the primary is reached earlier than the maximum of the sum of the two currents, and the maximum of the secondary currents later. This fact introduces interesting modifications in the form of the magnetic indicator diagram of the two circuits to which I wish to draw attention. I will suppose that the maximum of magnetic induction is coincident in time with the maximum of the algebraical sum of the primary and secondary currents.

The phase of the primary current may precede, and the phase of the secondary current may follow, that of the magnetic induction by a value varying from 0 to $\frac{1}{4}$ when T is the period of a complete cycle. The currents are taken as harmonic functions of the time. To transform Ewing's cyclic curve of hysteresis into the corresponding diagram for the primary or secondary circuit whose phase is $+a$ or $-a$ in advance of the phase of induction, let the maximum abscissæ represent the magnetic force due to the maximum force due to the maximum current in that circuit, and describe a circle with this abscissæ as radius, and the zero of co-ordinates, O, as centre.

Take any point, P, on Ewing's curve. Draw its ordinates,

* Paper read before the British Association at Birmingham.

Digitized by Google

P, M. Let this line produced, if necessary, cut the circle in Q Q. This line cuts Ewing's curve in two points, P, P^1. If P be the higher of these points, operate on Q the higher of Q Q^1, and contrariwise. Draw Q Q^1 inclined to O Q at an angle $+\alpha$ or $-\alpha$. Draw the ordinate Q^1 M^1 and cut off P^1 $M^1 = P$ M. P^1 is a point on the new curve corresponding to P on Ewing's curve.

In this manner other figures have been drawn for the primary and secondary circuits of a secondary generator for cases where the acceleration and retardation of phase are $\frac{1}{8}$ and $\frac{1}{4}$.

In all these curves work is done in a complete cycle by the electric circuit on the iron when the curve is traced in a direction contrary to the motion of the hands of a watch, and contrariwise. We can now notice several facts.

1. In all diagrams for the primary circuit the curves are described in the same direction as Ewing's curve, showing that it does work on the iron.

2. In both diagrams for the secondary circuit the curve is described in the opposite direction to Ewing's curve, showing that work is done by the iron on the circuit.

3. When the acceleration of the primary is $\frac{1}{4}$ no work is done by the iron on the primary circuit at any part of the cycle.

4. When the retardation of the secondary is $\frac{1}{4}$ no work is done by the circuit upon the iron at any part of the cycle.

5. In the diagram for the secondary circuit, if the retardation be the angle corresponding to the absissæ, O, A, the curve passes through the origin, and the work done in a cycle is zero.

6. If the retardation be less than this, work is done in the cycle by the secondary circuit on the iron core.

7. It follows from this that owing to magnetic hysteresis the retardation of the secondary current cannot be less than the angle corresponding to the abscissæ O A, except in so far as it derives energy by direct induction from the primary.

In most early attempts to make secondary generators the mutual induction of the primary and secondary coils was very slight, and here the retardation must be at least equal to the angle indicated.

These remarks hardly apply to Gaulard and Gibbs's secondary generator, who made it a commercial success mainly by causing the direct mutual induction of the circuits to be a maximum.

Lord Rayleigh has pointed out that since hysteresial dissipation of energy per unit volume of iron is the same whether the magnetic circuit be opened or closed, while the total work done on or by the electric circuits is greater with an open magnetic circuit, therefore the most efficient secondary generator is one with an open magnetic circuit. This is only when hysteresial dissipation is the only cause of the loss of efficiency. It has appeared, however, that in actual secondary generators hysteresial dissipation is but a portion of the cause of the loss of efficiency. Resistance of the generator itself is a principal cause, and the loss from this cause varies as the square of the current, and would be much greater with the high currents proposed by Lord Rayleigh for his elongated elliptical iron core than in a secondary generator with a closed iron magnetic circuit. The efficiency which Lord Rayleigh proposes to gain in hysteresial dissipation is proportional to the current. The loss due to resistance is proportional to the square of the current.

Throughout this investigation I have assumed that magnetic induction does not lag behind the magnetic force.

The second part of this paper has relation to the molecular hypothesis. This hypothesis, as developed by Weber and Maxwell, gives no account of hysteresis. Ewing has proposed a further assumption, that a molecule has a friction (not a viscous friction, but what Maxwell called striction), which prevents it from turning until the turning force exceeds a constant value.

It seems to me that the fewer assumptions we make the more near to the truth are we likely to be. Weber has made the assumption that a constant force tends to restore the molecule to its original position. The simpler assumption seems to be that in ideally soft iron the molecules take up positions depending upon the influence of the others. I suppose that when there is no magnetisation the molecules naturally group themselves in pairs with poles of opposite name in juxtaposition, and that the value of the resolved part of the magnetic force required to separate them must reach a certain value, K, before any deflection takes place, and then the deflected molecule sets itself in the direction of the magnetic force. This seems to be a very likely hypothesis for iron of ideal softness. If H be the magnetic force, and θ the inclination of the axes of a pair of molecules to the magnetic force, the molecules acted upon and set with their axes parallel to the direction of the force are those for which $\sin\theta$ is greater than $\frac{K}{H}$. The number of these varies as the magnetisation. Calling the magnetisation I, we have

$$I = \int_{\sin^{-1}\frac{K}{H}}^{\frac{\pi}{2}} a \sin\theta \, a\beta = \frac{\alpha}{H}\sqrt{H^2 - K^2}$$

for magnetising forces less than H = K, I = O, for other values we have

H = K	I = 0
= 1·2 K	= ·55
= 1·5 K	= ·74
= 2·0 K	= ·86
= 5·0 K	= ·98
= 10·0 K	= ·995

The curve deduced from this has the characteristics of extremely soft annealed iron. The only want of resemblance is the suddenness in the rise of the curve after H has reached the value K. This would doubtless be smoothed by any want of perfect mobility of the molecules, such as is involved in Maxwell's addition to Weber's hypothesis, which must be taken into account in explaining the behaviour of steel, which has no connection with the cause of hysteresis.

After a certain magnetisation is attained the magnetisation of the iron (if there be no demagnetising influence of ends) must retain each molecule in its axial direction, and the demagnetisation cannot commence until a reverse magnetic force is applied.

The effects deduced from this hypothesis are the same in character as those deduced from Ewing's friction hypothesis, but it seems to me that perfect mobility rather than friction is more likely to be the explanation of a property specially possessed by the softest kinds of iron, and I have thought that the hypothesis is at least worthy of consideration.

EXPERIMENTS ON THE MELTING PLATINUM STANDARD OF LIGHT.*

BY CHARLES R. CROSS.

We have been favoured with an advance proof of this paper, which is as follows:—

Notwithstanding the fact that the amount of light emitted normally by a square centimetre of platinum at its point of solidification has been adopted as a standard both by the International Electrical Conference and by the United States National Conference of Electricians, but very few experiments have been made to determine whether it can be made reliable and capable of practical use. An approach towards giving the method a practical form was made by W. Siemens,† who proposed to substitute the light emitted by a given area of platinum at its melting point instead of at its point of solidification, and suggested a means by which, with this modification, the standard could readily be utilised.

The following experiments resulted from a conference of a portion of the Committee on Standards of Light appointed at the Electrical Conference at Philadelphia in 1884.‡ They had for their object the ascertaining of a single fact, viz., the amount of the average deviation which would arise in a series of measurements of

*Contribution to the American Academy from the Physical Laboratory of Massachusetts Institute of Technology. Presented June 16th, 1886.

the light emitted by a strip or wire of platinum of given surface when at the melting point.

A few preliminary experiments were made by the writer, in which a measured length of fine platinum wire, four one-thousandths of an inch in diameter, was placed at one end of the bar of a Bunsen photometer, with a gas jet shining through a limited aperture at the other end. A current from a small hand Gramme machine was carried through the wire, which was made to glow more and more brilliantly by increasing the speed of the machine. Following the method of Siemens, the greased disc of the photometer was moved farther and farther from the incandescent platinum, so as to keep the disc uniformly illuminated, until finally melting occurred. The last reading of the position of the disc gave the illuminating power of the wire at melting. An unexpected constancy in the results was found, so that it seemed worth while to make a longer series of such observations, which was done in the following manner :—At one end of the bar of a greased disc photometer 200 centimeters (78·74in.) long was placed a circular aperture, through which shone the light of an Argand burner. A platinum-wire lamp was constructed, in which a given length of wire was stretched between two fixed knife-edges, and held by clips, thus allowing of speedy adjustment of the wire. The disc used was furnished with two mirrors inclined at 45° in the usual manner, and it was always placed so that the two sides as seen by reflection appeared alike—a method of measuring much more satisfactory than the one commonly employed with the Bunsen photometer. The length of wire used was measured between the edges when cold, and allowed to expand freely. An attempt was made to use a slit of given length in front of a longer wire, which was abandoned owing to errors arising from inequality in the length of that portion of the wire whose light passed through the slit when the wire expanded. The use of a small weight stretching the wire tight, as suggested by Prof. Pickering and employed by him in a small lamp, presents some advantages, but was discarded from fear of elongating the wire and so causing it to break before complete fusion was reached. Melting was brought about by the use of a slide-resistance of German silver wire in circuit with the platinum wire and a dynamo machine. The variable resistance of the slide was lessened until the platinum wire melted, the photometer-disc being meanwhile moved repeatedly, its final reading giving the light emitted by the platinum in terms of the light emitted by the aperture opposite.

No attempt has been made in these experiments to determine the absolute illuminating power of the wire, but only to ascertain whether ordinary commercial platinum wire has any practical value for use as a primary or a secondary standard.

Two different sizes of wire were used, whose diameters were ·004in. and ·006in. respectively. Wire from two different makers was also used, ordinary wire drawn without special care being taken because of its availability. The length used was always the same when cold, viz., two inches. A very large number of measurements were made, chiefly by Messrs. F. H. Crane and H. E. H. Clifford, students in the laboratory, and careful and accurate observers.

Five sets of observations on successive fusions of wire were made by each observer, and the mean taken. The mean and the average deviation from the mean of a long series of such sets were then found. The tables give the results of the measurements. In all cases the distance between the opposite lights is 78·74in. (200cm.), and the diameter of the aperture in front of the gas flame ⅛in. The recorded distances are measured from the aperture.

In order to give an idea of the degree of concordance of the separate individual readings, the following sets (Table I.) are taken at random. The numbers given are the final positions of the disc, in each experiment, in inches.

TABLE I.

Diameter of wire = ·004in.

Observer *M.*	Observer *N.*
43·7	43·6
43·6	43·7
43·7	43·7
43·6	43·5
43·5	43·8
Mean 43·62	Mean 43·66

A change of 0·1in. corresponds to an absolute change of 0·007 in illuminating power of opposite light = 1·1 per cent.

Diameter of wire = .006in.

Observer *N.*	Observer *N.*
37·7	37·4
37·8	37·2
37·4	37·4
37·2	36·8
37·2	37·2
Mean 37·46	Mean 37·20

A change of 0·1in. corresponds to an absolute change of 0·01 in illuminating power of opposite light = 1·0 per cent.

Table II. is given at length as indicating more clearly the variations among consecutive sets of measurements. I. P. denotes the illuminating power of the platinum wire in terms of that of the opposite light. The average deviation of I. P. is the change in this quantity produced by an increase in the scale-reading equal to the average deviation in inches.

TABLE II.

Diameter of wire = ·004in. Sample A.

Averages of 5 Experiments. Observer *M.*	Averages of 5 Experiments. Observer *N.*
43·6	43·7
43·7	43·5
43·6	43·5
43·7	43·4
43·5	43·4
43·6	43·6
43·5	43·3
43·6	43·6
43·6	43·2
43·5	43·7
Mean 43·59	Mean 43·49
Average deviation ·06in.	Average deviation ·13in.
I. P. = ·650.	I. P. = ·657.
Average deviation I. P. = ·004.	Average deviation I. P. = ·009.

Tables III. and IV. give the means of the various sets of experiments. Column 1 shows the sample used ; 2, the mean of the series taken ; 3, the number of observations from which the mean is derived ; 4, the observer ; 5, the illuminating power ; 6, the average deviation in inches ; and 7, the average deviation in terms of the illuminating power. It will be seen that the maximum average deviation in I. P. for the finer wire is 1·7 per cent., and for the coarser wire 1·6 per cent. of the total value.

TABLE III.

Diameter of wire = ·004in.

Sample.	Mean.	Number of Obs.	Observer.	I. P.	Av. Dev. Inches.	Av. Dev. I. P.

TABLE IV.

Diameter of wire = ·006in.

Sample.	Mean.	Number of Obs.	Observer.	I. P.	Av. Dev. Inches.	Av. Dev. I. P.
A	35·37	20	*N*	1·504	0·15	·024
A	37·19	30	*N*	1·249	0·14	·019

In order to determine the possible accuracy of setting the photometer disc several series of readings (Table V) were taken, in which two apertures through which a gas flame shone were balanced against each other. These readings were taken with apertures of different sizes, in order to test the accuracy of setting in different parts of the scale ; that is, for different relative brilliancies of the lights. Series 3 and 4 were taken so as to bring the disc in the same position as that which it occupied with the ·004in. and ·006in. platinum wire.

TABLE V.

Series.	Number of Observations.	Mean.	I. P.	Av. Dev. Inches.	Av. Dev. I. P.
1	50	31·35	2·286	·076	·019
2	50	31·40	2·273	·054	·012
3	50	43·92	0·628	·042	·003
4	50	36·48	1·342	·044	·005

It appears that the average deviation of the different readings when the opposite illuminated apertures were balanced against each

Digitized by Google

other is in general considerably less than that of the readings with the melting wire. The maximum average deviation of I. P. is 0·8 per cent. of its total value; the minimum value is about half as great.

Marked differences in the illuminating power of the platinum wire of the same diameter on different days were observed, contrasting strongly with the uniformity of the results of successive measurements. This undoubtedly arose from changes in the quality, and hence in the illuminating power of the gas, as the height of the flame was kept constant. In future experiments I hope to obtain a more constant standard by using a moderator lamp with aperture, or else by employing the pentane burner.

A consideration of the results given in Tables III. and IV. shows that the light emitted by a filament of commercial platinum at the melting point is quite constant in successive measurements, and it appears to present greater uniformity than many of our commercial standards. There is little doubt, moreover, that by the use of a wire longer, and perhaps of larger diameter, the results would be improved, as there would be less liability to error from the cooling of the ends of the wire by contact with the metal supports (an action, however, which can easily be removed altogether), and from accidental minute inequalities in the length of the wire used. It would also be desirable to use platinum of better quality than is usually found in commercial wire, and to have special care exercised in drawing to insure accurate cylindricity.

It is also evident that such a wire as I have used cannot at best be employed except as a secondary standard, since the ratio of the luminosities of the two gauges of wire employed is not at all in the ratio of the projection of their surfaces.

Still further, a difficulty may arise in the use of a melting platinum wire or strip, even as a secondary standard, from variations in the physical condition of the metal, due to cracking, occluded gases, or other causes. No certain evidence of this was observed with the samples of wire employed, but I am not at all sure that it may not occur with different specimens of commercial wire. From a few preliminary experiments of a series still in progress it appears probable that successive heating and cooling, or continued heating of the wire even under ordinary atmospheric pressure, tend slightly to raise its point of fusion, an action which Edison has shown* to be carried to an extreme degree when continued heating in vacuo is employed. Thus, in one experiment the wire was heated by the current and cooled from one to ten times, and then carried up to its melting point, photometric readings being taken as in previous experiments, with the following results. The wire was ·006in. in diameter. Each value given is the mean of five measurements.

	Mean Reading.
Without reheating	37·65
Reheated once.....	37·42
,, twice	37·42
,, 3 times	37·62
,, 4 ,, ...	37·26
,, 5 ,, ...	37·06
,, 10 ,, ...	37·20

The lesser readings indicate greater luminosity of the melting wire.

In another experiment, the wire in its ordinary condition melted when the reading (mean of five measurements) was 37·8in. After annealing in a Bunsen flame, the mean reading at melting (for five experiments) was 37·2in. After heating to a yellow heat by passing a current of electricity through it for half an hour, the reading at melting (mean of 23 measurements) was 36·9in.

If further experiment should show conclusively that the light emitted by melting platinum is variable beyond narrow limits, it is clear that any photometric standard based on the luminosity of *melting* platinum will present no advantage over those standards now in ordinary use, unless specially prepared platinum freed from gases and consolidated by Edison's process of heating in vacuo is found to be available. Probably solidifying platinum, provided its point of solidification is sufficiently definite, would be free from this objection, although this can hardly be accepted without experimental proof.

CITY AND GUILDS OF LONDON INSTITUTE EXAMINATION PAPERS.

ELECTROTECHNICS—Course B.

1. Find general expressions for the speed and torque of a motor. Show also that if a shunt-wound motor has a negligible armature resistance its speed will be independent of torque when supplied at constant potential. How does the speed vary with the torque (at constant potential) when the resistance is not negligible?

2. Calculate the "commercial efficiency" and the "economic coefficient" of a shunt dynamo from the following data:—

One revolution of pulley	=3·65ft. advance of belt.
Difference of tension of belt at two sides of pulley	= 684lbs.
Speed	= 764 revolutions per minute.
E.M.F. at terminals	= 110·12 volts.
Main circuit current	= 358 amperes.
Field magnet ,,	= 6·5 ,,
Resistance of armature	= ·009947ohm.

3. Describe fully, with suitable diagrams, the process of testing the efficiency of a dynamo.

4. Write a concise account of the importance in designing dynamos of giving a proper form, &c., to the magnetic circuit. Sketch examples of good and bad designs.

5. Define the coefficient of mutual induction. Why is it sometimes called the coefficient of mutual potential. How is the mutual induction between two coils affected by the presence and form of metal in the intermediate space?

6. Describe the ordinary electrometer method of measuring a high resistance with special reference to the precautions to be taken to ensure accuracy. State and deduce the formula used. How would you modify the method if it were not sufficiently sensitive?

7. Describe, with sketches, some form of pump suitable for exhausting glow lamps; explain its action clearly, and point out how you would use it for the above purpose, and what precautions you would take to ensure a good result.

8. Give, with diagrams, the chief methods of arranging a telephone circuit; and describe the ordinary Blake transmitter and Bell receiver.

9. What are the conditions that a *good* arc lamp should satisfy? Describe some such lamp in which "series," "shunt," and "cut out" coils are used, and state what relative resistance you would employ for these.

ON ELECTROLYSIS.

BY PROF. OLIVER J. LODGE, D.SC.

(Continued from page 500.)

VI.—Addenda.

Electrostatic Calculation of E.M.F. needed to effect Decomposition, (a) *of an Electrolyte,* (b) *of a Dielectric.*—(*a*) I do not think the process is justified by anything Helmholtz has said, but I have allowed myself to reckon through what atomic distances mutual electrical attraction of two charged atoms might be overcome by means of an electrode differing in potential from a liquid by, say, a volt, *i.e.*, by means of a slope of potential of 1 volt in 18^{-8} centimetres.

Let y be the effective distance between two oppositely charged atoms in a molecule, so that the force between them is $\frac{q^2}{y^2}$, and let this molecule come within range of the electrode, and so under the influence of the separating stress $q\frac{dV}{dx}$; then decomposition will be effected when

$$q\frac{dV}{dx}=\frac{q^2}{y^2},\ i.e.,\ \text{when } y^2=q\frac{dx}{dV}.$$

Taking, therefore, $q=10^{-11}$, and $\frac{dV}{dx}=\frac{3\frac{1}{3}}{10^{-8}}=\frac{1}{3}\,10^6$, y comes out 10^{-9} or thereabouts—a very respectable atomic distance. This perhaps indicates that, within molecular range of either electrode, actual decomposition or tearing asunder of molecules may occur, but that through the rest of the liquid the action is propagated in some other way, *e.g.*, by a divorced atom being projected so close to one of the constituents of a molecule as to combine with it in place of its former partner, and so on. In this way two postulates may be avoided—1st, the existence of continuous dissociation in ordinary liquids unexposed to electrical influence, a hypothesis to which I understand chemists see some objections; and 2nd, the attraction of matter for electricity postulated by Helmholtz, so far as it is necessary to the explanation of polarisation. Polarisation would then really be the E.M.F. needed to tear asunder molecules of the given compound within molecular range of the electrode; and automatic interactions of the molecules must be trusted to carry the action forward throughout the whole mass.

It appears that on this hypothesis an E.M.F. of one or two volts would be sufficient to decompose acid water, or other similar compound, if atomic distance were something comparable with 10^{-9}. But it may be considered that the magnitude of this distance points to something like at least incipient dissociation as necessary to electrolysis. Let us find its value more carefully.

Put the problem thus:—To find the relation between molecular distance, x, and the least distance at which atomic electric attraction can be overcome by a slope of potential of 1 volt per x centimetres; on the hypothesis that ordinary electrostatic laws are applicable.

$$\frac{V}{x}q=\frac{q^2}{y^2}.$$

But $$q=1{\cdot}5\times10^{13}.x^3,$$

Digitized by Google

and $$3 \times 10^{10} V = 10^8,$$

so $$\frac{q}{V} = 4{\cdot}5 \times 10^{16} \cdot x^3,$$

and $$y = {\cdot}67 \times 10^8 \cdot x^2.$$

The most probable value of x at the present time is, I suppose, $\frac{1}{2}\ 10^{-8}$; and the fact that y comes out so nearly equal to x is at least noticeable.

Distinction between Electrolytes and Dielectrics.—Homogeneous electrolytes and dielectrics behave very similarly when supplied with electrodes at slight difference of potential, but the distinction is that, whereas in an electrolyte the whole of the strain is thrown upon a pair of thin films, the bulk of the medium being as quiescent and unstrained as a metal, in a dielectric the strain exists throughout the medium, sloping steadily down from anode to cathode; if these terms be still permissible. In the one, therefore, the $\frac{dV}{dx}$ strain is excessive, and very small differences of potential easily cause decomposition; in the other, the strain on each molecule is insignificant—there being a whole series of them to share it—and accordingly it takes a great difference of potential to effect decomposition, or disruptive discharge, as it is in this case called, especially if mechanical locomotion of the medium, or a chain of dust particles, be avoided.

In rare gases it seems likely that, by a locomotion of molecules, a steady convective discharge can be maintained, distinct from true disruption; indeed, mobility of particles may play an important part in the giving way of any fluid. But, ignoring this, we can reckon roughly on electrostatic principles how much E.M.F. a given thickness of a dielectric ought to bear; and this is what, at the beginning of the present section, I call

(*b*) *Calculation of E.M.F. needed to decompose a dielectric.*—Let the distance of the plates be z; there will be a series of $\frac{z}{x}$ molecules to share the $V - V'$ between them.

Now, since there are about 10^8 molecules per linear centimetre in a liquid, and about 10^9 in an ordinary gas, the slope of potential in a dielectric will be some 10^{-8}th of what it is in the films of an electrolyte for the same potential difference; and accordingly, since it takes one or two volts to decompose a liquid, it will require one or two hundred million volts per centimetre to burst a liquid dielectric, and a tenth of this for a gas. This is probably much too high—certainly it is for a gas; but then what is one to think about the electrification of the atoms of a simple gas like nitrogen? The hint of Helmholtz occurs to one, that possibly even molecules of elements possess some electric charges; and if one could fancy that the atomic charge in such molecules, instead of being 10^{-11}, was something like 10^{-16}, the experimental value of the dielectric strength of air (viz., 33,000 volts per centimetre) would be obtained, on the preceding hypothesis; and it would vary with the cube root of the pressure.*

Probably, however, one is now not on the right track, and it is better to refrain from further guess-work; though I must just point out that if one reckons the distance at which fully charged atoms would be able to cling together, on this hypothesis, if they are to give ordinary dielectric strength, though it is too great to be reasonable, it is not outrageously so. The simplest plan is, perhaps, just to quote the arithmetic. To reckon the greatest atomic distance when the atoms of a molecule are just being torn asunder electrically. Call it y. The actual stress which can be supported by ordinary air, according to experiment, is given by the equation

$$\frac{V^2}{8\pi z^2} = p = \tfrac{1}{2} \text{ gramme weight per unit of air}$$

so a centimetre thickness can stand $V = 110$ electrostatic units, or 33,000 volts. This would give a force of 110 dynes per electrostatic unit,

or $$110 \times 1{\cdot}5 \times 10^{-11} = 1{\cdot}65 \times 10^{-9} \text{ per atom.}$$

The attracting force of two atoms at distance y, is $\frac{2{\cdot}2 \times 10^{-22}}{y^2}$.

So when a molecule is on the verge of giving way,

$$y^2 = \frac{2{\cdot}2 \times 10^{-22}}{1{\cdot}65 \times 10^{-9}} = 1{\cdot}33 \times 10^{-13},$$

or $$y = 3{\cdot}65 \times 10^{-7} \text{ centimetres, when just giving way.}$$

This is for common air, and is much too big; a stronger dielectric will be satisfied with a smaller limiting atomic range, though still not with one small enough.

It is difficult to suppose that *molecules* tend to get separated instead of *atoms*, and that accordingly ordinary mechanical, not chemical, tenacity is the force to be overcome in a dielectric; for how can this apply to the case of a liquid or a gas?

Consequences of an atomic theory of electricity. Possible electrostatic saturation.—The fact that atoms in electrolytes have a constant charge which is the same for every kind of atom, or at least can only be multiplied by an integor, is so striking that one is constrained to think whether electricity is something necessarily associated with atoms of matter, whether all electrical actions are simple electrostatics among the atomic charges, and whether no quantity of electricity smaller than an atomic charge can exist. The notion is repugnant, but it just wants considering, though I should hardly have ventured to suggest it but for the support Helmholtz has given to the view as at least a possible one (see above). The first difficulty which meets us is the serious one that, since air and gases are not electrolytes, nothing is known about the atomic charges of their molecules. On the atomic theory, however, the unit of electricity is about 10^{-11}, and nothing smaller is possible; so we must provisionally use this as applicable even to air atoms; for it is hardly reasonable to suppose that the aqueous vapour, or other true compound, present is essential to electrostatic actions.

Consider a centimetre cube of air at pressure p dynes per sq. cm.; the number of atoms in it is $\frac{p}{10^6} \cdot \frac{n^3}{800}$ or say $10^{15} p$.

The number in each face of the cube is $10^{-6} n^2 p^{\frac{2}{3}}$, or $10^{10} p^{\frac{2}{3}}$.

The available quantity of electricity of either kind on a face of the cube, *when every molecule is fully polarised*, is therefore,

$$10^{10} p^{\frac{2}{3}} \times 10^{-11} = \frac{p^{\frac{2}{3}}}{10} \text{ electrostatic units.}$$

This is, therefore, the maximum possible density to which an air condenser could be charged, on the atomic theory. If p is a millionth of an atmosphere, this gives 400 volts per centimetre as the maximum possible. If p is one atmosphere, it gives 4,000,000 volts per centimetre. A *liquid* condenser would have 400,000,000 volts per centimetre as its maximum charge. It is to be understood that this calculation has nothing to do with the dielectric strength of the medium. It is not considered whether the medium can *stand* this stress or not; all that is reckoned is the maximum that can possibly be *produced*, on the atomic hypothesis. If every dielectric refuses to stand anything like so much, it is difficult to test the hypothesis; but if the maximum possible were to come out something comparable with what a substance under certain conditions can stand, then it may be possible to try the experiment and to discover some evidence of the existence of an upper limit to the charge a condenser made of that substance is able to receive. One effect naturally suggests itself. If the maximum possible charge is insufficient to burst a given kind of condenser, then that condenser cannot be burst—it will behave as if infinitely strong.

Now, if what I have said has any sense (an improbable assumption) the law of variation of maximum charge with pressure in a gas is as $p^{\frac{2}{3}}$. The dielectric strength of air is ordinarily far below the maximum charge, but if it varies with pressure more rapidly than the $\frac{2}{3}$ power, say as p—it follows that at some high pressure it will overtake the maximum charge and pass above it; and in that case an air condenser at some very high pressure would be unburstable, *i.e.*, the dielectric strength of sufficiently high-pressure air would be infinite. On the other hand, if dielectric strength were to vary, say as $p^{\frac{1}{2}}$, then very low-pressure air would possess this property. Experimental evidence tends to show that, over a moderate range, dielectric strength varies roughly as p; but that at very low pressures this law is largely departed from, dielectric strength rapidly falling to a minimum, and then apparently increasing again as the exhaustion proceeds.

Cailletet found that air at 50 atmospheres was tremendously strong, a millimetre of it being able to resist a powerful induction coil. But it is well known that high vacua are apparently very strong too; though the latter is open to a doubt suggested by Shuster, who does not feel sure that the potential applied to small electrodes is really communicated by them to the gas.

Another mode of attacking the question, whether an upper limit to charge exists, would be by seeking for a diminution in the capacity of a condenser when highly charged. It is generally assumed that the capacity of a condenser is a constant quantity; but perhaps our evidence for this is at present insufficient. The electrostatic permeability of a medium (*i.e.*, its specific inductive capacity) may be found to diminish with high strain, and tend toward zero; in other words, a dielectric may become "saturated with electricity," just as magnetic permeability tends towards zero in a substance very highly magnetised, or nearly "saturated with magnetism." Unless it has been already done, condensers of various material (and air is the easiest) ought to be examined over a very great range of absolute potential; for a departure from the law of simple proportion between charge and E.M.F. could not fail to have an important signification, whether it be the signification I have hinted at or no.

In conclusion, I must confess that the latter portion of this communication has been perhaps too widely speculative; and it behoves me to explain that only a small portion of the whole paper was spoken by me at the meeting of the Association at Aberdeen; and that in ordering it to be printed *in extenso* the Committee have not made themselves responsible for the contents of the whole. I judged, however, that a little latitude would naturally be allowed in the opening of a discussion, and have therefore set down all the matters which, had time and convenience served, I was prepared to bring forward. The preliminary notes published in *Nature*, September 10, 1885, will accordingly now serve as a table of

---

* On any such theory, the bursting potential will vary as the number of molecules in a row between the plates, *i.e.*, as the cube-root of the pressure in the case of a gas. This is by no means true for the potential required to *begin* discharge, but it is not hopelessly out of accord with some measurements by Röntgen (*Wied. Elek.*, IV., 465), of the minimum potential sufficient to maintain a discharge already begun in pure dry air, as the following table shows. Though indeed the *fourth* root of the pressure would do better still:—

Minimum Potential.	Pressure.	$\frac{V}{\sqrt[3]{P}}$
639	615	75
577	499	73
503	385	69
402	198	69
301	68	74

contents. I expect my suggestions to receive a severe and salutary criticism, but trust that my admitted ignorance of much that has been done may be pardoned, for it is to be remembered that I was not called upon to draw up a conclusive report, but to furnish food for reflection and discussion.

LIST OF SUGGESTIONS.

It seems permissible and convenient to print here the list of suggestions issued, soon after the meeting, to the committee appointed by the sections A and B, "for the purpose of considering the subject of Electrolysis in its Physical and Chemical bearings," in case they might aid any member in deciding on a special subject of investigation. Some of the statements have been slightly amended; Nos. 11 and 12 have been added.

1. *Is Ohm's law true for Electrolytes?*—We know that it is roughly true for many electrolytes within certain rather wide limits of possible experimental error, but its *exact* verification for any one electrolyte has not yet been attempted, and it is very important. The question is whether, eliminating all effects due to rise of temperature, the resistance-coefficient of an electrolyte is absolutely constant for infinitesimal, ordinary, and powerful currents. There are two or three plausible ways in which a discrepancy from the exact law may be expected to arise.

(*a*). Supposing the ions absolutely dissociated and to make their way through the liquid according to customary laws of fluid friction, propelled as it were by the electric forces, as is assumed in the theories of Wiedemann, Quincke, Kohlrausch, and others, then so long as the frictional or viscous resistance they meet with varies simply as their velocity, Ohm's law is obeyed. But for very strong currents it is possible that the fluid friction may vary according to a higher power of the speed, and if so, the E.M.F. needed to drive a given current would be a little higher than that calculated from Ohm's law.

(*b*). If the ions are not absolutely dissociated, but exhibit a trace of chemical cling, then some finite though small E.M.F. may be needed to start a current, and thus a violation of Ohm's law may occur in the same direction as that already suggested, but most noticeable with infinitesimal currents. Helmholtz has shown that, for ordinary dilute acid, such an effect, if existent, is almost too small for observation; but in some worse conducting liquids it might conceivably be found.

(*c*). Very viscous or highly resisting electrolytes, such as glass, water, turpentine, &c., may show some discrepancy. In fact, this may be treated as a separate question, and asked thus:—

2.—*Is Ohm's law obeyed by very bad conductors?*—In other words, is the rate of leakage from a charged electrometer simply proportional to the potential with which it is charged, no matter what kind of slight earth connection is established? Polarisation E.M.F.'s are in this case probably too small to have much influence, and so the problem is in some respects simplified. The investigation is, in fact, precisely similar to an examination of the accuracy of Newton's law of cooling.

(*To be continued.*)

ELECTRIC ILLUMINATION OF LIGHTHOUSES.*

BY J. HOPKINSON.

The employment of the electric arc as a source of light for lighthouses has received attention for many years, but no apology is needed for returning to the subject, as the rapid development of electric apparatus brought about by the use of the electric light for other purposes, and the perfecting of new forms of motive power continually introduce new aspects of the question. An elaborate experimental inquiry has recently been conducted by the Trinity House concerning the relative advantages of electricity, oil, and gas as lighthouse illuminants, the actual experiments being addressed mainly to a comparison of the results obtainable in a practical shape by each illuminant in its maximum development, and it was conclusively proved that whether in thick weather or in clear the most powerful light at a distance and the most penetrating in fog could be exhibited from the electric arc. A further inference was drawn from a consideration of estimates of cost of the three systems, viz., that the electric light was necessarily costly, and could only be economical when enormous power was needed. The latter inference is no doubt valid so far as the particular electrical and mechanical appliances considered by the Trinity House Committee are concerned. The question may, however, be looked at from another point of view—given a limited permissible outlay and a limited annual charge for attendance and material, what can be done for the mariner by the aid of electricity?

Let us first see what are the intrinsic advantages of the electric arc. They all lie in great power in exceedingly small compass. The effect of the small size of the arc light upon the power of the light when used with optical apparatus, has been often pointed out, and the accuracy with which positions of danger can be marked by coloured sectors is also familiar to engineers. Less consideration has been given to the fact that it is undesirable to make the brightness of the light at any distance unnecessarily great, as the excessive brilliancy dazzles the eye. It is a desideratum, then, whilst directing as powerful a beam as possible to the distant sea, to avoid throwing more than a moderate illumination on the nearer sea. It is possible to realise this desideratum far more effectually with a small source of light like the electric arc than with any other illuminant; but with the exception of one lighthouse, so far as I know, it has been very partially attempted, the reason being a fear that the proper position of the arc could not be maintained. Almost the only complaint made by the mariner of existing electric lighthouses is that at a moderate distance they are dazzling. This is solely due to the fact that too much light is directed to the sea, or, which comes to the same thing for this purpose, the beam directed to the horizon has, in order to cover any possible error of position of the arc, too much divergence imparted to it. Owing to improvements in lamps and carbons, it is now safe to concentrate the light much more closely upon the horizon, with the double advantage of greater power where the light is wanted and moderated power where excessive power is injurious. This view is fully confirmed by the experience of the two most powerful lighthouses yet erected, otherwise than by way of experiments, Macquarie in New South Wales, and Tino in Italy, both constructed by Messrs. Chance Brothers and Co. The former is a first order optical apparatus, focal distance 92cms., and although the concentration on the horizon is greater than in any previous lighthouse complaints have been occasionally made that the light is too bright at short range.

Tino is a second order 70 cms. focus, and the principle of strictly limiting the divergence and giving a smaller proportion of the whole light to the nearer sea is carried much further. The result is that in clear weather the apparent brightness of the light as seen from the sea increases with the distance, till a distance of eight or ten miles is attained, when full power is reached. By means of the simple optical appliances provided there has never been any difficulty in keeping the source of light accurately at the focus. Experience, then, shows that a specially advantageous distribution of light between the nearer and more distant sea may be obtained with the electric light, provided a large and suitable optical apparatus is used.

Distinction of lights apart, the true measure of efficiency of a lighthouse may be said to be the fewness of the occasions at which it fails to be visible at its advertised distance, subject to the condition that at no distance shall its brightness be an annoyance. This is obtained by greater optical concentration towards the horizon, with limited illumination of the sea, together with the power of widely varying the intensity of the source of the light, conditions which can be better realised with the electric arc than with any other source. The electric light possessing the advantages named, it is its supposed great cost which bars its introduction in many lighthouses.

Why, then, should the electric light be so excessively costly in a lighthouse for any but the very greatest powers, such as are only worth providing for a few important landfalls? The great cost both of first outlay and maintenance appears to arise almost entirely from the fact that the machinery is arranged to supply on each and every night, however clear, an unnecessary amount of power; consequently the heavy machinery always used is remote from the lantern, and it is necessary that two men shall always be on duty, one in the lantern, and another with the machinery. Further, the dynamo machinery selected has been of a costly and cumbrous description. The essentials for a cheap electric lighthouse are that for ordinary states of the atmosphere there shall be provided a plant under the easy control of the lightkeeper himself, and which shall be precisely adapted to produce that amount of light which is wanted in ordinary states of the atmosphere; but for thick weather there shall be provided a much more powerful engine and dynamo, available also as a reserve in case the smaller machinery from any cause breaks down. The occasional machinery may be more remote from the lantern, as it is a small matter to require a second man to work on the comparatively rare

* Paper read before the British Association at Birmingham.

Digitized by Google

occasions when the maximum power is needed. A small gas engine and dynamo machine can be placed without any crowding in the room immediately below the lantern, and arrangements can be made whereby the light keeper, whether he is in the lantern or in the engine room, can ascertain at a glance whether the arc is in its proper position, with an error of less than one millimetre. The attendance on the lamp rotating apparatus of the lens (if a revolving light), engine, and dynamo would be easy when the whole is brought together so as to be under observation at once; in fact, the gas engine and dynamo and lamp constitute together a gas burner which, though consisting of many parts, is automatic throughout, and when at work requires nothing but the constant presence of a custodian, exactly as the gas lamp in a lighthouse requires a custodian as a guarantee against failure. The same end, viz., the concentration of the whole mechanical and electrical apparatus, under one pair of eyes could be attained of course in other ways; accumulators could be used, or a petroleum engine; but in order to give definitions and afford facilities for criticism, the better course will be to describe a suitable machinery, state what it will do, what attendance it will require, and what it will cost.

I propose, then, for an electric lighthouse, where small outlay is essential, the following:—A Dowson gas-producing apparatus and gas holder, the generator and superheater being in duplicate, each capable of making 1,200ft. of gas per hour, the gasholder having a capacity of 3,000 cubic feet; an 8 horse nominal Otto gas engine and series wound dynamo machine, placed in a room near the base of the tower, and copper conductors to the lantern, the dynamo having magnet coils divided into sections so as to supply a small current when required; a one horse nominal Otto gas engine and dynamo machine placed in the room immediately below the lantern floor, with gas pipe from the gas holder; one spare armature; current and potential galvanometers and switches; three electric lamps to receive either carbons of 25 mms. diameter, or any lesser size with complete adjustments for accurate focussing; the positive carbon below; one paraffin lamp as a stand-by; an optical apparatus of the second order, 70 cms. focal distance, extending from 29° below the horizontal to 80° above. The cost of this apparatus would depend upon the character of the light it was intended to exhibit. To fix ideas let it be assumed that the light is to be a half minute revolving light showing all round the lighthouse. There could then be supplied a 16-sided apparatus, with pedestal and revolving machinery. Provision would be made in the optical apparatus for giving the horizontal and vertical divergence desired by the same methods successfully used in the lighthouses of Macquarie and Tino.

Two focussing prisms would be fixed to form magnified images of the arc on pieces of obscured glass let into the pedestal floor, so that the keeper, whether in the lantern or in the engine room, can see at a glance the state of the arc, and observe whether it is of proper length with the carbons in line, whether it is exactly at the right height and in the centre of the apparatus. An error of one mm. would be glaringly apparent, and call for immediate adjustment, although its effect would be only a displacement of the beam five minutes of angle. The lantern would be 10ft. diameter with bent plate glass. The cost of the whole of the above described would be materially less than £3,400, the cost of a first order light and lantern with oil lamp and large burners.

Let us now see what result would be obtained. In fine weather the small engine would be used. Its effective power on the brake is fully 1½ horse-power; from this 1½ horse-power the dynamo machine produces considerably over 800 watts, say 800 watts on the arc itself, or 20 amperes through a fairly long arc of 40 volts. Of course the value of this in candles depends upon the colour in which it is measured and the direction in relation to the axis of the carbons. In red light the mean over the sphere would certainly exceed 1,200 candles. In clear weather or in slight haze or rain the beam of this light through the lenses would be much more powerful at the horizon and on the distant sea than any single focus light in oil or gas, or at least would be fairly comparable with anything yet exhibited with oil or gas, whether triform or quadriform. But on the nearer sea the illumination would be reduced, so that no annoyance would be caused by dazzling flashes.

In really thick weather or, indeed, in any weather when there was a doubt as to the visibility at the horizon of the lower power, the large engine would be used under the superintendence of the second keeper. This engine will give ten horse-power on the brake, and there is no difficulty in obtaining eighty-five per cent. of this as useful electrical energy outside the machine, that is 6,340 watts. From this deduct 10 per cent. for the leads and the lamp, and for steadying the arc, leaving 5,710 watts in the arc itself, or 114 amperes, with a difference of potential of 50 volts. Having regard to the fact that the optical apparatus here proposed acts upon a larger portion of the sphere than that used in the South Foreland experiments, that the vertical divergence is less, and that the potential difference is greater, and the current continuous, although less in quantity, we may safely assume that the power of the resulting beam would not be inferior; indeed, the maximum number of watts actually developed in the arc in the lantern in the South Foreland experiments must have been materially less than $175 \times 40 = 7{,}000$ watts.

It hence follows from the South Foreland experiments that in any fog whatever the flashes would penetrate farther than those of any existing gas or oil light. The increased size of crater compared with that produced by the current of 20 amperes, will give increased vertical divergence and so cause the maximum illumination to be obtained at a less distance from the lighthouse. The attendance of two men would suffice for all the duties of the lighthouse, because under ordinary circumstances one only need be on duty excepting whilst gas is being made. The usual course would be that with the exception of from 2 to 3 hours at the beginning of the night, the gas producer would be damped down, and when the small engine was at work the supply be taken from the gas holder. Consider the case of a long night of 15 hours. Immediately before lighting up, the producer would be put to work, and would require occasional attention from one keeper, but not his continued presence. For the first three hours of the night the engine would be using between 230 and 240 cubic feet of gas per hour, and the producer supplying between 1,200 and 1,300ft., so that at the end of three hours there would be a store of 3,000 cubic feet, more than sufficient for the night unless thick weather come on, so that after three hours one keeper only would be on duty at a time, and he would always be in attendance on the light. In the event of a fog the keeper on duty would ring up his mate, who would start the larger engine and set the producer to work, and remain in attendance on engine and producer so long as the weather continued thick. A staff of two is adequate at all times, but it is true that more work would have to be done both by day and night, about two hours in gas making and perhaps one hour in additional cleaning of machinery. It would be a question of expediency, depending on the amount of thick weather to be provided for, whether a third man should be employed, or additional pay be given to two men for the additional work demanded from them. Adopting the latter course the extra attendance would be covered by about £35 a year, with an extra allowance when full power is in use.

The consumption of coal would 4lb. per hour of lighting, of water about half a gallon, of carbons about 4in. per hour, allowing for ends wasted. Comparing with an ordinary first order light illuminated with paraffin the account for lower power would stand somewhat thus:—

Credit.

Oil and wicks and glass chimneys, an expense varying with time and place, but not less than annually.	£85	0	0

Debit.

Coal—9 tons at 25s.	£11	5	0
Wages	30	0	0
Oil and waste	6	0	0
Carbons—1,460ft. at £10 per 100ft.	14	12	0
Extra repairs and contingencies	15	0	0
	£76	17	0

which suffices to show that the charges would not differ materially from an oil light. The substantial advantage resulting would be that at a trifling cost per hour there is available at any moment a light of the greatest penetrative power.

Various objections may be taken to the arrangements here proposed and collateral points be raised, and it may be convenient to anticipate some of them.

A Dowson gas plant is unsuitable to a lighthouse built upon a rock offering no space beyond that occupied by the tower. True, until there is a paraffin engine burning oils as safe as the oils now used in lighthouse lamps, it is probable that the electric light will be excluded from such stations.

Gas engines and dynamos require a different training of attendants from that which they have acquired with lamps for oil. Again true; but it is also true that starting with fresh men it would be as easy to teach them to manage the electric plant as the highly developed burner now used. Still, no one interested would desire to see the electric light introduced into any service unless the keepers were intelligent and well trained, and the supervision vigilant. Indeed, the electric light should be introduced gradually into lighthouses, though not so gradually as has been the case, giving time for the light keepers and inspectors to gain the necessary experience.

The object of this communication is merely to prove that the minimum cost of an electric lighthouse is not *necessarily* greater than that of an ordinary oil light. The maximum power would not be available if the eight horse engine and dynamo from any cause failed. The engine and dynamo could of course be duplicated at moderate cost, about £400; but this appears hardly necessary, as the small engine, though of vastly less power, is still available. The purpose of the larger light is to reduce the number of occasions on which the light ceases to be visible at a stated distance, let us say to reduce it from 50 occasions per annum to 10. If, on some one occasion, this was not accomplished, the mischief would be the same as if on that one occasion the atmosphere had been a little thicker. The large engine is a complete stand-by for the small one.

A question well worthy of discussion is this. In thick weather is it desirable to direct the maximum illumination to the nearer sea instead of to the horizon? The correct answer to this question will undoubtedly depend upon the particular circumstances of each lighthouse, upon the height of the focus upon the sea, and upon whether the light is for the guidance of the maritime traffic and the protecting an extensive reach of coast, or whether it is primarily intended to mark some point of danger, such as the Wolf Rock, or the Eddystone. The presumption is in most cases against dipping the light; it implies robbing the distant sea. The keeper has to exercise his discretion from the appearance of the atmosphere in his vicinity, or in particular directions, and to decide whether it is impossible that the light is reaching its advertised range; if he judges wrongly he may restrict the range of his lights when it is unnecessary to do so. Some guidance may be obtained from the following conditions: With a second order light, and a continuous current of 114 amperes, practically maximum illumination will extend over a vertical angle of about 20′, and over a greater angle the illumination is not much less; we may, therefore, assume that 10′ below the horizon the illumination is as great as in the direction of the horizon, whatever efforts are made to concentrate on the horizon. If the focus be 100ft. above the water, the sea horizon is distant 11·6 nautical miles, and the range from a ship's deck about 15 nautical miles; but a ray dipping 10′ below the horizon will strike the sea at only 3·2 nautical miles from the lighthouse. If the focus were so changed that the light usually going to the horizon would dip 10′ below the horizon, the light which would usually strike the sea at 3·2 miles, would strike that surface at 2 miles distant from the tower. Probably the wisest solution is to duplicate the larger engine and dynamo, and in actual fog to use both engines and dynamos and both gas producers. The resulting current of 220 amperes not only has the effect of more than doubling the power, but also of increasing to a material extent the vertical divergence. In conclusion, I would repeat the points I seek to establish. An electric light need cost no more either in first outlay or annual charges than a first order oil light of ordinary construction. Economy can be secured by concentrating the machinery used in ordinary weather—*i.e.*, by bringing the engine and dynamo into proximity with the arc. It is a radical mistake to diminish the capital outlay by reducing the focal distance of the optical apparatus.

Discussion.

Prof. Adams, who was invited to open the discussion, begged to be excused on the ground that he had no intention of speaking when became to the meeting.

Prof. Forbes said he would like to emphasise most strongly the remark that was made towards the end of the paper, to the effect that it was false economy to think of trying to diminish the optical part of the apparatus, because they had so perfect a focus in the electric arc lamp. He remembered his attention being called to that fact by Mr. Thomas Stevenson, of the Northern Board of Lighthouses, that gentleman having upheld that view from the first. When the electric light was first introduced, one of the most important points that its advocates mentioned was that they might have the optical apparatus made to the size of a hat, because of the small focus. The long focus optical apparatus which they used in oil lamps and gas lamps, and which improved them so enormously, was capable to an equal extent of improving the electric arc lamp; and he wished most emphatically to support the opinion expressed by Dr. Hopkinson that the optical arrangements for the electric light should be of as long a focus as they were for oil and gas.

Prof. Barrett said he had had no experience of the value of the electric light in lighthouses, and therefore he did not quite understand why he had been called upon to address the section; at the same time, he could not disguise the fact that he had had some experience of the value of gas for lighthouses. If it was not out of order, therefore, to refer to the subject, he might mention that during the last autumn and winter Mr. Wigham gave him the opportunity of witnessing the extraordinary effect of his double quadriform, and it so happened that on both the evenings when the experiments were being conducted a fog intervened between the position in which he was placed and the lighthouses. On the second evening the fog was so dense that the fog siren erected there, and which was driven by a gas engine, could not be heard. That he regarded as a very remarkable circumstance, because he did not think there was any evidence that the electric light would penetrate fog of sufficient density to extinguish the sound of a fog siren; but there was no doubt whatever that the double quadriform was veay clearly seen, and that the whole shape of the light could be made out very well. He thought that one of the most striking features of the light was the diffused glare cast on the sky, which would create an impression on the eye, even when the electric light could not be seen. The experiments at Shoeburyness he had no doubt were conducted with great care, but so far as he could judge they were not pitted against the highest forms of gas, and it would be very desirable in his opinion that there should be comparative experiments made between the highest forms of gas light and electric light for the purpose. It was a pity, indeed, that the very best form of the arc light and gas light had not been tested on that occasion, to settle the question once for all. He knew that it was generally believed that in a fog of uniform density the electric light had the greatest penetrating effect, but in a fog of alternating density he fancied that if gas could be lighted from the pipe, whereby a large amount of energy could be liberated in a short space of time, then such a system in a fog might be even more effective than the electric light. With reference to the kinds of fog, he knew that the law being worked out showed the intensity of the light in a fog of uniform density, and here came into play the advantage of a large diffused light such as that given by the double quadriform light.

Mr. Wigham most heartily concurred in what had been said in the paper and also by the gentleman opposite (Prof. Forbes) with regard to the advantage of using a large optical apparatus in connetion with the electric light. He was exceedingly glad to know that so high an authority as Mr. Thomas Stevenson, of Edinburgh, should have pronounced in favour of the long focus lenses. He had before advocated their use, and he was greatly pleased to think that they had been adopted. With respect to the question of first cost, he ventured to express the hope that Dr. Hopkinson was quite right in his calculations, for he (the speaker) thought that this was a most important part of the question. It was very desirable that they should endeavour to reduce the expense in connection with such powerful lights. Dr. Hopkinson's method of doing it seemed promising, and, if that gentleman could also arrange the electric light for lighthouses in the way which he proposed to do—that was to say, by increasing the intensity of the illuminant in thick or foggy weather and diminishing it in clear weather, and as a natural consequence thus diminish the cost—it seemed to him (the speaker) a most reasonable course of proceeding. He took exception, however, to what Dr. Hopkinson mentioned as an undoubted fact that in the South Foreland experiments the electric light in clear or in foggy weather was found to be superior to the other illuminants tried. He happened to be present on one or two of the occasions when the experiments were being made, and the electric light in clear weather seemed to him to be surpassingly splendid, and conveyed the idea that it could not be beaten under any circumstances; and yet, notwithstanding that brilliancy, which was so great that at two miles distance one could read by its aid the smallest print and see the second hand of a watch, when the fog intervened one was surprised at the enormous extent to which it had been reduced by that circumstance. Mr. Dixon, than whom he supposed there was not a more careful and accurate manipulator and observer living, stated that the electric light in fogs at South Foreland was, he thought, about 16 per cent. greater than tha [of gas or

Digitized by Google

oil. Prof. Adams, he thought, on the contrary, told the British Association last year it was 60 times greater. Now 60 times greater was a very large percentage, very much larger than 16 per cent., so that between even scientific gentlemen there was a wide divergence of opinion as to the extent to which the electric light in fogs exceeded other lights. But under these circumstance, and especially under the circumstances referred to incidentally in the paper, that the electric light at South Foreland was not directed to illuminate the whole of the horizon as an ordinary lighthouse light would do, but was directed—not always, but on some of the occasions recorded, and on which this percentage of superiority was based—where the position of the observers was known, and where the electric beam was thrown upon them—when that was taken into consideration, as well as the very small percentage which the electric light showed, according to Mr. Dixon, not to speak of the difference of scientific men as to that percentage, and when it was also remembered that at the present moment, owing to questions and requisitions made in Parliament, the Board of Trade had promised to publish the correspondence which had taken place with all their authorities, and with shipowners and others who were not quite satisfied with the experiments at South Foreland, he thought it would be well for the public to withhold its judgment, and not to accept as an undoubted fact that the electric light was more powerful for lighthouse illumination than gas.

Prof. W. Grylls Adams said that there were one or two remarks which fell from Prof. Barrett and Mr. Wigham with direct reference to his own report as to the South Foreland experiments that he felt bound to ask the indulgence of the meeting for a few moments in replying to them. Prof. Barrett, in commenting upon the experiments in Ireland, said that when the fog was intense the fog siren could not be heard—that it could not penetrate through the fog. Now he (the speaker) was astonished at that, because he thought if they had a very thick fog indeed, still the sounds would spread perfectly well—that the fog, in fact, became the medium of the sound, which it conveyed from one point to another, and therefore, provided that it was tolerably homogeneous, the sounds would certainly not thereby be shut out. He did not know whether the idea was meant to be conveyed that the fog siren would be nowhere in comparison with the electric light exhibited on the occasion, but he thought that the general conclusion at which previous observers had arrived was that for near distances—not, say, more than two miles from a lighthouse—in the very thickest weather no light whatever would penetrate that fog, and then they were dependent on the fog siren for the protection of the shipping in the neighbourhood. The experiments which had been made proved that fog conveyed sound remarkably well. It depended, in fact, on the homogeneousness of the fog. With regard to Mr. Wigham's statement as to the difference between his (the speaker's) report and Mr. Dixon's, there was a little mistake as to the facts of the case, for Mr. Dixon did not state that the electric light was only 16 per cent. better. That, he thought, was the result of the general observations made, and he thought that they emanated from the members of the Trinity House and not from Mr. Dixon's report—in fact, from the observations made by unskilled persons in various parts whose reports had been sent to the Trinity House. With regard to his own report and that of Mr. Dixon, he must say that they agreed wonderfully in respect to the intensity of the electric light in different states of weather. There was not what might be called any serious disagreement between the two, as might appear from what Mr. Wigham had stated. He thought that Mr. Wigham's own figures would bear him out as to the difference between the intensity of the electric light and that of any other light, namely, that it was 60 times as bright as that which any other illuminant gave. Mr. Wigham himself stated that at very great distances from the lighthouses, for instance, the light was so intense that they could see to pick up a pin.

Mr. Wigham: Sixty times greater in the fog, you said.

Prof. Adams replied that it depended on the character of the fog. He did not think that he stated it so in his report. A small portion of the report taken without regard to the context might not represent the case as it actually stood. The results which he gave were the results of definite measurements of intensity of light—not any assumptions whatever, but simply the result of measurements—and the whole matter was fully discussed in the report, to which he would draw attention, and he thought it would be found by all who consulted it that there was no essential difference between Mr. Dixon's report and his own; in fact, they were both astonished to find so close an agreement between the results. Of course Mr. Dixon's report referred to one series of experiments made on one night, and his (the speaker's) to a series conducted on another night, so that they might appear to be very different. But it was very easy to contract a leaning in one direction or another without being conscious of any such leaning. He thought, however, that if the whole of the reports were gone through—the general result of his work and that of Mr. Dixon—it would be found that there was a very remarkable agreement between them, and that at any rate they would form a scientific basis from which any one would draw correct conclusions, because there were figures given as to the intensity of the light, and so on, as well as the circumstances under which the experiments were made.

Sir Wm. Thomson said he was sorry that he was not present during the reading of the paper, but he could see from the short abstract of it that Dr. Hopkinson's proposal was one of very great weight, and one from which they might hope to see satisfactory results in practice. With reference to the power of electric light, he did not know whether an erroneous impression which had got abroad from observing the lights on the Thames Embankment had been completely dispelled. Those who were scientifically engaged with electricity had, he thought, got rid of any wrong idea they might have entertained as to the relative power of the electric light and the other ordinary lights; but he did not know that the result of their investigations had been as yet quite appreciated, because he thought that many people were still under the impression that the electric light was less powerful for penetrating fog than gas, so that though the former might be greatly superior in favourable circumstances—when there was no fog—there was still an idea that it lost that superiority in fog. He thought he was right in saying that the result of the investigations of the president and those referred to by Prof. Adams generally had been to show that there was no discernible difference between the penetrating power of the electric light and gas light in a clear white fog.

The President: A very small difference.

Sir W. Thomson: Fogs at sea were white in character, not that kind of fog that they were all familar with in London, Glasgow, and Birmingham, in which the substance that consumed the light—converted the light into heat he should say—was not particles of transparent water, but sooty particles. When the fog was such as to redden the sun or moon seen through it, then, in relative comparison of power, gas or oil would have the superiority; but when the fog was such as to leave the sun or moon white as seen through it, there would be no sensible difference or no difference at all between them. Lord Rayleigh had given a practical mathematical explanation of the absorbing power of fog upon light, and had shown how it was that there should be no difference in the case of a white fog, although there ought to be a large one in the case of a smoky fog. There was one point, however, which Sir James Douglass might probably answer. In the first place, Lord Rayleigh's proposition that there was no loss at all in a white fog seemed startling. The whole light on lighthouses passed away as light, and none of it, or but a small proportion of it, was converted into invisible heat. The light itself became invisible as a point, because of its scattered effect, but the light was all there. The result was this, that the loom of the electric light in a fog, though not visible as a point, might still be most valuable to the mariner. In fact, when the light itself could not be seen at all, a general lighting of the sky in the direction of the light would be visible, and would give the light wanted by the mariner. So that even when the light was not seen practically at all there was still the same relative superiority of the electric light over gas, and if the electric light gave sixty times as much illumination as the oil light, at a distance where neither the one nor the other could be seen, the electric light would have sixty times the power of illuminating the sky. He would like to ask whether the loom of the light on the sky was largely of practical importance in navigation. He could not say whether it was or not; it certainly was in certain other conditions. He thought, from what was stated in Dr. Hopkinson's paper, that they might fairly hope that in point of economy, as well as in point of its great advantage in case of fogs, the electric light would commend itself more and more as a scientific result, which was now ready to be put into practical form and taken advantage of very much more than had hitherto been the case.

Mr. W. M. Mordey was understood to ask whether it was not the fact that in the French lighthouses, where the electric light was used, they employed continuous instead of alternating currents for their apparatus?

The President: Both.

Mr. Mordey said that this was a point on which he wanted information—namely, the cause which had led Dr. Hopkinson to recommend the use of continuous currents. He was glad to see that Dr. Hopkinson did recommend that course, because, like most practical electricians, he had a prejudice against alternating currents for most purposes. He believed there were some practical advantages for the use of alternating currents. The distribution of the heat in the arc was more even, for instance, than it was in the case of the continuous current. The heat was greater at the positive carbon, and the other carbon was similarly affected, and with the continuous current there was a flame much more difficult to deal with than was the case with the other current. As the point was mentioned in the paper which had been read, and was of some practical interest, he would be glad to get some information upon it.

Prof. Barrett remarked that he did not intend to say that a gas lighthouse was superior to a fog siren in all cases, but what he said was that on the particular evening on which the experiments were made the fog siren was not heard at the place of observation though they had listened for it, and the light of the quadriform was seen. The fog was probably not homogeneous. They knew it was dense round the lighthouse because all the lights were on, and it was dense round the place at which they were making observations six miles off, because they could not see neighbouring lights, but the intervening space might have been clear, and in a light of that description it seemed as if the quadriform light was superior to a fog siren. There was another fact that he wished to emphasise, and that was that gas could be usefully resorted to where they could use a large amount of energy suddenly—that was to say, by a sudden large flare of gas at periodical intervals, which ought to be seen at great distances.

Mr. Swan said that if there was any value in Prof. Barrett's suggestion of using a large gas flame, he thought that it was quite possible that a similar effect might be obtained from an electric accumulator with the electric light. If it was a desideratum for the economisation of the apparatus that intermittent effects should be produced in the manner which Prof. Barrett suggested, very similar effects might be produced through the mediation of an electric accumulator.

Mr. C. H. W. Biggs remarked that there was a reason why a certain admiral did not fire a salute, and perhaps there was a cause why the siren was not heard on that particularly bright night. Was there any proof that the siren was going on the occasion in question?

Mr. Kenward (who had read the paper in Dr. Hopkinson's absence), replying to the question put by Sir William Thomson, as to whether any practical results had been obtained from the luminous glare on the horizon from the electric light, said that he could quote one instance where such an effect had been of considerable service. At the present moment the largest lighthouse apparatus in the world was that at Sydney Heads, which was known as the Macquarie light, and which had been erected by the

Digitized by Google

enterprising colony of New South Wales. With regard to that light, mariners had reported that the luminous glare had been seen from it at a distance of sixty miles, and had been accordingly of great use to vessels far off, which had thus been able to get a sort of *avant courier* of the direct beam of light.

The PRESIDENT said that before calling on the section to accord a vote of thanks to Dr. Hopkinson for his very valuable paper he would offer a few observations. He did not think he was intruding on his hearers at the present time, as he had been a great many years connected with light-house engineering, and as he was connected with the South Foreland experiments, and as he was so ably assisted in a portion of the work by Prof. Adams, by Mr. Harold Dixon, Mr. Vernon Harcourt, and others, he would make a few remarks on what was done there, simply because the experiments conducted there had been referred to in connection with the paper read. Dr. Hopkinson had brought forward a very important subject in connection with the electric light as applied to lighthouse illumination. Dr. Hopkinson had attempted to show them (he was not sure that that gentleman had succeeded, however, although he assured them that it was a fact) that he was able under nearly all conditions of ordinary lighthouse illumination to compete with oil and gas by electricity. Dr. Hopkinson had entered upon a thorny path, because it was one of the most difficult applications of lighting to compete with. It must be remembered that in such a task they were dealing with very small installations, and in all cases they were dealing with an individual installation and a smallish one. They were dealing with it in an isolated position, in some cases of great difficulty. They must all be aware that mineral oil was difficult to compete with, if for no other reason than because of its cheapness. He remembered the time when they used to pay 6s. 8d. per gallon for sperm oil, but they were now able to obtain an oil greatly superior to the sperm for sixpence a gallon, and therefore that was a bold man who said he could illuminate a lighthouse by electricity as against oil at sixpence a gallon. What had occurred in connection with the South Foreland experiments was this. They had with oil and gas gone to powers ten to sixteen times greater with a single illuminant than they had a few years ago—so recently, in fact, as the French Exhibition of 1867. Electricity had been going on in a greater ratio, and it was now determined by those who had charge of the experiments at the South Foreland—by the Trinity House—in which scientific men from all parts of the country agreed, that at the present moment gas and oil reached an intensity of illumination to meet the ordinary requirements of the mariner. In narrow waters they could very easily overdose the mariner with light, and there were instances on record where the seamen had asked for the intensity of the light to be reduced. Of course that was never said in thick or foggy weather, but in clear weather it was not necessary to have so great a light. Of course, as they had been told, they might as well attempt to compete with the electric light as an illuminant as to expect that a single candle would compete with the sun. It was out of the question to talk of competing with electricity by means of oil and gas, although they had progressed so far that both oil and gas were far ahead of what they used to be. Again, they had an intensity 200 times the initial intensity per square inch of focal area. Therefore, anyone could appreciate the advantage of the electric arc. It was quite true, as Mr. Wigham had observed, that the apparatus at the South Foreland was focussed on the observers, but it must be remembered that the apparatus there was experimental, and therefore it had not time to be seen but from particular points of observation. But that was one of the merits and not one of the sins of the electric light, because they had thus a small arc which they could adapt to special circumstances, and by which they need not rob the mariner of any portion of the light which they were giving him in thick weather. In other words, the utmost intensity of the light could be directed to the position in which it was necessary. Prof. Barrett referred to the case on the Irish coast where the siren was not heard when the gaslight was seen, but all that he (the speaker) had to say in reply to that was that it must have been a very poor siren, because a siren should be heard in any circumstances during fog at a distance of two or three miles. It was quite true that it was one of the most disappointing instruments that he had ever anything to do with. They had sirens at work where they had 150 horse-power put into the sound, and yet that sound at times was not heard a mile away, generally in fogs, but frequently, on the other hand, the sound was heard 10, 12, or even 20 miles distant. There were times when it was not heard at two or three miles. But this occurred at the South Foreland—he did not ask the Section to believe him, but he asked them to look upon him as a disinterested observer—on one occasion during a thick fog they were turned out, as they were subject to be at any hour of the night during thick weather, between one and two in the morning, and they found that they had to walk up to within nearly half a mile of the lights before they could see them. At the moment they were hearing the South Sand Head sound at a distance of three miles clearly. Well, it occurred to him, why should they waste this light, when one of their feeblest sirens, with only 1½ horse-power, was giving them an intelligible sound at such a distance. Several vessels in the offing near to them were heard distinctly, so that it must have been a very different state of things, or the instruments must have been different. Another point was referred to, he thought, by Mr. Wigham (and it was not the first time that it had been referred to) on which he would like to say a few words. It was this. When they commenced the experiments at the South Foreland it was intended that each of the illuminants, mineral oil, gas, and electricity, should do its very best. Mr. Wigham suggested four lamps, a superposed apparatus and four elements, four of the largest burners for lenses, all superposed, and they prepared three for the electric light. They expected at the time that they would place all their energy in one arc. It was thought desirable to determine the question whether it was most economical to place all the light in one, or in two, or in three arcs. They soon found that they could work the one electric arc with all their energy most efficiently in one focus. And the apparatus referred to to-day of the second order—750 millimetres focal distance—had been decided on for the present. That, he might remind the Section, was a very important question. It was not absolutely necessary that they should have a second order apparatus for the electric arc, and not that he would say that the second order of apparatus was right. The French had gone from the fifth order to the sixth, and probably they might go further, but this he thought unnecessary. It was very desirable for the manipulation of the light that the keeper should enter the apparatus, and the second order size was just sufficient. If the second order size with such a pair of carbons (shown) would meet their requirements as to the necessary duration of the flashes (if they had not the necessary length of flash they would, of course, require a smaller apparatus), and if that were sufficient to meet all requirements, any enlargement of that apparatus was a positive waste of money. With regard to the question of direct and alternating currents referred to by another gentleman, there was a crater produced in the carbon by an alternating current. When they had had a direct current the crater in one carbon would be very much larger than in the other. It was very evident that when they placed two carbons in that way the best of their light was lost—locked up in the craters; and even with a single crater with a direct current there must be at all times a great loss of light, because the positive carbon must cover it to a very great extent. He had been making experiments with carbons fluted, for which he thought there was a great future. By using fluted carbon they abolished the carbon altogether, which was a very important point. He had a model (shown) of a carbon that had been at work with an arc of 30,000 candles. The walls of the crater were completely eaten or licked away by the attack which was made upon the crater in the flutes. Then, again (and this was another very important point referred to just now), they had the arc held centrally in the carbon. That for lighthouse illumination was a very important matter. Any departure from the central position of the carbon affected the flashes, sometimes affecting their duration. A flash might begin too soon or end too late, or it might be too prolonged. When prolonged it was considerably weaker, and, consequently, the flash might be entirely lost from want of intensity. Then, again, nothing to his mind could be more perfect than the luminary formed by a pair of the best carbons. They had in that case a luminary which was perfect as regarded its compactness, perfectly central, and with large increase of radiance vertically by the light which passed between the flutes above and below compared with the solid carbon. They found also that the carbon was cooler. The heat was localised at a point, which was so much the better for the lamp.

Mr. WIGHAM said that as the President had mentioned his (the speaker's) name in connection with his address, he thought it was right that the audience should know that it had been his desire that all the illuminants should have been tried at their very best and under all circumstances.

The PRESIDENT then moved a vote of thanks to Dr. Hopkinson, which was cordially passed, and the proceedings terminated.

COMPANIES' MEETINGS & REPORTS.

Eastern Extension, Australasia, and China Telegraph Company (Limited).

The twenty-sixth ordinary general meeting of this Company was held on Wednesday, at Winchester House, 50, Old Broad-street.

The chair was occupied by John Pender, Esq.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting, and the minutes of the last meeting, which were confirmed by the present meeting, and signed by the Chairman as correct.

The CHAIRMAN: I presume you will take the report as read. I will, as usual, before asking you to approve of the report, make some few remarks and give some figures as to the working of the Company in the last six months. The gross receipts for the half year have amounted to £224,843, against £259,476 for the corresponding period of 1885, showing a decrease of £34,633. This loss of revenue is in some measure attributable to the general depression of trade, but it is chiefly owing to the absence of any stirring incidents, such as those which were of continual occurrence last year, and which, if you remember, I referred to very fully in the speech which I made six months ago. This will be understood when it is mentioned that in the six months ending June, 1885, public interest was excited by the Egyptian campaign, to which New South Wales sent a contingent; the Penjdeh incident in Afghanistan; and the hostilities between China and France, arising out of the annexation of Tonquin. All these events caused a considerable exchange of telegrams, by which we, as well as other telegraph administrations, largely benefited. Our revenue was never so large as during the sitting of the Berlin Conference, to which, as you are aware, this Company was invited to send representatives. We were urged on all sides to lower our tariffs, which were alleged to be prohibitive, and, although we did not see our way to reduce them to the extent desired, we partly yielded to the wishes of the Australian representatives, encouraged by the growth of traffic, which, as regards Australia, had for some years past shown an annual increase of over 10 per cent. It is a singular circumstance that within a few months after the Conference, when we were committed to make some reductions of tariff, the traffic began to show some signs of falling off, which has continued ever since. The decrease for the half year under review is spread over the whole

Digitized by Google

of our system, as will be seen from the figures I will mention. This may appear a rather gloomy view of the question, but, as I have often said on all these occasions, telegraphy is greatly influenced by trade, and, as we observe, there is a very great change going on now in trade. Even in the City they are talking of "booms," and I expect we shall begin to feel that excitement before long. In the six months under review our income from Australasia shows a reduction of £13,000; from Java, £2,500; from Tonquin, Cochin China, and Siam, £5,200; from China and Japan, £5,000; from local traffic, £2,200; from the New Zealand subsidy, £2,700, and lost by exchange £4,000. That is the silver question, which is engaging a very great deal of attention at the present time. All these sums amount to £34,600. They are together a large sum at present; but there is nothing in them that may not be materially altered when I have the pleasure—if I have the pleasure—of addressing you six months hence. Unfortunately, since the close of the half-year, the traffic has shown a proportionately larger decrease than in the first six months, amounting to £30,000 for the three months ending September, against a loss of £34,000 in the previous six months. Only a portion of this amount is attributable to the reductions of tariff which came into force on the 1st July, there being, except in the case of Australia and Java, an actual falling off in the number of messages, and this diminution of traffic was unfortunately aggravated by our misfortune last month, when both of our India-Penang cables were simultaneously interrupted for the first time since this portion of our system was duplicated nine years ago. I am pleased to remark that as far as Australia is concerned, there was in the last quarter a small increase in the number of words transmitted over the corresponding three months of 1885, which slightly lessened the loss occasioned by the reduction of tariff; but in regard to China, Tonquin, and Cochin China, we have not only to bear the loss resulting from the reduction of tariff, but also the loss arising from the falling off in the traffic. The working expenses for the half year have amounted to £81,775, against £74,418 for the corresponding period of 1885, showing an increase of £7,357. This increase is practically accounted for by our having had an additional maintenance ship, as compared with the corresponding period of 1885. This expense will, however, be saved for the current half year, the ss. "Agnes" having been sold at public auction in July last. The usual interim dividends at the rate of 5 per cent. per annum have been paid for the half year, but in consequence of the decrease of revenue already referred to, your Directors considered it prudent not to pay any bonus, but to carry forward the whole balance of £34,980 to the current half year. If the figures during the current half year admit of a bonus being distributed, it can be dealt with at the end of the year—that is six months hence. In fact, when we first established the principle of bonuses we agreed that the bonus should be paid at the end of the year, but some of the shareholders were anxious to get the benefit of it at the end of the first six months, and expressed a wish to the Directors to that effect, and said that the money would be better in their pockets than lying at the bank, and therefore we agreed to give them the bonus half yearly, being perfectly satisfied that it was earned. I hope there will be a better state of things next half year, and if the figures warrant the payment of a bonus it will be dealt with at the end of the financial year. It will be seen from the printed report that the policy of strengthening the Company's system has been continued by the renewal in June last of the Singapore-Penang (original) cable. A considerable portion of the old line was recovered, and when overhauled and repaired, will be taken into the Company's stock of spare cable at Singapore for future extensions or renewals. The cost of the operation will be dealt with in the current half year's accounts. I have on various occasions referred to those cables and the principle upon which we are renewing them. I have always told you that we have had to contend against an insect, the teredo, which is very destructive, and that the injury thus done to the cables was such that we thought it better to meet the difficulty at once, and lay down brass sheathed cables so as to prevent anything like damage or interruption from the teredo. We have done this successfully, and, so far, since we have used this precaution, we have had no fault from the teredo. The maintenance ships have been kept busily employed during the greater part of the half year in effecting numerous repairs, but no interruptions of importance occurred to the traffic until after the close of the six months under review, when both our India-Penang cables were interrupted, as already stated. Fortunately, however, they were both repaired after thirteen days total interruption, notwithstanding the south-west monsoon prevailing at the time. All the cables are now working well. Our relations in regard to the China system, I am glad to say, have been materially strengthened since I addressed you six months ago. I went over to Copenhagen to meet the Directors of the Great Northern Company, with whom we work this system. There were difficulties and sores which had existed for a considerable time. These were not likely to be removed by correspondence. The result of my visit was that we placed our relations with the Great Northern Company on a most satisfactory footing. Those relations will continue for a very long period of time, and, so far as I can judge, will be very beneficial to both companies, and, I think, lead to considerable economies in the working of the two systems. We are going to work at Shanghai under the same roof, and also at Hong Kong. The effect will be economy, and, I believe, efficiency. We have gone into this question with a minuteness that ought to insure stability in the working of the system. We had with us a representative from China of our system, and a representative from China of the Great Northern system, and, putting all our heads together, I believe we have made such an arrangement as ought to be very satisfactory, and very beneficial to all concerned. The next question I have to deal with, and which I referred to at the last meeting, is the negotiation that has been going on with the New Zealand Government. Nearly nine months ago, the subsidy of £7,500 per annum which we received from the New Zealand and New South Wales Governments came to an end. I made proposals for renewing it. The New South Wales Government were quite prepared to renew it for 10 years, but the New Zealand Government objected to renew it for that period, but agreed to a renewal for five years. We did not consider that the five years' renewal was sufficiently beneficial to us, because we had found during the whole of 10 years that the return from the cable did not give us, after calculating amortisation, more than 2 per cent. on the capital invested. I therefore held that we were entitled to have the subsidy renewed for the full period. However, after some negotiations, and the Parliament having decided on the five years, we reconsidered the question, and, looking at it in connection with the larger questions which we hope to see carried out eventually in the Australasian colonies, we agreed to accept the five years. Negotiations then went on again with the Postmaster-General of New Zealand, Sir Julius Vogel—a gentleman very well known in London and all over the colony, when at the head of the Government, and it was with him that I conducted these negotiations. After trying in every possible way to conciliate the New Zealand Government, and to get them to renew for five years, we have been driven into this position—that they have declined the five years, and they have declined arbitration; and the reason given for this is that they think that any subsidy would interfere with the laying of an opposition cable between Australia and Europe *vid* the Pacific. Now, it is well that you should know the whole of the facts. There is no immediate possibility—I do not think that there is any possibility—of a cable being laid in opposition to our cable, for the simple reason that I do not suppose that the colonies at the present moment, but particularly New Zealand, have too much money to throw away. I do not think this would be approved, and I doubt if the people of New Zealand would approve of the spending of money on an opposition cable when they can get from the present Company a cheaper and more efficient system of telegraphy than can possibly be procured by another cable. I make this statement advisedly, and I wish it to go before the public by the press taking full notice of it. I will give you figures which will bear out my statement. Taking the figures of the proposed opposition, and taking the subsidy which they would require to cover expenses and obtain 5 per cent. on their share capital as compared with the cost of our guarantee proposal, calculated on the same basis and giving precisely the same tariff, the cost to the Colonies apart from any subsidy that might be obtained from Canada would be as follows:—

Colony.	Subsidy for Pacific Scheme.	Guarantee for Existing Companies.
Victoria	£35,680	£16,353
New South Wales	34,194	15,672
South Australia	11,610	5,321
Western Australia	1,223	560
New Zealand	20,945	9,599
Queensland	21,503	5,274
Tasmania	4,845	2,221

I think you will agree with me that no body of sensible men, either at home or in the colonies, would be justified in subsidising a company with a single line of cables in opposition to an existing one doing the work so well as we are doing it—with a duplicate system. I therefore have no fear of any opposition coming if it is dependent on receiving a subsidy from the British or Australasian colonies. I will go a little further than that. If, instead of subsidising an opposition company, they will give us the subsidy which the opposition company desires to get, that is £100,000 a year, we will give them a tariff of 2s. 6d. instead of 4s, the tariff which the opposition proposes to give. That would be an extraordinary revolution, to have a message carried to Australia on such a tariff as 2s. 6d. We are prepared to do it if they will give us the terms the opposition company want, and without obtaining which it could not cover expenses, and even then the tariff would be 4s. I speak from practical experience of a great many years of submarine telegraphy. Gentlemen who try to get up opposition companies frequently know nothing about telegraph working, but if they can get millions sterling to manipulate, they expect a considerable amount may be shared between them in the form of promotion money. Your Company has not been established in that manner, but upon fair and sound principles, and by sound principles we are determined to stand. I think we can meet all competition, come from what quarter it may, if it is dependent on subsidy from the Governments of Australia, New Zealand, and England. I think I have shown you pretty clearly how we stand at the present moment. I will say one word more in regard to the correspondence which has taken place in regard to the New Zealand cable negotiation. I have told you that we have exerted every possible means of bringing about a conciliatory arrangement. We have got with us—which was not always the case—the Press of New South Wales and the Press of Victoria. I believe I may say that the Governments of those two great colonies also approve the position we have taken up. When we offered to refer the case to arbitration, we thought it was not possible that Sir Julius Vogel could decline the proposal. He has, however, this morning, after a week's delay, refused arbitration. He does not see that there is any necessity for it. Now, gentlemen, on Monday next we shall put up our rates between Sydney and New Zealand from 6s. to 10s. per ten words for Intercolonial telegrams (hear, hear), and we shall show them that private enterprise, having done so much for the colony, is not to be trodden down in the way which they have attempted. Nay, more than that. Our bargain with New Zealand was that even after the termination of the subsidy they were bound to give us the same accommodation for the following ten years, whether the tariff was raised or not. They now threaten to take away that accommodation. If they do we shall shut the door and lock it till they give us the amount that will enable us to carry on the traffic with a fair profit. I think you will approve of that policy [applause]. I am perfectly satisfied that if you do the public of Australia and of

Digitized by Google

New Zealand will not tolerate a suspension of traffic for one week, but will force Sir Julius Vogel's hand, if it does not force him from power. I am sure you will give us your approval of putting up the tariffs, and they will remain up until we get such a satisfactory arrangement as a company of this importance, dealing with such interests, is entitled to at the hands not only of New Zealand but from every Government in Europe. We have had that consideration, and we shall insist on maintaining the dignity and position of this Company by not being trodden on by the Government of New Zealand. Gentlemen, I have spoken strongly and warmly, but I think it just as well that these remarks should go abroad strengthened by the approval of the shareholders whom I am now addressing. With these remarks I beg to move, "That the report and accounts now submitted be received and adopted."

The Most Hon. the Marquis of TWEEDDALE seconded the motion.

A short discussion ensued, during which Mr. GUESDON deprecated the practice of sending out proxies unless in blank and unstamped, and called attention to the increased working expenses in recent years, and urged economies; and Mr. GRIFFITH warmly supported the policy of the Board, whereupon

The CHAIRMAN said: I have heard Mr. Guesdon speak on the same subject for a good many years. He is one of those whom I call economical reformers; but I am always glad to hear his side of the question. I am bound, however, to say that I cannot in the least degree agree with him. In the first place I will deal with the question of proxies I may tell you that we are perfectly aware of the decision of Mr. Justice Kay on the question of proxies; and the proxies that have been sent out have not been at your expense. The Directors have sent them out at their own expense. Now let me say one word for proxies. We wish to act legally, but also fairly, to the large body of shareholders. We have nearly 5,000 shareholders, and there are not more than 100 here to-day. Is it right or fair that the absent 4,900 shareholders should be left entirely to be dealt with by the 100 who are present? I may say, further, that there is one-fifth of the shareholders in Ireland, and it is not always convenient for them to take such a long journey to attend our meetings. I think, as has been often explained at these meetings, that the least that shareholders having confidence in the Directors can do is to give them, at an unfortunate time like this, their proxies if they cannot be present themselves. I should like it very much better if all our shareholders were present, as then our policy could be fairly judged, and they would consider what was best for their own interests and vote accordingly; but I cannot see the justice of letting 100 shareholders control the affairs of 4,900. The decision the other day might have been just. I daresay it was, or it would not have been given by one of our eminent judges, and therefore we, acting in the interests of the large body of shareholders, preferred to pay ourselves for proxies rather than that their interests should be for one moment jeopardised. That is my view of the proxies. Now, in regard to economies which Mr. Guesdon has suggested, he forgets that this Company has become a company of very great magnitude indeed. He cannot have followed its growth if he thinks that the same number of clerks and the same amount of accommodation are sufficient for the Company to-day, as when it was first introduced before the public. We have grown "by leaps and bounds," we have paid you high dividends. We have been obliged to open stations in almost every part of the world where civilisation and commerce exist. We have followed the flag everywhere, and do you expect that that can be done without a large extension of expenditure? We have increased our income at the same time, though I have told you to-day that we are just now passing through a crisis of depression. We cannot be exempt from the existing depression any more than other institutions. We live by trade, and, as I have frequently said on these occasions, there are cycles of good and cycles of bad times. Curiously enough, we have grown under all these cycles, and although we have lately had depression, I see even now a return of better times. We have made this Company great and prosperous, because we have acted liberally and justly in the conduct of your affairs. If you are to bind us down to what I call a small way of conducting your affairs, I am afraid we shall not be able to show you anything like the results we have been able to show you in the past.

The CHAIRMAN then put the motion to the meeting, which was unanimously carried.

Mr. GIBB: I wish to propose a vote of thanks to the Chairman and Directors for their services. I think that no one can have been here to-day without seeing the zeal and ability with which our affairs are conducted.

Mr. VARLEY: I have great pleasure in seconding the motion.

The resolution was then put to the meeting and carried unanimously.

The CHAIRMAN: I am very much obliged to you, gentlemen. We are always watching your interests closely. There was some remark made about the attendance of the Directors. I assure you that it is not only your Board meetings that you must think of. There are attendances by some of us at every hour of the day. For myself, for instance, there are very few days on which I am absent from the office. As long as we are here, we will maintain the dignity as well as the financial position of this Company to the utmost of our power.

The proceedings then terminated.

Brazilian Submarine Telegraph Company.

Report and accounts of the Directors for the half year ended 30th June last, to be submitted to the twenty-sixth ordinary general meeting of shareholders, to be held at Winchester House, 50, Old Broad-street, E.C., on Thursday, 4th November, at two o'clock.

The revenue for this period amounted to £75,856. 10s. 10d., and the working expenses to £12,695. 5s. 4d. After providing £9,680 for debenture interest and sinking fund, and £1,430. 7s. 4d. for income tax, there remains a balance of £52,050. 18s. 2d. To this is added £2,123. 16s. 4d. brought forward from 31st December last, making a total of £54,174. 14s. 6d. A quarterly interim dividend amounting to £19,500 has been paid, and £13,000 transferred to the reserve fund, leaving a balance of £21,674. 14s. 6d. The Directors now recommend the declaration of a final dividend of 3s. per share, making, with the interim dividends, a total payment of 6 per cent. for the year ended 30th June, 1886, and that the balance, £2,174. 14s. 6d., be carried forward to the next account. Since the last general meeting the African Direct Telegraph Company have completed their system of cables between this Company's station at St. Vincent and the British possessions on the West Coast of Africa, viz.:—Bathurst, Sierra Leone, Accra, Lagos, Brass, and Bonny. The traffic from these lines will pass over this Company's cables between St. Vincent and Lisbon. The subscription by this Company of £75,000, being one-third of the share capital of the African Direct Telegraph Company, authorised by the extraordinary general meeting held 21st January last, has been effected by a second issue of 5 per cent. debentures, at the price of £105 per £100. The various sections of the Company's line are in good working order. Senor Carlos Frederico Taylor and Mr. Frederick Youle retire by rotation at this meeting, and being eligible for re-election as Directors, offer themselves accordingly. The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

BUSINESS NOTE.—In consequence of a misunderstanding which appears to prevail among the trade, Messrs. Goolden and Trotter ask us to state that while the foreign agency of their dioptric glass (Trotter's patent) is in the hands of Messrs. Woodhouse and Rawson, the English trade remains in their own hands as heretofore; there being no sole agency for Great Britain.

NOTES.

ELECTRIC RAILWAY IN BAVARIA.—An electric railway has been opened for public use at Schwabrig, Bavaria.

BOOKS RECEIVED.—From Messrs. Iliffe and Sons we have received a copy of "Practical Dynamo Building for Amateurs," by F. W. Walker.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 29th ult. amounted to £4,104.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ended Oct. 31st were £4,825.

LUBECK.—The Municipality of Lubeck has voted the sum of £17,000 for the establishment of a central electric lighting station to supply both arc and incandescent lamps.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October amounted to £49,374, and to £56,994 in the corresponding period of 1885.

DARKEHMEN.—The village of Darkehmen, in the Western Prussia, has been lit by electricity, the motive power for which is furnished by turbines on the River Angeraph.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of October, amounted to £2,013, against £1,756 in the corresponding period of last year.

PERSONAL.—We understand that Messrs. Bernard Drake and J. M. Gorham have left the service of the Electric Power Storage Company, and will shortly establish themselves as consulting electricians.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 31st Oct. are £2,091, as compared with £1,942 in the corresponding period of 1885.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October amounted to £37,185, and to £43,986 in the corresponding period of 1885.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 29th ult. were £3,307, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THUNDERSTORMS IN BAVARIA.—The number of severe thunderstorms in Bavaria has this summer been unprecedentedly large. No less than 591 instances of personal or material damage from lightning are reported for the three months ending in June last.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this company for October were £22,240, and the receipts for the period from 1st January to 31st October, £217,800; for the corresponding months in 1885 and 1884, £241,640 and £234,680 respectively.

THE TELEPHONE IN RUSSIA.—It appears that up to the present time about 10,670 kilometres of telephone lines have been erected in Russia, of which about 4,000 kilometres are in St. Petersburg and about 3,000 in Moscow. The number of instruments in use is not stated.

INTERRUPTION OF CABLES.—The cables between St. Vincent and Grenada, and between Dominica and Martinique are interrupted; and there is, therefore, at present no telegraphic communication with the Islands of Martinique, St. Lucia, St. Vincent, and Barbadoes.

GUTTA PERCHA MOULDS FOR ELECTROTYPES.—According to the *Organe Industriel* gutta percha moulds for electrotype reproductions can be advantageously made from a hot saturated solution of the rubber in linseed oil. This solution sets hard on cooling, and the mould is then treated in the usual way.

ELECTRIC LIGHT AT A CONCERT.—A smoking concert was held on Saturday last, by the Lewisham Bicycle Club, to celebrate the last run of the season. The building was illuminated with incandescent lamps, supplied with current from accumulators from the works of Messrs. Arthur B. Gill and Co., electrical engineers.

THE SOCIETY OF TELEGRAPH-ENGINEERS.—The next meeting of this society will be held at the Institution of Civil Engineers, 25, Great George-street, S.W., on Thursday, 11th Nov., at 8 p.m., when a paper will be read upon "The Predetermination of the Characteristics of a Dynamo," by Gisbert Kapp, associate.

THE ESTIENNE TELEGRAPH.—We recently notified the fact that the French Telegraph Administration had determined to adopt the Estienne system upon an extensive scale. We now learn that the results of the experience of the last few weeks are deemed highly satisfactory, considering the comparative inexperience of the operatives.

THE CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of October was 2,783, estimated to produce £2,400, against 2,694 messages, producing £2,156 in the corresponding month of last year. The traffic receipts for the month of July, estimated at £2,800, realised £2,818.

THE EXPECTED RIOTS.—It is said that on Lord Mayor's Day the whole of the principal police-stations of the metropolis will be in telephonic and telegraphic communication, so that the reserves may at once be despatched to any point where their presence is required. The Post Office Volunteers will on this occasion form part of the Lord Mayor's procession.

AN ELECTRIC TOY.—We have received from M. E. Reynaud, of 58, Rue Rodier, Paris, an illustrated description of an ingenious electric toy which he calls "praxinoscope théâtre électrique." The performances of the puppets on the mimic stage proceed automatically by the help of an electro motor and battery, and the whole is illuminated by electric light.

"THE REPETITION CODE."—We have received a copy of "The Repetition Code," designed to economise the time and labour necessary to obtain the repetition of doubtful words in foreign telegrams, arranged by the managing director of the Eastern Telegraph Company, and by the superintendent of the company's London stations. This book is printed at the office of *The Electrician*, 1, Salisbury-court, E.C., and is published by subscription only.

TENDERS ASKED FOR.—The Cheshire Lines Committee invite tenders for the supply during the year 1887, among other things, of telegraph materials and instruments, galvanised iron, and copper wire. Patterns can be seen, and specifications, with forms of tender, obtained, on and after 8th November upon application to Mr. W. H. Legge, storekeeper, Cheshire Lines, Warrington. Tenders to be sent in by 10 a.m. on 3rd December to Mr. E. Ross, secretary, London-road Station, Manchester.

MALICIOUSLY CUTTING A NEWS WIRE.—At the Worship-street police-court on Friday last a man named A. Saunders, of 52, Upper-street, Islington, was charged with having

Digitized by Google

maliciously cut wires belonging to the Exchange Telegraph Company, in Bethnal Green-road, in order to delay news. At the request of the prosecution the matter was dealt with by the magistrate, and the prisoner, who had rendered himself liable to two years' imprisonment, was sentenced to three months, with hard labour.

INSTALLATION AT POOLE.—Messrs. G. and T. Belber, millers, of Poole, Dorset, have recently had their premises fitted up throughout with electric light. The installation has been carried out by Mr. Wilson Hartnell, of Leeds, and consists of 104 Edison-Swan lamps, of 16 candle-power, supplied with current by a No. 4 Crompton compound-wound dynamo, running at a speed of 1,000 revolutions per minute. A Turner vertical engine is used, for which steam is supplied by the boilers belonging to the mill engines. Hartnell's patent three-circuit switch-boards are used.

TESTING THE STRUCTURE OF LAMP FILAMENTS.—Mr. Weston has devised the following simple and ingenious method for examining the filaments of glow lamps for structural defects. The lamp is mounted upon a whirling table, and connections are made with suitable mercury contacts. When a current is sent through the lamp while very rapid rotation is imparted, any part of the filament which has a higher resistance appears as an excessively brilliant band of light. In this way it becomes possible with practice to form a good idea as to the probable length of life of the lamp.

HOME NEWS FROM ABROAD.—We learn from a Transatlantic contemporary that the City of London now contains the second largest Edison Central Station in the whole world, New York coming first, and Milan third. The London station is said, moreover, to contain the largest Edison dynamos yet constructed. We are not told how many machines are employed, but they have each a capacity for 12,000 lamps. We are very pleased to hear this, on the authority of one of the leading technical journals of the States; but the affair has hitherto been kept uncommonly dark over here.

THE TELEPHONE ON GERMAN RAILWAYS.—From a report recently issued we gather that the telephone has come into extensive use upon the German railways. No less than 33 companies have given it a trial; the results are, as a whole, satisfactory, but it has not been found practicable to rely entirely upon the telephone for signalling service, except upon lines where the traffic is very slight. On busier lines the telephone has proved to be a valuable supplement to the telegraph equipment, and in the large stations it is extensively used to connect the various offices and departments. Altogether nearly 30,000 kilometres of telephone wire have been erected upon the German railways.

THE ELECTRIC LIGHT IN MADRID.—At a meeting of the Madrid Mercantile Club, held on the 24th ult., it was determined to proceed with the scheme for establishing a large central electric light station. Some details of this scheme we gave last week. A company is to be incorporated forthwith, under the title of the *Union Mercantil é Industrial de Alumtrado Electrico*. It was stated that two foreign companies were prepared to contract for the supply under the stipulated conditions (the principal of which is that the cost should not exceed three centimos per hour per 10 candle-power lamp) but only upon the further understanding that the guaranteed minimum consumption shall not be less than the equivalent of 6,000 lamps "per day" (of how many hours does not appear). It was also mentioned that a third company would be willing to undertake the work at the price of one centimo per 10 candle-power lamp per hour.

EVENING UNIVERSITY LECTURES ON IRON AND STEEL.—A course of eight lectures on this important subject has just been commenced at King's College, by the Demonstrator of Metallurgy, Mr. W. G. McMillan, F.C.S. These lectures will be delivered on Tuesday evenings, from 7 to 8, and it is proposed in them to treat of the general methods by which the different qualities of malleable iron, cast iron, and steel may be produced and prepared for use in the arts; of the effect of the various foreign substances contained in these metals upon their strength and fitness for the purposes to which they are to be applied; of the extent to which these substances are injurious, and the means by which they are commonly eliminated. There can be no question that an acquaintance with the metallurgy of iron must be of great value to all electricians who are in any way concerned with the manufacture of dynamo-electric machinery.

A NEW HEAT BATTERY.—Signor V. Riatti has constructed a somewhat novel arrangement for effecting the direct conversion of heat into electricity. He takes a rectangular vessel tall in proportion to its sectional area. Two copper tubes are passed through the sides of the vessel, one near the top and one near the bottom; these tubes pass through from side to side without opening into the vessel itself. The latter is then filled with a solution of sulphate of copper, and a current of cold water is passed through the lower tube, while superheated steam under a pressure of several atmospheres passes through the upper tube. Under these circumstances on closing the circuit with the two tubes as electrodes a current is obtained which passes externally from the cold to the hot tube, while copper is dissolved from the upper and deposited on the lower tube The battery is described as being "economical and easy to maintain," but it is not very clear how it can be expected to receive any commercial application, except possibly in large telegraph offices. Compared with Mr. Case's heat cell it labours under the disadvantage of not being reversible, as it would scarcely do to heat the lower tube.

THE ELECTRIC LIGHT AT GREENLANDS. — The following paragraph recently appeared in *The Times*:—"The country seat of the Right Hon. W. H. Smith, M P., at Greenlands, has recently been lighted by electricity. The installation is very complete, and consists of nearly 250 Swan glow lamps. The current is conducted by underground wires from the engine house, which is about 200 yards from the mansion. The generating machinery consists of a locomotive boiler and a Paxman 12 horse-power compound engine, driving two Crompton dynamos, each capable of supplying the current to 200 glow lamps, and regulated by a Willans automatic electrical governor, which maintains a constant electromotive force at all times, thus insuring perfect steadiness in the lights. In order to save running the machinery on Sundays, or at other times when the full number of lamps is not required, a battery of accumulators is used. The wires are all laid in wood casing painted with three coats of asbestos paint, and every precaution against fire has been taken." Messrs. Crompton and Co. inform us that the dynamos supplied for this installation have realised, on testing, a commercial efficiency of 90 per cent; and also that the accumulators supplied are able to maintain the full current for three days' running, while the period required for charging has been reduced to such an extent that the actual personal attendance required will not exceed two half-days per week.

THE LIGHT OF OTHER DAYS.—A letter appears in the *Pall Mall Gazette*, setting forth the views of one who describes himself as having encountered a heavy blow, on making the discovery that the electric light had been placed in the Temple Church. "No more gathering shadows in the beautiful roof,

Digitized by Google

no more golden candle lights, shining like jewels" in the sepulchural gloom. "In the one place where London fog and gloom and darkness were apotheosized, they are expelled for ever." This is sad indeed. Yet we do find people here and there who would be prepared to back a glow lamp for "shining like a jewel" against any farthing rush-light. There are others who would prefer a stage-coach to a Pullman express, flint and steel perhaps to a lucifer match, and tallow to electricity. In our issue of the 25th June last we referred at some length to the electric lighting of the Temple Church, which was carried out by Messrs. Mortimer, Shepherd and Co., of 2, Great Queen-street, on the occasion. of the visit of the Princess Louise. This installation although intended to have been merely of a temporary character, has ever since remained in use. Several experimental alterations have been made in the grouping of the lamps, and the arrangement adopted at present consists of three light wrought-iron chandeliers suspended from the centres of the arches in the round tower, and a single light at each of the four corners of the capitals of the columns in the nave. The installation has received unqualified praise, and from the æsthetic point of view the effect has hitherto been the subject of general admiration.

"COFFERDAM."—The name of "cofferdam" has been given to a curious substance, a preparation of cellulose, which has recently been obtained by a young French chemist, M. P. Germain. Its uses in connection with electricity have been investigated by M. André Regnier, the electrician to the Société Générale des Téléphones. From a report which has been written by M. Reynier for *L'Electricien* we gather that "cofferdam," or "sporique," as its finer variety is termed, is prepared from the husks of the cocoa-nut; it has the colour and aspect of cocoa powder. The extraordinary properties of this substance arise from its extreme lightness, its specific gravity being represented by the abnormally low figure of 0·08. Under the simple pressure of the hand its volume can easily be reduced to one-third, and even then its density is only about one-fourth that of good sponge. Its absorbing power surpasses that of all other known materials. A given volume of cofferdam can easily be made to take up a volume of liquid equal to itself, without any perceptible increase in the total volume; or, in other words, the volume occupied by the cofferdam in the combination is *negligible*. A good sponge will absorb seven times its own weight of water, cofferdam absorbs 12·5 times its weight of water. The substance has hitherto been found to be insoluble both in acids and in alkalis and in solutions of salts. It is therefore evident that it will thus readily lend itself for use in primary or secondary batteries. M. Reynier states that the resistance of the battery is not perceptibly increased by its presence, and it is suggested that by saturating two separate slabs of the substance it may be employed in two fluid batteries, thus doing away with the porous cell. Not only are the liquids thus kept separated and preserved from accidental spilling, but it is also found that the loss from evaporation proceeds much more slowly. It would appear that the substance is certainly worth a trial for the purpose indicated.

SHIP LIGHTING BY ELECTRICITY.—Last week the official trial of the electric installation on board the Indian troopship "Dalhousie" took place on the voyage between Greenock and Birkenhead. The installation consisted of 168 Edison-Swan lamps of 20 candle-power, and 16 lamps of 50 candle-power arranged in two yard arm reflectors. The dynamos were two Goolden-Trotter A type, driven direct by Willans three-cylinder compound tandem engines at 300 revolutions, each capable of maintaining the entire number of lights. The engines were started on the full installation at 10 a.m. on Thursday morning, and ran without intermission for fifty-four hours at full load, the vessel being at sea during the last twenty-four hours of the run. The engines and dynamos ran faultlessly while in harbour, but the value of the test at sea was shown by the detection of a defective arrangement of the connection of the steam pipes with the boiler, which allowed water to reach the engines when the vessel was under weigh, and at times gave some trouble. So far as the electrical details were concerned, however, the lighting was a pronounced success, and when the fault in the steam connection is remedied the installation will be perfect. We are informed by the contractors that the lamps gave a light of 20 candles at 80 volts, though marked 16 candle-power, taking an average of 73 watts, thus showing an actual efficiency of 3·4 watts per candle, and nominally of 4·45 watts per candle. It is, however, a doubtful economy to run lamps at 25 per cent. above their nominal capacity. Mr. Jopp, Director-General of Stores, inspected the installation on the arrival of the vessel at Birkenhead. The work was carried out by the firm of Goolden and Trotter, of Westminster, the ship being fitted on Admiralty specification, under the supervision of Mr. Scott, their superintending engineer. The "Dalhousie" and "Lawrence" were finished together in 12 weeks from the commencement. Both ships sail for India this week, and are the first vessels of the Indian marine which have been fitted with the electric light.

OVERHEAD TELEGRAPH AND TELEPHONE WIRES.—At the meeting of the Metropolitan Board of Works, on Friday last, a report was presented from the Works and General Purposes Committee on the subject of overhead telegraph and telephone wires. The committee stated that they had proceeded upon the resolution of the Board of the 8th January, referring it to them to inquire into the recent accidents by overhead telegraph and telephone wires, and the danger to the public arising therefrom; and as to the necessity of any proceedings or future legislation on the subject. The committee had also had before them the several communications which had been referred to them by the Board from vestries and district boards of the metropolis with reference to this question. The Board were aware that the House of Commons last year appointed a select committee to consider the law relating to the control of over telegraph, telephone, and other wires. From their report, which was made to the House on the 12th of May, it appeared that the committee had come to the conclusion that the risk of danger to the public from overhead wires had been exaggerated, but at the same time they were of opinion that the probable development of the telephonic system made it desirable that there should be some change in the law with a view to the better supervision of the wires. The committee, after carefully considering the reference, and having, as directed by the Board, obtained from the surveyors to the several vestries and district boards information as to damage which had resulted from the breakage of wires within their districts, concurred in the opinion expressed by the Select Commitee that better supervision is desirable, and submitted the following resolution:—"That a communication be addressed to her Majesty's Government calling attention to the danger likely to arise from the increasing number of overhead telegraph and telephone wires, and suggesting that such wires should be placed under proper supervision, as recommended by the Select Committee of the House of Commons in the year 1885."—Mr. Edwards, without comment, moved the adoption of the report and resolution, which was agreed to.

Digitized by Google

THE LIGHTING OF THE BARTHOLDI STATUE.—The New York Correspondent of the *Daily News* telegraphs:—The Bartholdi statue was illuminated by the electric light for the first time on Monday night, being the first pleasant evening since the unveiling. The torch was lighted by nine arc lights arranged in two horizontal circles, one inside the other. Each light is placed midway between and opposite two horizontal rows of glass lenses set in the face of the torch to illuminate the outer surface of the statue itself. There are five 8,000 candle-power electric lights in five of the salient angles of the fortifications surrounding the statue. Behind each light is a cylindrical parabolic reflector, by which the light is focussed on the pedestal and statue. Each light is four times as powerful as an ordinary arc light. Four lights are planted at four opposite points to form a square in an eight-pointed star, which outlines the fortification. The fifth light is directly in front of the goddess's nose. The reflectors are tilted to throw the light upward at an angle of about forty-five degrees. The lighting was witnessed by enormous assemblages of people at the Battery, and along the wharves. The water was alive with craft of all kinds. When the signal for lighting was given fireworks in bewildering profusion blazed from the forts, islands, wharves, and vessels, followed almost immediately by a flashing white light from the torch, which sent dazzling rays over the waters of the harbour and far out to sea. The effect was marvellously beautiful. Tremendous roars of delight broke from thousands of throats, accompanied by the shrill whistles of every tug and steamer in the harbour. The lighting of the torch was pronounced successful, but that of the statue itself not. Held high above the statue's head, the light from the torch makes a brilliant beacon for the entire harbour, and is plainly visible for many miles at sea. The arm holding it is in shadow, and at a distance of a mile the statue itself is invisible. It is intended to remedy this by a different arrangement of the lower lights. Seen from Brooklyn Bridge the light of the torch is brilliant, but only the pedestal and uplifted arm are visible.

MILITARY TELEGRAPHS.—Colonel Macdonald, Commandant of the Queen's Edinburgh Rifle Brigade, has devised a very useful and compact equipment for the purpose of a regimental field telegraph, as distinguished from the divisional field telegraph. Colonel Macdonald expresses his views upon this point in the following words:—"It is highly desirable that every regiment should carry its own telegraph appliances, so that it may establish telegraphic communication with its own outposts when acting alone, and that when acting with others telegraphic communication may be more rapidly established by each regiment laying its own cable on reaching camping ground, instead of the whole telegraphic plant for a division being carried in separate waggons and worked by a separate department. This field telegraph is designed to enable the necessary plant for telegraphing to be carried regimentally. It consists of:—1. One mile of double conductor insulated cable. The main wire is in the centre, and covered with insulating material. The 'return' consists of five small wires wound round the covering of the inner wire, and this is again covered. The 'return' thus makes the obtaining of an 'earth' unnecessary, and also acts as a protection to the main wire. The cable is wound in two lengths on two bobbins. 2. Telephone transmitters and receivers for ordinary speech, or, where articulate sounds cannot be heard, a special arrangement by which the Morse alphabet can be read by telephone. (This latter instrument is designed by Samuel Vyle, Esq., late of the Telegraph Department, G.P.O.) 3. A special coupling for rapidity, and which avoids the use of all screws, which might get lost, or sockets, which might get clogged, in the rough usage of a field telegraph. 4. Poles to carry the cables across roads where traffic might injure it. The guying arrangements of these poles make them adaptable to any position, and enable the erecting, taking down, and re-packing to be effected with great speed. 5. Two bicycles to carry the plant. The poles are carried over the handles of the bicycles, and each bicycle has a half-mile bobbin supported on its backbone. The bicycles are trundled by the telegraph troop, the draught being extremely light. If surprised, the poles, which are of comparatively trifling value, can at once be thrown off and the bicycles mounted for escape." The apparatus is on view at the Edinburgh Exhibition, and has been awarded a silver medal.

THE RESISTANCE OF SOFT CARBON UNDER PRESSURE.—The true cause of the variation in the electrical resistance of soft carbon under varying pressure has long been and still remains a vexed question. The tendency has been to regard the result as being due merely to the variation in the extent of the surfaces in actual contact; but while no one has questioned that this is a *vera causa*, it remains doubtful whether the whole of the observed effect is due to this cause, or whether an actual variation in the specific resistance of the carbon does or does not account for some part of the phenomenon. Prof. Mendenhall has always upheld the latter theory, and writing to *Silliman's American Journal*, he now adduces the results of some experiments which offer in his opinion conclusive evidence of the existence of a variation due to this cause. For hard carbons a certain small variation of specific resistance with pressure was established by Mr. Tomlinson some five or six years ago, as the result of experiments which were at that time communicated to the Royal Society, and this fact alone must be allowed to afford *primâ facie* evidence on behalf of Prof. Mendenhall's theory. The professor conducted his experiments upon a thin diaphragm of soft carbon, which by ingenious manipulation was made to separate the horizontal limb of a U tube into two equal parts. Mercury was then poured into either side, and platinum electrodes dipping into the mercury enabled the circuit to be completed through the disc. It may then be fairly assumed that after the mercury has attained a certain height on either side the surface contact is fully established, and will be independent of any further addition to the statical pressure. If this assumption be challenged, it is still open to anyone to decline to admit the validity of the professor's conclusions. The additional pressure was obtained by means of compressed air, which was admitted upon either side of the mercury column. The electrical connections for measuring the resistance of the disc were of a very simple character, and do not require any detailed description. "Very many experiments were made, all without exception showing great diminutions in the resistance of the disc by increase of pressure." It was even found that the arrangement was sufficiently sensitive to show very slight changes in atmospheric pressure. The disc recovered its normal resistance with rapidity upon the removal of a small stress, but with heavier stresses the recovery was slow and sometimes imperfect. The results were independent of the current employed in the measurements so far as the observations extended. When a disc of hard carbon was employed the diminution of resistance under pressure was far less marked; and inasmuch as the "surface contact" under slight pressure is less perfect with hard than with soft carbon, Prof. Mendenhall considers this as an *experimentum crucis* on behalf of his theory.

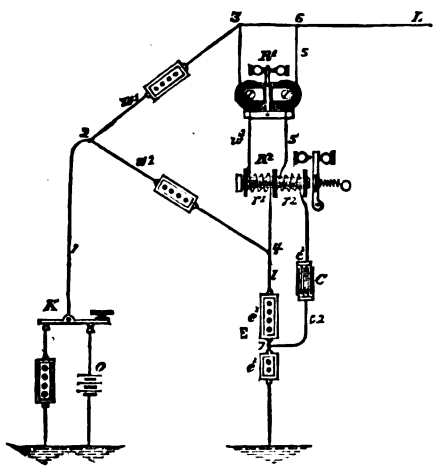
A NEW ARRANGEMENT OF THE QUADRUPLEX.

There has recently been introduced on the lines of the Baltimore and Ohio Telegraph Company a new arrangement of the quadruplex devised by Mr. Wm. Maver, jun., and designed to more perfectly overcome or counterbalance the effects produced by the static discharge of the main line.

The arrangement consists, in general terms, in applying to the coils of the receiving-instrument supplementary or additional coils included in a conductor extending from the main line to one plate of a condenser, the remaining plate of which is connected with the artificial line at a point between the earth and a portion of the artificial resistance.

The accompanying diagram explains clearly the connection of the circuits. Here L represents the main line and K a key system for transmitting from the battery O. A conductor, 1, leads from the key to a point, 2, where the two arms w^1 and w^2 of a Wheatstone bridge diverge. The arm w^1 is connected with the main line L at a point, 3. The arm w^2 is connected with an artificial line, l, at a point, 4. The points 3 and 4 are connected with each other by a bridge conductor, w^3, in which there are included one coil or set of coils of the two receiving instruments R^1 and R^2.

The instrument R^1 is represented as a polar relay, and is provided with a second set of coils included in a conductor, 5, leading from a point, 6, in the main line to a plate, c^1, of a condenser, C. The instrument R^2, which is represented as a neutral relay, is also constructed with two coils, r^1 and r^2, the former of which is included in the bridge conductor



New Arrangement of the Quadruplex.

w^3, as already stated, while the second coil r^2 is included in the conductor 5. The remaining plate c^2 of the condenser is connected with the artificial line l at a point, 7, intermediate between the two sections e^1 and e^2 of the artificial resistance E, employed for equalising the line resistance. The coils of the instruments R^1 and R^2 are so connected in the conductor 5 that the effects of the discharge of the condenser through them shall tend to neutralise the discharge of the main line. It will be readily understood that the charge taken by a condenser will depend upon the difference in potential of the points 6 and 7, with which the respective plates are connected. For this reason a portion, e^1, of the resistance E is located between the point 7 and the bridge, and the greater the amount of this resistance the greater will be the charge taken on by the condenser. It is desirable also that a portion of the artificial line resistance shall be between the point 7 and the earth.

It will be apparent that when a current is transmitted from the battery O to line, a charge will be received by the condenser C. The discharge of the line L will tend to produce a false signal by traversing the bridge conductor w^3. The current or impulse from the plate c^1 upon the discharge of the condenser C, however, will neutralise the effects of the line discharge in the receiving instruments It is also apparent that by a simple arrangement the resistance e^2 could be obtained from the coils of the rheostat used to form an artificial line in duplex or quadruplex telegraphy, thus dispensing with the expense of additional rheostats.—*Electrical World* (New York).

NEW EXPERIMENTS UPON THE ELECTRIC TRANSPORT OF FORCE.

M. Hippolyte Fontaine has recently been engaged in experimenting with some new Gramme machines specially designed for the transmission of force. We gather the following details from a note upon the subject presented to the Academie des Sciences by M. Mascart upon the 26th of October:—The experiments were carried out at the workshops of the newly-formed "Compagnie Electrique," whose existence we notified last week. The machines were constructed to the design of M. Gramme himself, and under his personal superintendence. The generators and motors were identical in type—a feature which is not in accordance with modern English practice in low tension transmission. Seven machines were employed, four of which were driven as dynamos, being connected in series to obtain high E.M.F., and the other three were employed as motors. The latter were also coupled electrically in series, and their armature shafts were connected mechanically by means of a pair of Raffard's flexible couplings.

The armatures of these machines were of the ordinary Gramme type, the ring having a diameter of 30 centimetres, and a breadth of 35 centimetres, and being wound with 200 coils. The resistance between the brushes measured 4·75 ohms.

The field-magnets are of the single horseshoe type, of cast iron, and are so arranged that the whole frame of the machine, including "the core which receives the wire, the pole pieces, and one of the plummer blocks," are cast in one piece. The resistance of the field-magnet coils is 6·65 ohms; the total internal resistance is therefore 11·4 ohms. From certain preliminary trials made with each machine separately it appeared that a current of 11 amperes could be passed through the machine for twenty-four hours without excessive heating, and that an E.M.F. of 1,600 volts was the maximum that could be obtained before the efficiency began to diminish. To obtain this E.M.F. it was necessary to drive the machine at 1,400 turns per minute, which gives the somewhat excessive circumferential speed of 4,080ft. per minute. "At speeds varying from 100 to 600 turns per minute an electrical efficiency of 79 per cent. was obtained, and between 600 and 1,400 revolutions the efficiency increased to 81 per cent.;" it may be added that the latter figure is equivalent to a commercial efficiency of rather less than 75 per cent. calculated on the cold resistance of the coil.

An artificial resistance of 100 ohms was placed between the two sets of machines; the experiments therefore apply to the case in which the line wire has a nearly perfect insulation. The horse-power expended was calculated by taking indicator diagrams from the cylinder of the engine when driving alternately (1) the dynamo, (2) a Prony brake. In the absence of a reliable transmission dynamometer, and provided that the load upon the brake did not differ much from that upon the machine, this method is no doubt capable of a very fair degree of accuracy.

The following table refers to some experiments which were made on the 19th ult:—

Revolutions of dynamos per minute	1,298
" motors " "	1,120
Difference of potential at the terminals of the four machines in series	5,996 volts.
Current	9·34 amperes.
Resistance of line	100 ohms.
Brake horse-power delivered on driving-shaft	95·88 h.-p.
" " received " "	49·98 "
Commercial efficiency.....	52 per cent.

The total weight of the seven machines was 8,400 kilogrammes, and the total cost 16,450fr. This represents 167 kilogrammes per horse-power transmitted, at a cost for the machines of 2fr. per kilogram.

THE STOCKWELL ELECTRIC MOTOR.*

Among the electric motors which have come into extensive use in the United States is the Stockwell motor, which has for some time been employed in the running of light machinery, especially sewing machines, and it is said that not less than a thousand of these are in actual service to-day.

The motor, which we illustrate in the engraving, Fig. 1, is enclosed within a case, one end of which is removed so as to expose the interior. The magnets are of the converging, consequent pole type, and form an integral part with the top and bottom of the casing. The two sides are cast separate and held together by screws.

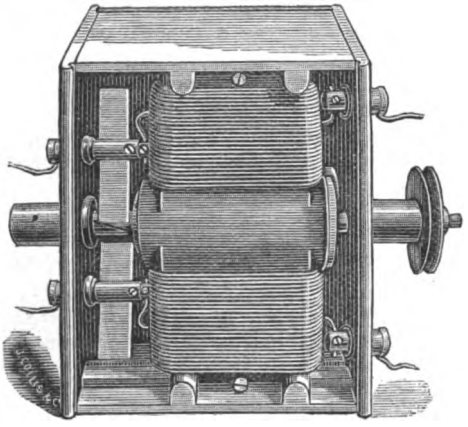

FIG. 1.

The armature, or more correctly the armatures, for there are two of them, are shown in Fig. 2. As will be seen they are of the Siemens shuttle-wound type, and are placed at right angles to each other. The commutator has four segments and the terminals of the wire on each armature are connected to opposite segments. The latter are not made parallel with the spindle, but are helical in shape, so that there is no break in the circuit at that point, since the brush passes the current to one armature before leaving the

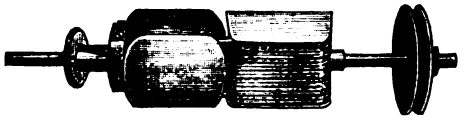

FIG. 2.

other. By this arrangement only one armature is in action at one time, the cut-out being effected just before the armature pole approaches that of the magnets, so that there is no dead point, and the motion is smooth and continuous.

Where the motors, as usual, are connected in series with each other, an adjustable resistance is provided which is contained within a box, such as that shown in perspective

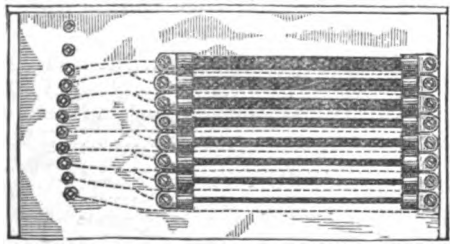

FIG. 3.—Diagram of Resistance Bars.

in Fig. 3. This adjustable resistance is placed in a shunt to the motor, and consists in a series of carbon bars of gradually decreasing conductivity. As the switch lever is passed over the successive contacts, increasing resistances are introduced in the shunt, which consequently allows more current to pass into the motor and increases its speed correspondingly. The spring attached to the switch lever keeps the latter in the position of "no current" in the motor, and by attaching a cord or other device connected to a treadle the operator on a machine has both hands free to work with.

The carbon resistance bars are copper-plated at their ends and firmly clamped, and by making them of gradually decreasing cross-section a relatively greater increased resistance is thrown into the circuit as the switch-lever passes from one contact to another. A wide range of control is therefore afforded with a comparatively limited movement of the lever.

The motor is provided with a clamp so that it can be readily attached to a table or work bench, and its simplicity of construction makes it little liable to get out of order.

* From the New York *Electrical World*.

THE ELECTRO-MAGNETIC ROTATION OF THE PLANE OF POLARISATION OF LIGHT IN IRON.

By A. KUNDT, in *Wied. Ann.*, Vol. XXVII., 1886.

In a former paper the author showed that iron, nickel, and cobalt rotate the plane of polarisation in the positive direction, and that the rotation is enormously greater in these bodies than in other magnetic and diamagnetic substances.

Dependence of the Amount of Rotation on the Intensity of the Magnetic Field.

In the case of all diamagnetic and feebly magnetic bodies, the amount of rotation for light of given wave-length, traversing a given thickness of the substance in a uniform magnetic field, may be assumed to be proportional to the magnetic force parallel to the beam of light. In fact, the amount of rotation per unit length of the substance in a field of unit strength, when the light rays are parallel to the lines of force, is what is known as Verdet's constant. Now, as the author has found so far, that in diamagnetic and feebly magnetic bodies the induced magnetism is also proportional to the magnetising force, it may be said, in the case of these substances, that the rotation for each element is proportional to the component in its direction of the magnetic moment at the position of the element. In the case of iron, cobalt, and nickel, however, the induced magnetism is not proportional to the magnetising force, but increases, at least in iron, at first more rapidly than the magnetising force, then more slowly, tending ultimately towards a maximum limit; and the experiments showed that in iron the rotation was not proportional to the magnetising force, but it also approached a maximum limit, so that in the case of iron Verdet's constant has no meaning, and one can therefore no longer speak of a specific rotatory power of iron, as was formerly done by the author.

It was found, however, that the maximum rotation was, within the limits of accuracy of the observations, proportional to the thickness traversed, which gave a new specific constant to be determined, viz., the maximum rotation per unit length.

Method of Observation.

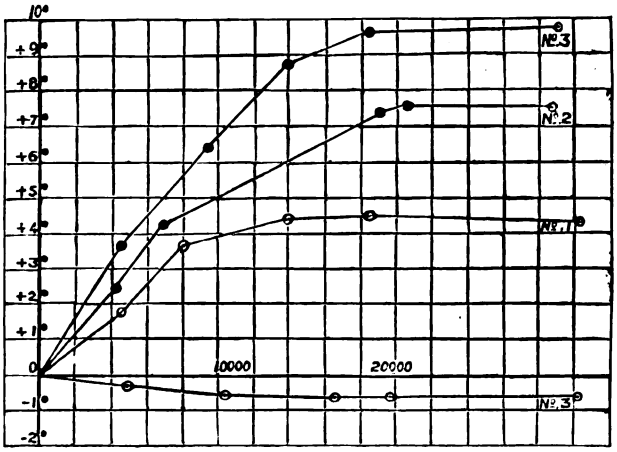
The layers of iron were obtained, as in the author's former researches, by electrolytic deposition on platinised plates of thin glass of the kind used for covering microscopic slides. The glass alone only gave a rotation of 20′ or 30′ in the magnetic field used for the observations. The magnetic field was produced, as before, by means of a Rhumkorff electro-magnet of the ordinary construction, excited by means of a Gramme machine, the current from which could be varied by altering the resistance in the circuit. The small portion of the magnetic field included between the hollow portions of the conical pole pieces was sensibly uniform, and this was the only portion of the field that was employed; its strength was determined by measuring the rotation produced by a glass plate which had had its rotatory powers previously compared with

Digitized by Google

some substance for which Verdet's constant was known, such as water or bisulphide of carbon.

Sunlight having passed through a red glass of such a tinge that its mean ray approximately corresponded to the Frannhofer line C, was polarised by means of a Nicol prism, and allowed to traverse the metallic layer, passing through apertures left for that purpose in the pole pieces.

The accompanying diagram shows the nature of the relations



between the intensity of the magnetic field and the amount of rotation produced, observed with three films of different thicknesses, as shown by the three curves in the upper portion of the accompanying diagram, in which the ordinates represent the intensity of the field in C.-G.-S. units, and the abscissæ represent the corresponding rotations in degrees.

Maximum Rotation per Unit Length.

To determine the maximum rotation per unit length, six of the iron layers had their thicknesses determined by weighing. A very accurate determination could not be expected, as the method of weighing would merely give the average thickness.

The results are given in the accompanying table, in which

d = thickness in centimetres of layer of iron,

Ω = total observed maximum rotation in degrees,

ω = maximum rotation in degrees per centimetre length.

d.	Ω	ω
.0·00000419	1·66°	396000°
0·00000592	2·00	338000
0·00000759	3·20	422000
0·00001025	4·97	485000
0·00001148	5·38	467000
0·00002123	8·51	401000
	Mean	418000°

The numbers in the third column differ considerably, as was to be expected from the roughness of the method; but though the existence of any law connecting the amount of rotation with the thickness cannot be inferred from them, as a first approximation the rotation may be assumed to be proportional to the thickness, and on this assumption the observations give the result that the simple rotation per centimetre in iron magnetised to its maximum intensity is roughly equal to 200000°, or the rotation in a length of ·01mm. is rather greater than π. The strength of the magnetic field was about 20,000 C.-G.-S. units, and increasing the strength of the field beyond this value does not cause a sensible increase in the rotation, as is clear from the curves given in the diagram.

It would be of great importance to obtain a determination of the magnetic moment of the layers as a function of the intensity of the field in order to see whether the rotation is proportional to the magnetisation. The author has not succeeded in finding any simple method of determining the magnetic moment of a layer placed transversely in the field, but it was easily found that when placed longitudinally the magnetic moment reached its maximum value in a field of the strength of about 2,000 C.-G.-S. units.

Reflected Light.

In the case of rays normally incident on the magnetised iron layers it was also found that the rotation was not proportional to the magnetising force, but that it attained a maximum with a strength of field of about 20,000 C.-G.-S. units.

The results of these observations are shown graphically in the lowest curve of the diagram previously referred to. The amount of rotation was found to depend on the thickness of the layer, but more particularly on the nature of its surface. In the case of the layers of iron, nickel, and cobalt, the presence of a film of oxide, which produced little or no effect on light traversing it, produced a great disturbing effect in the case of reflected light, sometimes strongly rotating the plane of polarisation, sometimes producing an elliptic polarisation of the reflected light, so that very little difference in clearness was perceived on rotating the Nicol prism. On warming the iron layer, so as to cover it entirely with a film of oxide, hardly any rotation was observed.

It is easily seen that very little rotation would be caused by the film of oxide in the case of light traversing it, but in the other case a portion of the plane polarised light incident normal to the surface, would be reflected at the outer surface of the film of oxide, and a second portion would be reflected at the surface separating the oxide from the metal. Rotation of the plane of polarisation takes place only in the case of the latter portion, and the two portions of the reflected light interfere.

In all experiments on the rotation of the plane of polarisation by reflection the greatest care must therefore be taken to ensure the absence of any trace of oxide from the surface of the metal.

Remark on the Negative Rotation of Solutions of Magnetic Salts.

Verdet has shown that a concentrated solution of chloride of iron gives a negative rotation, viz., in an opposite direction to that produced by a diamagnetic body, and that many salts of magnetic metals are able, at any rate, to diminish the rotation which would be produced by the solvent alone. These phenomena, which seem to show an opposite behaviour on the part of magnetic and diamagnetic bodies respectively, with regard to electro-magnetic rotation, are of importance with respect to the true nature of magnetism and diamagnetism, and Maxwell says ("Electricity and Magnetism," Vol. II., p. 412, Second Edition):—"This shows that the difference between ferromagnetic and diamagnetic substances does not arise merely from the magnetic permeability being in the first case greater and in the second less than that of air, but that the properties of the two classes of bodies are really opposite."

He adds, it is true, that all magnetic substances do not show negative rotation, nor all diamagnetic substances positive rotation, as, for example, the neutral chlorate of potassium, which is diamagnetic, and gives a negative rotation.

This conclusion of Maxwell's and all attempts to explain the negative rotation produced by many salts of magnetic metals by means of the negative rotatory power of the magnetic atoms must be abandoned, since iron, nickel, and cobalt themselves produce a positive rotation.

The author points out that possibly some light may eventually be thrown on the reason of the different behaviour of iron itself and its salts, by the observation that all elementary substances hitherto examined, whether strongly magnetic or strongly diamagnetic, show a positive electro-magnetic rotation, a negative rotation being only shown in the case of chemical compounds.

The elements which have been shown to give positive rotation are Fe, Co, Ni, Br, Se, S, P, C (the diamond), O, N, H. Negative rotation is only shown by chemical compounds containing atoms which are strongly magnetic, such as salts of iron, &c.

NEW METHOD FOR DETERMINING THE TIME OF OSCILLATION OF A MAGNET.

In a recent number of the *Annalen der Physik und Chemie* H. G. Hausemann describes a new arrangement for determining the periodic time of a suspended magnet. This method, which can be adopted for any similar purpose, consists of an ingenious application of photography for recording the differences of agreement in position between the magnet under observation, and a seconds-pendulum. The magnet is provided with a mirror in the ordinary way, by reflection from which the divisions of a scale mounted before it can be read off in a telescope. A small mirror fixed to the pendulum and parallel with its plane of oscillation, reflects when at rest the beam of an electric light on to a prism, provided with a broad slit crossed by a narrow vertical bar; from the prism the light is reflected on the mirror of the magnet, from which, when near its neutral position, the barred slit is focussed in a small photographic camera specially constructed for the purpose. The slide of the latter is furnished with a micrometer screw, so that the plate can be moved through a known distance between any two exposures. The elongations can be read on the telescope in the usual way, and by measurement of the distance between the images on the negative, the number of oscillations of the magnet corresponding to a given number of those of the pendulum can be accurately determined, if the times of exposure are chosen when the pendulum and magnet are both near their positions of rest. This method naturally admits of extreme accuracy in the determination of the quantities sought for, besides reducing the time required.

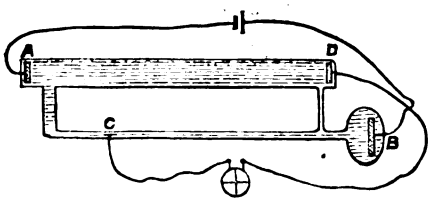
ON ELECTROLYSIS.

BY PROF. OLIVER J. LODGE, D.SC.

(Concluded from page 518.)

Surface Films.—Among bad conductors, the films on the surface of glass rods are to be remembered and studied. It would be interesting to know the absolute resistance of some such films, if it be possible to specify their conditions. Optical observations, combined with electrical conductivity determinations, like those of Reinold and Rücker with soap films, may be expected to lead to further knowledge of their thickness, nature, &c. A hygrometer founded on the resistance of such films would perhaps indicate not what is ordinarily called the "humidity" of the air, *i.e.*, its nearness to saturation, but its actual vapour pressure.

Possible methods of answering Question 1.—I find it difficult to make useful suggestions with regard to an experimental attack on the question of Ohm's law in electrolytes. It is to be remembered that experiment is useless except on a very good and well-considered plan. Something like 1 in 1,000 accuracy must be obtained, and higher may be aimed at. Although the best experiments hitherto are probably those of Kohlrausch and Nippoldt with alternating currents, it does not seem to me that such currents, employed with electrodes, are suitable for a really accurate determination. The capacity of polarisable electrodes is enormous, and apparently instantaneous, and the use of alternating currents by no means avoids effects due to this polarisation; although it is possible very nearly to eliminate these effects by calculation, as Kohlraush did. Methods of avoiding all polarisation, by working in closed circuits wholly electrolytic, are tempting. Such, for instance, as the damping effect, when a magnet swings over a liquid, or when a vessel of liquid is spun between the poles of a magnet (*e.g.*, Guthrie and Boys).* The electrolyte may be made to partake of the motion of the vessel by using a jelly. But the calculation of such experiments would (to me, at any rate) be difficult, and it is not likely that the experiments themselves are susceptible of minute accuracy. Probably the best plan of research would be some modification of the ingenious method planned by Maxwell for the British Association Committee on Ohm's law in metals. (See Brit. Assoc. Report, Glasgow.)



If perfectly similar tapping electrodes could be got, it would be sufficient to compare the E.M.F.s at the ends of two troughs or tubes, one wide, the other narrow, placed in series, so that the same current might flow through both. A null method of comparing E.M.F.s is simple enough. For instance, a liquid Wheatstone bridge might be made, one branch consisting of the very wide and very narrow tubes, the other of a uniform tube or trough of moderate width (see figure). A and B are battery electrodes, while C and D, which are carefully chosen, make connection with an electrometer, C being movable. A galvanometer seems dangerous, as allowing slight currents, which might disturb the equality of the tapping electrodes. The liquid employed might be chosen for convenience, and a natural liquid to use would be sulphate of zinc, with amalgamated zinc electrodes. It is not to be assumed that the polarisation of these is really nil, but it is certainly feeble, and will thus diminish the uncertainty and risk of error attending the experiment.

To avoid difficulties due to the inevitably unequal rise of temperature, an intermittently strong and weak current can be employed, as in the Maxwell-Crystal method* (cf. Schuster, Brit. Assoc. Report, Belfast). If any positive discrepancy were obtained, it would be necessary to consider to what it was due, and whether the effect of *surface* had anything to do with it. The fine tube might, for instance, be replaced by a tube packed full of thin glass rod, so as to have about the same capacity, but much more surface.

3.—*Are Electrolytic and Metallic Conduction thoroughly distinct, so that no substance has a trace of both conductivities at once?*—In other words, has any electrolyte a trace of metallic conductivity? or can any compound metal experience a trace of electrolysis? Is electricity able to slip through or among ions, instead of necessarily propelling them; and is it able to do both things at once? A positive answer to this question need not be given in the form of a disobedience to Ohm's law, for there is no reason for supposing that a metallic slip of electricity through the ions would be more prominent with small than with great current intensity. Insufficient polarisation E.M.F., and constant leakage of a current against it, are the facts which have caused many experimenters to suspect such metallic slip; but secondary actions would so easily account for the same thing, that it is necessary to be extremely cautious in interpreting such observations. Helmholtz's air-free cell proves that if any effect of the kind takes place it must be excessively small for ordinary acid (Faraday lecture). Clerk's experiments show that no such explanation of the behaviour of certain anomalous fused salts is *necessary*.† But it is impossible to give a certain negative answer to the question, on experimental grounds, until every substance has been tried with minute quantitative accuracy. A positive answer for any substance would of course be a denial of the applicability of Faraday's law to that particular electrolyte.

To the second half of the question,

Can any metallic alloy conduct electrolytically?—Seems easier of attack. Experiments have been made, on tin and lead, potassium and sodium, sodium and mercury, gold and mercury, cast-iron, with negative results so far.‡ But none of these alloys except sodium and mercury are well chosen. It would seem advisable to choose two metals far apart in the voltaic series, or in the thermo-electric series, so that one might cling more to positive electricity, and the other more to negative, if possible. Or they might be chosen with their so-called "specific heats of electricity" very different. Or, again, it may be well to choose two metals differing considerably in conducting power, so that one might be rubbed along with the current, so to speak, more than the other. I might suggest gold and lead, or copper and tin,§ or copper and zinc, or bismuth and antimony; beside, of course, mercury and zinc, or mercury and sodium, or, again, copper and zinc dissolved in mercury, &c. But it is to be remembered, from the experiments of Dr. Guthrie, Prof. Chandler Roberts, and others, that diffusion in all such cases is excessively rapid, and that precaution must be taken to diminish its effect in restoring uniformity of composition. A U tube with a constriction at its bend might be used, the whole filled with homogeneous alloy, and kept just above the fusing-point. Pass a very strong current through the U, and gradually cool down till the whole is solid, keeping the current on all the time. Then analyse the two legs, and see if they show any difference in composition.

4.—*Is there any relation between Optical Opacity and Electrolytic Conductivity?*—Metallic conductors are opaque, but electrolytic conductors are, ordinarily speaking, transparent. At the same time, ordinary water is by no means so transparent as bisulphide of carbon; it absorbs a great deal of some kinds of radiation. Does this opacity increase as conductivity increases, say by addition of acid, and diminish as the water becomes purer; or is there no relation between conductivity and opacity in liquids? Vision through long tubes is the simplest mode of attacking the question, but to get anything like a complete or satisfactory answer, the absorption spectrum of liquids in the less refrangible ultra-red region would have to be observed.

There are two obvious ways of explaining the transparency of a conducting liquid on the electro-magnetic theory. One is to assume that the minute and rapidly reversed electromotive forces which constitute light are incompetent to effect anything like alternate decomposition and recombination, so that the liquid to such forces behaves exactly like a dielectric; a supposition which would be equivalent to admitting a slight disobedience to Ohm's law, and which is a very reasonable one. The other is to assume that electrolytic conduction only occurs among *dissociated* atoms, and that these free atoms constitute so small a percentage of the total number as not appreciably to affect the transparency or dielectric character of the bulk of the liquid. On this second hypothesis, however, some slight absorption of radiation ought to be expected, and it might increase as the conductivity, *i.e.*, percentage of dissociated atoms, increased.

It may be difficult to maintain perfect homogeneity if change of tem-

Digitized by Google

perature be attempted, else, of course, warming a liquid ought, on this second hypothesis, to make it less transparent.* On the first hypothesis it is possible that exceedingly intense radiation might develop an opacity in liquids quite transparent to ordinary light.

5.—*Under what circumstances is solid matter deposited in the path of a current.*—It is known, from the experiments of Davy and others, that if at the junction of two liquids the opposite ions can form an insoluble compound, then such insoluble compound is formed, those ions drop out of action, and others have to convey the current. For instance, if a current be sent from a vessel containing a barium salt to another containing a sulphate, through an intermediate vessel containing, say, dilute HCl, then $BaSO_4$ is precipitated in this vessel. I propose to make this intermediate vessel in the form of a tube, and examine whereabouts this formation of $BaSO_4$ first appears; varying intensity of current, density of solutions, &c.; and other similar experiments. (See Question 7).

Sir William Thomson, at the meeting, made some important observations about deposits of solids in general, and about the possibility of a long-established current producing solid concretions of a nature not naturally to be expected. As, for instance, nodules of copper in the sawdust of a Menotti cell, possible accretions in the joints of animals, &c. Some porous substance seems most likely, according to present observations, to have such crystals and nodules formed in it, and steady currents might be kept up through porous or cracked crockery, or sawdust, or sand, and secular observations made on the subject. It is not easy to see why deposits of this latter kind should appear, except by the reason of the surface action known as capillary E.M.F., and by some interference with Faraday's law; so that, for instance, the amount of copper going down current, and of SO_4 going up, should not be exactly equivalent, but a slight excess of copper be left, which has to drop out in mid-stream. If it is allowable thus to regard some deposits as isolated ions, their study becomes of considerable interest.

6.—*Is it possible for opposite corresponding Ions to travel at different rates?* The notion of different speed for different ions is founded upon the facts of "migration," but if it can be shown that migration phenomena can be accounted for in another and simple manner, all *necessity* for the hypothesis breaks down. There only remains the fact that some solutions conduct better than others; and this may be accounted for, either by greater speed of their ions, or by a greater number of dissociated atoms able to take part in the conveyance of electricity. It affords no answer to the question as to whether the opposite radicles travel at the same or at different rates.

In favour of Kohlrausch's and the customary migration theory, it may be truly urged that it is reasonable to suppose that each ion should have a rate of travel independent of any other from which it is completely detached; in fact, that it is difficult to see how the velocity of any given radicle can be controlled by the nature of the other radicle, which is travelling at its own pace in an opposite direction.

And *against* this independence of the corresponding ions I have only to urge that it would mean that an electric current could consist of *unequal* opposite currents of positive and negative electricity, and that in some cases at least this is certainly not true. Thus, in a simple fused or homogeneous electrolyte, it is quite certain that opposite ions are travelling at the same rate, and that therefore the current in them consists of *equal* opposite streams of positive and negative electricity. Now if such an electrolyte is put in series with salt solutions, and the same current sent through all, it is difficult to suppose that in one part of the circuit the current consists of equal opposite streams, and in another part of unequal; yet this is what Kohlrausch's theory necessitates.

Again, when a Holtz machine or other replenisher is used to produce a current, half the plate is carrying positive in one direction, and the other half is carrying negative in the other direction, so that in the visible convective part of the circuit it is easy to ensure the existence of equal opposite currents; and there is no evidence that the decomposition produced by such currents differs in any respect from that produced by equally strong voltaic currents. But whence the repugnance to admitting that a current may be at one place ½ positive and ½ negative, and at another place ¾ positive and ¼ negative? Only from the habit of picturing positive and negative electricity as both obeying the laws of an incompressible fluid, with identity or continuity of existence, and the consequent difficulty of supposing that ¼ stream of negative electricity and ¼ stream of positive can at one point rush towards each other, meet, and disappear, leaving no trace behind of either. For this is what must happen at the junction of a fused electrolyte, in which opposite ions are going at the same pace, with a dissolved electrolyte, in which the positive ion is travelling three times as fast as the negative ion. If there is no validity in the objection, then Kohlrausch's theory is probably true pretty much as it stands; but if any difficulty may be legitimately felt in the direction indicated, some modification must be made in Kohlrausch's theory.

7.—*On the apparent relative velocity of opposite Ions*—The facts of migration may, I believe, be accounted for by assuming that the solvent and the dissolved salt *both* conduct the current; but the result is to produce an apparently unequal velocity of ions, which has been mainly examined by subsequent analysis of the liquid near either electrode. I propose to examine it further by means of electrolytes in series:—*e.g.*, noting whereabouts in the path of a current a solid precipitate, caused by uniting ions, first forms. I am, indeed, now engaged in these observations (see Question 5).

A disobedience to Faraday's law of electro-chemical equivalence might in the same way be detected, either by an escape of an excess of one ion past another with which it should wholly combine and become insoluble, or by a deposit of the excess of one ion because it finds insufficient of the opposite ion with which to combine and remain soluble.

It may also be possible to examine the speed with which an ion, starting from a vessel at one end of a long tube, makes its appearance in another vessel at the other end of it, there being in this second vessel some sensitive chemical test for faint traces of it; such, for instance, as iron or sulpho or ferro-cyanide, silver in chloride, copper in ferro-cyanide. Or again, by putting a detecting substance in the tube, the journey of an ion may be continuously watched. Other things more or less vague might be tried; such as seeing whether there is any difference between applying a high E.M.F. to given electrodes in a long narrow vessel, and a small E.M.F. to similar electrodes in a short wide vessel, so that the same current goes through both. One must not expect any variation in the *primary* products of electrolysis probably, but there may be some difference in the secondary effects.

8.—*How much of the Current is conveyed by the water and how much by the dissolved salt in any given case?*—To answer this question it seems to me sufficient to determine the amount of free acid generated at either pole, and to compare it with the amount of metal deposited in the same time by the same current. For instance, with copper sulphate solution and platinum electrodes. If the salt conducted the whole current, one equivalent of free acid would be produced at the anode; if water conducted the whole, one equivalent of free acid would appear at the cathode. It is easy to see this by drawing the section of a cell and considering its action; and so, by determining the proportion of free acid which actually *does* appear at either pole for given strength of solution and intensity of current, it is easy to reckon how much of the current is by each substance conducted. It is obviously necessary to diminish diffusion between the cathode and anode vessels, and to avoid electric endosmose and the use of porous diaphragms. It is also probably advisable to stir or scrub the surface of both electrodes, so as to avoid a layer of some other liquid forming there, and so confusing the whole reaction.

Migration data, if explained in the way I suggest, will also give a determination of the proportion of current conveyed by salt and by solvent; and it will be interesting to compare the two methods of determination, and see if they give the same result. If there is a discrepancy, as is very probable, it will be necessary to examine its cause, and to see whether it wholly upsets the suggested migration hypothesis, or only entails some slight modification.

9.—*Is any quasi-electrolysis possible across an air-space?*—If there are in acid-water any free dissociated atoms electrically charged, it is just possible, though very unlikely, that they might be pulled out of the liquid by electrostatic attraction. Thus, if hot acid liquid be one plate of a condenser, the other plate being a hot metal slab half a millimetre above it, and kept at a very different potential, it is just conceivable that the evaporating steam might contain a trace of free hydrogen or free oxygen, according to the sign of the potential of the plate.

10.—*Does the energy of Secondary Action contribute to E.M.F. in a cell just as much as the energy of Primary Action, or do secondary actions directly generate heat?*—Dr. Wright distinguishes between what he calls "adjuvant" and "non-adjuvant" chemical actions in a cell—those which help the current on, and those which do not.

Lord Rayleigh raised the same question at the meeting, in considering a Clark cell; for the sulphate of mercury, being nearly insoluble, must certainly be mainly reduced by secondary action if anything like a current is kept going; and yet it seems to contribute to the E.M.F. of the cell. But one may ask whether the polarisation produced by a moderate current in such a cell is not evidence of the speedy exhaustion of the *dissolved* $HgSO_4$, and of the time taken to replenish the solution from the nearly insoluble paste, thus showing that it is, after all, the dissolved salt which is really efficient. Moreover, it seems to me that all reversible effects must contribute to the E.M.F. Helmholtz certainly considers the minor attraction of solvents to be as proportionally effective as the main affinities of ions. The behaviour of cells which are able to heat or cool themselves, and the variation of their E.M.F. with temperature, are of great interest in the light of the recent theory of Helmholtz. A result deduced from the second law of thermodynamics is pretty surely founded; but experimental verification is always satisfactory, and one can seldom have too much of it. The laws that want examining are these: Measure the total heat, H, developed per second in cells of various kinds (internal resistance R) by a known current, C; measure also their change of E.M.F. per degree of temperature, dE/dt; then see whether.

$$\frac{RC^2 - JH}{C} = (274 + t)\frac{dE}{dt}.$$

Further examine whether each of these quantities is also equal to the difference between the observed E.M.F. of the cell and that calculated from purely chemical data, viz., to $E - \Sigma (J\epsilon\theta)$.

11.—*Is specific inductivity a constant, or does it tend towards zero for very high strains in the same sort of way that magnetic permeability does?*—I am not aware that the capacity of a highly-charged condenser has ever been seriously measured. It seems a desirable but difficult thing to do.

12.—*How does dielectric strength depend upon density?*—Considerable work has been done in measuring the dielectric strength of different gases at various pressures, but we cannot be said to know the law even for air; nor is the truth about the great strength of approximate vacua on the one hand, and very high-pressure gas an the other, at all certain. The dielectric strength of insulating liquids ought also to be measured; and it might be tried how far pressure affects them. The effect of pressure upon electrolysis has been worked at, and may be said to be fairly understood. The effect of pressure on disruptive discharge, and the internal pseudo-conductivity of gases after elimination of discontinuities, such as cathode-resistance, is more obscure.

* It is here assumed that better conduction means more dissociation; this is not at all certain, it may mean less viscosity; and it apparently does mean this, for the case of rising temperature, though not for the case of increased complexity of constitution.

CABLES TO NEW ZEALAND.

A writer in the current number of the *Fortnightly* says that this "is an age of loose thinking, and of looser writing; of idle words, servants to shallow fools." "Never, perhaps," he continues, "was there an age in which the trade of the sophist, whose business it is 'to make the worse reason appear the better,' was carried on so successfully. Never was there an age in which a writer who feels that he is 'a teacher or nothing' had greater need of well considered and accurate language." These words apply with peculiar force and directness to many purely commercial questions, and we think are applicable to the case submitted by the chairman of the Eastern Extension Company to the ordinary meeting of that company, held last week. We never remember a more direct appeal to the Press to take cognisance of a subject than was discussed at this meeting. The question is one of more than local interest, it demands attention outside a circle of shareholders or the governing body of a small colony. It appeals directly to the commercial, manufacturing, and working classes of the Empire. Putting aside for the moment the position of New Zealand in the cable system, we will start with the fact that the cable system of the world is an outcome of civilisation, that it is essential to the well-being of nations to the development of trade, and the progress of commerce. It is none the less a fact that this all-important link in the chain of civilisation is the result of private enterprise. No doubt the rapid development of submarine telegraphy has taken place with the assistance of subsidies from various Governments. The question originally for the consideration of New Zealand, or any other individual colony, was "telegraphic communication or no telegraphic communication." Private enterprise could hardly be expected to take all the risks, to expend hundreds of thousands of pounds in laying and maintaining cables, unless there was a good prospect of receiving interest upon the capital expended. Experience has shown that during a ten years' trial the return from the New Zealand cable did not give more without the subsidy than two per cent. on the capital invested after calculating amortisation. In other words, New Zealand has had the immense advantages of cable communication years before private enterprise could, under ordinary circumstances, have taken a cable there, solely through the subsidy granted by the colony, added to the receipts obtained from the undertaking, giving the investors a fair interest upon the capital expended. To put the matter in another way. The cable business obtained from New Zealand as a strictly commercial enterprise only pays two per cent. upon the capital—a return out of all proportion to the risk.

The present position is as follows:—The original agreement between the Cable Companies and the New Zealand Government came to an end by lapse of time eight months ago. Negotiations were opened with the Government to continue the subsidy for another ten years. From the first difficulties arose, but the Government at one time inclined to renew for five years. Naturally the company asked for the longer period, in order to pursue some settled policy, and to make the large reductions proposed in the tariffs relating to Intercolonial messages passing over the New Zealand cables. Constant changes are far from beneficial to any business concern, and especially is this the case in cable work, where tariffs, code books, and administrations are affected by every change. Ultimately the New Zealand Government declined to renew, even for five years, and refused arbitration on the question. So far as we know, not one single word has been said against the management of the Cable Company. Its work has been performed satisfactorily. The cable opened in 1876 has never been interrupted—a good proof of the care in its manufacture and in placing it in its position. Of course from time to time the question of tariffs being too high has arisen, but this is a purely financial question, and we think all adverse criticism falls to the ground when the interest paid to the shareholders is considered. That, surely, has not been excessive, nor has too large a sum been placed to reserve.

The result of the policy adopted by the New Zealand Government may not inaptly be termed the one man policy, as emanating solely from Sir Julius Vogel. This policy has led, on November 1st, to the raising of the tariff—a necessity, so far as the Company was concerned, in order to make up for the loss of the subsidy. The worst part of the business is that the New Zealand Administration have increased the terminal charges from 6d. to 4s. 6d. per ten words—an additional tax upon Australian telegrams paid solely by Australians, and intended to be used as a set-off against the Telegraph Company for its increased tariff. New Zealand, in fact, says: We intend to pay what we please for telegrams, whether it suits your shareholders or not, and if you increase your tariff we shall increase our terminal charges proportionally, so that we lose nothing. Commercial circles in Australia and New Zealand are not likely to remain quiet under these cir-

Digitized by Google

cumstances, and already there are signs of rebellion against the action of New Zealand. No reason has been advanced for the policy, except that the renewal of the subsidy "would interfere with the laying of an opposition cable between Australia and Europe, *vid* the Pacific." This opposition cable seems to be favoured by Sir JULIUS VOGEL. Its promoters ask New Zealand for a subsidy of £20,955, as against £9,599, the guarantee for existing companies. The tariff of the proposed Pacific cable is to be 4s. per word, while the existing companies offer to give a 2s. 6d. tariff if they receive a subsidy equal to that asked for by the promoters of the Pacific cable. There is no doubt but that the Eastern Extension Company could arrange with the companies in connection with it to enable the proposal of a 2s. 6d. tariff to be carried out, or Mr. PENDER would have been less emphatic on this point. The above figures apply solely to the New Zealand contribution to the subsidy; the figures relating to the whole subsidy to be paid for both schemes will be found in our report of the meeting previously referred to. We have endeavoured to show that from a purely business point of view the action of New Zealand is surprising. Why should a subsidy larger in amount be paid when the lesser amount answers just as well. Or, if the larger amount is paid, why are the less facilities to be taken? We do not intend to re-discuss the Pacific scheme, having long ago pointed out the unbusiness-like character of the whole proposal. One phase, however, should not be overlooked—it is that should the scheme ever be carried out, the benefit will be almost entirely on the side of America, while England will proportionally suffer.

TELEGRAPHIC FRAUDS.

Under this heading a paragraph was published in our issue of the 1st October reflecting on certain of the "local officials of the Western Union Cable Lines," and in our next issue of the 8th October we published what we hoped would have satisfied anyone, that no accusation or imputation whatever was intended by us against any person connected with the receipt or forwarding in this country of any cable messages, and in what we thought, and still think, fitting terms expressed our regret for any pain or annoyance that the appearance of the paragraph might have caused. It has been represented to us, however, that from the terms in which our withdrawal was expressed there might possibly exist some misapprehension as to our meaning, and in order to obviate this we now unreservedly acknowledge that the statements contained in the paragraph of the 1st of October were entirely erroneous, and repeat our regret that it should have ever appeared, or have caused annoyance to any one connected with the Western Union Company. We think it only due to ourselves to state that the original paragraph was written and published during the unavoidable temporary absence of the responsible editor, and without his knowledge, an explanation that has already been furnished to the parties who have complained of the statements contained in it.

CORRESPONDENCE.

CABLE RATES TO NEW ZEALAND.

TO THE EDITOR OF THE ELECTRICIAN.

"SIR: As the dispute between the New Zealand Government and the Eastern Extension Company, to which reference was made by the chairman at the company's general meeting last week, is engaging considerable attention in the Australasian colonies and elsewhere, and as telegraphic communication is now so universally used, it may interest many of your readers to know the facts of the case. I am therefore directed by the chairman to send you the following outline:—

"In consequence of the serious inconvenience felt by the Government and public of New Zealand from the want of telegraphic communication with Australia and the rest of the world, an arrangement was made with my company in 1875 for the laying of a submarine cable from Sydney to Nelson, in consideration of the payment to the company of an annual subsidy for ten years of £5,000 from New Zealand and £2,500 from New South Wales.

"The cable was laid and opened for public use in February, 1876, and from that day to this has never been interrupted.

"In November, 1884, the company, finding that the earnings of the cable without the subsidy after nine years' working were insufficient, when working expenses and amortisation for renewing the line were deducted, to give more than a return of 2 per cent. upon the capital invested, opened negotiations with the Governments with a view to the renewal of the subsidy on its expiration in February, 1886.

"The New Zealand Government at first replied that the subsidy was no longer necessary, but the New South Wales Government expressed their willingness to renew their share of the subsidy for a further term of ten years upon the company undertaking to reduce the tariff for intercolonial telegrams over the New Zealand cable from 6s. per ten words to 5s. for ordinary messages, and 3d. per word for Press messages. The proposal was accepted by the company, and submitted by the New Zealand Government to their Parliament, but the latter negatived it, and would only agree to five years' renewal.

"Thereupon the company intimated that they would accept the shorter period, but as they considered the bargain under the circumstances a hard one, they could only give the reductions of tariff proposed by the New South Wales Government, provided the subsidy was renewed for the whole ten years.

"Subsequently the company submitted to the New Zealand and other Australasian Governments proposals based on the principle of guaranteeing the average earnings of the company for the past three years, for giving the colonies full control over the tariffs between Australia and Europe by making the rates any figure they pleased, and offered to accept the terms sanctioned by the New Zealand Parliament if the guarantee principle was applied to the New Zealand cable.

"This and all other proposals made by the company for bringing about an amicable arrangement having been refused, and an offer to refer the question to arbitration having also been rejected, the company have been reluctantly compelled to increase the tariff for intercolonial telegrams between Sydney and Nelson to 10s. per ten words from the 1st inst., in order to recoup the loss of the subsidy.

"The company have delayed taking this step for over eight months in the hope that the necessity for it might be averted, but having exhausted all conciliatory means of bringing about a satisfactory solution, the responsibility for the inconvenience caused to the public must rest with the New Zealand Government and not with the company.

"At one time the New Zealand Government threatened, if the tariff was raised, to withdraw the office accommodation which they are bound to give to the company for ten years after the expiration of the subsidy, but the company intimated that such action might compel them to close the cable and hold the Government responsible for damages, and the Government have not so far carried out their threats.

"The New Zealand Government now notify that their terminal rate of 6d. per ten words has been raised to 4s. 6d., and this amount the company are obliged to collect from the telegraphing public of Australia and add to their cable tariff, making the total rate for messages from the coast of Australia to New Zealand 14s. 6d. per ten words, against 10s. 6d. on telegrams from New Zealand to Australia.

"The New Zealand Government also intimate that they will not collect more than 6s. for the cable charge on telegrams emanating from New Zealand, but will apply their increased terminal rate on telegrams to New Zealand in payment of the increased cable charge, and thus relieve the New Zealand

Digitized by Google

public at the expense of the telegraphing public of the other colonies.

"The company cannot, however, believe that the public will, for any length of time, allow this regretable state of things to continue, and as some of the leading Australian Governments and Chambers of Commerce in Australia and New Zealand are supporting the company's action, we are hopeful that before long an arrangement satisfactory to all parties will be arrived at.

"I enclose a copy of the whole correspondence on the subject, and would invite your special attention to the last telegram, giving a summary of an article in the *Melbourne Argus* on the subject, which shows how the question is viewed in Australia.—I am, Sir, your obedient servant,

"F. E. HESSE, Secretary.

"The Eastern Extension, Australasia and China Telegraph Company (Limited), Winchester House, 50, Old Broad-street, E.C., Nov. 2."

ELECTRIC TRAMCARS, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue, on page 507, you make a remark which has a peculiar interest to me, viz.: "Whenever a fresh start is made the coils of the motor are necessarily subject for a short time to a current far greater than they can safely bear for any length of time, and this certainly tends to render the question of heating of even greater importance than ordinarily in the case of motors employed for this special purpose." This point I saw during practical experiments with the first electric street car operated in this country, at a comparatively remote period. The result was that I patented a method of working which entirely obviates the rush of current through the motor, and the car can be started with no heavier current through the coils of the motor than is used when running easily on a level track. The whole progress of electric traction depends on its economy, and points of this kind are of great practical importance.—Yours, &c.,

RADCLIFFE WARD.

10A, Great Queen-street, Westminster, S.W.,
3rd November, 1886.

ERRATA.—Prof. Forbes writes to us pointing out that the following corrections must be made in the report of his paper "On Hysteresis," read at the late meeting of the British Association at Birmingham, which appeared in our issue of October 29. In reference to these corrections we may say that our report was obtained from the original MSS. handed to the reporter, and it will easily be seen how the errors referred to arose. An indistinct T was copied as 1, π as 11, H as 11, a for α.—ED. *E.*

REPORT OF AN AMERICAN TRAMWAY COMPANY.

In the report of the Baltimore Tramway Company for the year ending September 25th, Mr. Robbins, the general manager, bears the following valuable testimony to the thorough practicability and unqualified success of electric traction. He says:—

"Our success by the change from horse and mule power to electric power has exceeded my highest expectations. It has largely increased travel on the route, and at a less operating expense than horse-power. The road has been running more than a year by electricity with as much regularity as any road in the country. I find less difficulty in getting men to run the motors properly than I do to get men to run the ordinary horse car properly. The road is now being run by persons who, before their employment here, were unfamiliar with electrical affairs. The overhead conductors that have been lately put up to carry the current overhead at the road crossings are working very successfully. We are now extending the overhead conductor over another branch of the road, which we expect will be completed before many weeks." He then gives the subjoined figures:—

For the year ending Sept. 1, 1886, the road carried, with two cars propelled by Daft electric motors, 311,141 passengers at 5 cents each	$15,557.05
For the corresponding year ending Sept. 1, 1885, the road carned, with three cars propelled by horses, 227,155 passengers at 5 cents each	11,357.75
Showing an increased gross earning by two electric cars of over the gross earnings of three horse cars for corresponding time the previous year.	$4,199.30
The average number of passengers carried per car per annum by electric power was	155,570
The average number of passengers carried per car per annum by horse-power was	75,718
Showing an excess of passengers carried per car per annum by electric power of over horse power per car per annum.	79,852
The average gross earnings per car per annum propelled by electric power was	$7,778.52
Average gross earnings per car per annum by horse-power was	2,785.91
Showing an excess of gross earnings per car per annum of in favour of electric power per car per annum over horse-power per car per annum.	$3,992.61

The average cost of horse-power per car per day is $6.50 The cost of the electric power per day on this road is:

1½ tons of coal, at $3.50 per ton	$5.25
An engineer at	2.00
A fireman at	1.50
Oil and waste	0.50
Interest and depreciation of plant	2.75
Making	$12.00

the cost of ample electric power to run three cars and three motors, which is an average cost per car per day for electrical power of $4.00.

He adds: "When I take into consideration the largely increased earnings per car propelled by electric power over the earnings per car propelled by horse-power, I am very favourably impressed with the large percentage shown in favour of electric-power over horse-power for propelling street cars. There are not two miles of street railroad in the country more difficult to operate, owing to the unprecedented grades and curves to overcome than the two miles that are being successfully operated here now by electricity. There are not 300ft. of level track at any one point on the road. The grades vary from nothing to 350ft. to the mile, with curves from 40 to 70ft. radius on heavy grades. With more favourable conditions—such as cheaper fuel, easier grades and curves—a much more favourable result could be obtained than on this road."

LEGAL INTELLIGENCE.

Bannatyne v. The Direct Spanish Telegraph Company (Limited).

This was a case heard by Vice-Chancellor Bacon, which came on upon a motion by Mr. Neil Bannatyne, at one time Chairman of the Direct Spanish Telegraph Company (Limited), and now a preference shareholder in the Company, on behalf of himself and the other holders of preference shares, against the Company, Sir James Anderson (its present Chairman), and the other Directors of the Company, for an interim injunction to restrain the defendants from acting on certain special resolutions passed by the Company for the reduction of their capital, and from presenting a petition to confirm the reduction.

Mr. Marten, Q.C., and Mr. H. B Howard (instructed by Messrs. Murray, Hutchins, and Stirling) conducted the case for the plaintiff; Mr. Rigby, Q.C., and Mr. W. P. Beale (instructed by Messrs. Blunt and Lawford) represented the Company; Mr. Burton Buckley appearing for the defendants, Sir James Anderson, and the other Directors.

Mr. MARTEN, Q.C., in opening the case for the plaintiff, said that the Direct Spanish Telegraph Company was registered on the 8th November, 1872, with an original capital of £130,000, in 13,000 shares of £10 each. By special resolutions of the Company passed in 1874 there was an increase made to the capital by the issue of 6,000 new shares at £10 each, making £60,000, all of which were paid up, being issued on the terms that they should have a preferential dividend of 10 per cent. per annum, and also, if there were insufficient money to pay such dividend, that it was to be made up out of the profits of any succeeding year. The dividends were paid on the ordinary shares of the Company up to the 30th of June, 1882, whilst the dividends on the preference shares were paid up to the 30th of June, 1884, since which time the money which was available for that purpose had been retained by the Company, with the result that they had now a reserve fund amounting to £14,300. The Company retained that money with the idea that in consequence of their loss of capital—or what was the same thing, the loss of one of their cables—they were bound to make good that loss. He ought to state that the 10 per cent. per annum on the £60,000 preference capital would amount to £6,000 a year, and what the Company purported to do by the special resolutions, which he would call his lordship's attention to, was this. They proposed to reduce the share capital by striking £5 per share not only from the ordinary capital but also the same amount per share from the preferential capital. By an arbitrary reduction of capital they reduced the amount of the preferential capital from £60,000 to £30,000. The result would be, according to their contention, that they would have to pay only £3,000 a year to the preference shareholders instead of £6,000, for which they originally bargained. In other words, they proposed to break the bargain upon the faith of which the preference shareholders entered into the Company and took their shares. On the other side it was suggested that if the Company were to be wound up the right of the preference shareholders to 10 per cent. per annum would avail them little, inasmuch as they could only share in such assets as there might be with the ordinary shareholders. That might or might not be the case, but it was sufficient for him to say that there was no idea of winding up the Company, which was now a going concern. The Company was reserving what should go in dividends for the purpose of making good what had been lost. That would end at a limited period of time, when the preference shareholders would enter upon their rights and would be entitled to be recouped for all the dividends temporarily withheld. With that statement of the case he would now ask his lordship's attention to the Memorandum and Articles of Association and to the terms upon which the preference capital was issued. Article 7 of the Articles of Association authorised the Directors, "with the previous sanction of a special resolution of the Company, to increase its capital by the issue of new shares to such an aggregate amount, with such preferential right to dividend, and such priority in the distribution of assets, or subject to such postponement of dividends, or in the distribution of assets, as should in such special resolution be provided." He did not think he would trouble his lordship with Article 8, but Article 9 provided that "all capital raised by the creation of new shares shall be considered as part of the original capital, and shall be subject to the same provisions in all respects as if it had been part of the original capital, except so far as these Articles, or the resolution authorising the raising thereof, may otherwise direct;" and Article 10 also authorised the Company by special resolution from time to time to reduce its capital, and to alter the amount and denomination of its shares. He did not think he would trouble his lordship by reading any other of the Articles of Association. He would now refer to the fact that there were passed on the 3rd of July, 1874, and confirmed on the 17th of the same month, special resolutions, by which the Directors were authorised to increase the capital by the issue of 6,000 new shares of £10 each, such new shares to be entitled to "a fixed preferential dividend of 10 per cent. per annum," and the deficiency in payment of such dividend in any year to be made up out of the profits of any succeeding year, as he had already told his lordship. As a matter of fact these shares were issued and paid up, and the plaintiff was the holder of some of them. On the 30th September of the present year, special resolutions were passed for the reduction of the capital, and were confirmed on the 19th of October. They were as follows:—"That in consequence of the abandonment of the Company's original cable, the capital of the Company be reduced from £190,000 (at present represented by 6,000 preference shares of £10 each, all issued and fully paid up, and 13,000 ordinary shares of £10 each, whereof 12,931 are issued and have £9 per share paid up, and 69 are unissued) to £95,000, and that such reduction be effected by writing off £5 per share from the amount credited as paid up on each issued share, and £5 per share from the nominal amount of each unissued share, the amount so written off the issued shares being capital not represented by available assets," and "That the Directors may make such regulations as they think fit for exchanging the certificates of shares for certificates in conformity with the foregoing resolution." He thought he had now stated the facts necessary to be brought before his lordship. He then proceeded to read from the affidavit of Mr. Neil Bannatyne, the plaintiff in the action, to show that that gentleman had attended both meetings, protested against the passing of those resolutions, and recorded his vote accordingly, on the ground that the effect of the resolution would be to deprive the preference shareholders of £3,000 per annum, or half the dividend they would be entitled to receive under the conditions upon which the preference shares were issued, and to put it into the pockets of the ordinary shareholders. He also quoted from the report and statement of accounts of Directors, presented to the meeting of the shareholders on the 30th September, as follows:—"The examination of the original Bilbao cable having resulted in showing that it could not be advantageously restored, the Company has now to adopt one of the alternatives pointed out in the opinion of Sir Horace Davey (to which reference has been made at previous meetings), and either discontinue the payment of dividend on all the shares (including the preference shares) until sufficient money is accumulated to lay a new cable, or else take steps to write off a proper amount of the existing capital as unrepresented by assets. The Board have considered the position carefully, and find that the former alternative would, with the present revenue, involve the suspension of all dividends for ten years. But, on the other hand, to place the Company in a sound and dividend-paying position by writing off the lost capital, the following step may be taken, viz., reduce the nominal capital by writing off £5 per share on all the shares. If this were done, the arrears of dividend on the preference shares (£2. 10s. per share to the 31st December, 1886), could be at once paid. [The report then gives the figures on which this calculation is based.] In the calculation the reduced ordinary shares are treated as £5 shares with £4 paid on each, thus leaving the £1 liability on the ordinary shares as at present, and the Directors consider that this liability should remain, as the debenture holders might object to the scheme if it were proposed to extinguish it. There is no occasion for calling up the amount at present. The accounts for the half year show, after providing for debenture interest, a balance to the credit of profit and loss of £4,573. 12s. 2d. The traffic receipts show an increase of £1,022 2s., as compared with the corresponding half year of 1885, and a decrease of £89. 10s. as compared with the last half year. The new Bilbao and the Marseilles-Barcelona cable continue in good working order. The Directors have already, by their circular of 16th July last, advised the shareholders of the result of the examination of the original Bilbao cable, and of the opinion of the firm of engineers, Messrs. Clark, Forde, and Taylor, who superintended the operations, to the effect that this line could not be advantageously restored, and the Board have accordingly abandoned it." He then read from the affidavits of Sir James Anderson and Mr. Henry Charles Forde, generally affirming what was contained in the foregoing statements, and proceeded to argue that the special resolutions passed at the meeting on the 30th September, and subsequently confirmed, were *ultra vires*. It was quite true that the Company were authorised to reduce their capital, but not so as to upset the conditions upon which a particular portion of that capital was issued. It was plain, however the matter might be obscured, that the fund which was now being accumulated, and would accumulate for a considerable number of years, would be distributed among the ordinary shareholders instead of being reserved to make good the capital of the Company. As matters stood upon the evidence of Sir James Anderson he agreed that a certain period must elapse before the profits could accumulate to such an extent as would enable the Company to pay dividends without having restored their capital. But there was no difficulty or obstacle in it. They were all familiar with cases of companies, such as water or gas undertakings, who were limited to 10 per cent. dividends, and who perhaps for a series of years never earned anything like that dividend, and who afterwards began to earn enough to pay their current 10 per cent, and make good out of the subsequent profits the sum that was necessary to recoup the shareholders who were entitled to it the full 10 per cent. In the same way, at the expiration of the 10 years the preference shareholders would have the capital restored to its original amount. That capital would be applied either to the reduction of debentures, whereby the position of the preference shareholders would be greatly improved, or put into investments, which would produce an income which would benefit the preference shareholders by increasing their security. When that period had elapsed the preference shareholders would, according to their bargain, enter into the receipt of their 10 per cent. per annum, and then they would be entitled to take the surplus until all their arrears were paid up. That was in accordance with the Articles of Association, and the special resolution of 1874. That was the bargain. Everybody knew perfectly well when that bargain was made that the Company was a Submarine Telegraph Company. Everybody knew the many contingencies to which such a Company was subject, as, for example, the liability to have its cables destroyed or rendered worthless by the action of the water or the scour upon them. These risks were contemplated, and the existing ordinary shareholders at that time thought it so expedient for the purpose of raising the necessary capital which was requisite for their then necessities that they entered into that bargain. He submitted, therefore, that it was plainly *ultra vires* for a body of shareholders to attempt thus to deprive the preference shareholders of that which was secured to them by their bargain. As he had said, the only argument suggested on the other side was that if the Company were wound up the preference shareholders would not have a preferential right in the distribution of the assets. That was unnecessary for him to argue. As he had pointed out, the Company was a going concern, and was not to be wound up. It was a prosperous Company, and

Digitized by Google

although it had had one of those misfortunes incidental to all telegraph companies, that would be repaired in a short time, and eventually everybody would get fairly well paid, and therefore he submitted that there was no ground or justification whatever for the aforesaid special resolution. In support of his contention the learned gentleman quoted the case of Blisset *v.* Daniel, page 493, Vol. X. of "Hare's Reports," and also the decision of Vice-Chancellor Bacon in the case of Alhusen *v.* Borris, reported in Vol. XV. of the *Weekly Reporter*, page 739. He submitted, in conclusion, that in the present case the ordinary shareholders, who were in the majority, had no right to help themselves to a portion of that which ought to be appropriated by the preference shareholders. It would be contrary to the truth and justice of the case, and contrary to the express terms of the bargain, which could not be overridden by any attempted act on the part of the shareholders.

Mr. HOWARD said he would like to draw his lordship's attention to what would be the effect of the resolution. As his lordship saw, the preference shares amounted to £60,000, at 10 per cent. That was £6,000 a year. Instead of the £6,000 a year going to the preference shareholders, under the new resolution only £3,000 would go to them, and £3,000 to the ordinary shares. In other words, it would take £3,000 out of the preference shareholders' pockets, and put it into those of the ordinary shareholders. He submitted that the scheme for reducing the capital was not a *bonâ fide* scheme for the benefit of all the shareholders, but for the benefit of the ordinary shareholders at the expense of the preference shareholders. That was its real effect. It was quite true that the Company might be able to reduce its capital, but there were other ways in which that could be done without encroaching on the interests of the preference shareholders. His lordship would at once see that if preference shareholders were to be dealt with in this way the security of all preference shareholders would be very materially endangered.

Mr. RIGBY, Q.C., in opening the case for the defence, said that the question submitted to his lordship was really one of a bargain, and of the powers that had been reserved by the Company bearing upon it. What the Company was doing his lordship would understand could not be attacked under any illegality outside the powers which were contained in the Articles, or the terms upon which the preference shares were issued. The Company was originally formed for the purpose of purchasing a cable already existing and laid down between the Lizard and some place in Spain. A cable in those days cost a large sum of money. £125,000 he thought was the price paid for it, and it formed a most important part of the assets of the Company. A second cable was laid down—he would not say side by side, but generally in the same direction, and a third cable was purchased by the Company in the Mediterranean between Marseilles and Barcelona. Now, of those assets the original cable had gone. It was not a question admitting of anything like controversy. With the full knowledge and approval of the shareholders of the Company the Directors had abandoned that cable as useless. They had gone so far as to pick up what could be got at. Something like 150 miles of it had been picked up, and, according to the reports laid before the shareholders, what remained of the cable would not pay the cost of picking it up. The cable was gone, and therefore an important part of the capital of the Company, to the extent of pretty well £112,000, had gone with it, just as completely as if an earthquake had taken place, and the Company was *de facto* shorn of that important part of the assets. The others that remained were perishable property—very perishable, indeed—and they required for the purpose, not of replacing the original one—that was hopeless—but for the purpose of creating a fund for preserving the life of the existing ones, after the payment of the debenture debt and other expenses, to carry forward a large sum—and it must be done according to the terms of Articles of Association—to constitute a fund for the replacing of those old cables. Now, under the circumstances, there was a class of preference shareholders, created under the terms of the Articles of Association, entitled to a preference as regarded dividend, but to no preference whatever as regarded capital. The preference shareholders really came there and said, "We are in this favourable position, that we are, as it were, annuitants on the profits, and you have no right at all to take into consideration the fact that one half of our capital is actually gone. Although the Act of Parliament says you may, and although it was provided by the Articles that you might, you have no right to take into consideration the misfortune that has happened to us in common with the other shareholders of the Company that half our capital is lost." Now the clause under which they were going provided for the power to reduce capital—to cancel any lost capital or any of the capital unrepresented by available assets. There was no conflicting evidence on that subject at all. The value—which they had taken at £95,000 of that lost capital—had disappeared. There was no dispute as to the figures, as to its fair value, or, at any rate, a moderate value, of the capital that was actually gone, and under the Companies Act the Company had power to cancel any capital unrepresented by available assets—in other words, to cancel that £95,000. He quite agreed—and his lordship would not hear anything from him to the contrary—that if there had been in their bargain with the preference shareholders anything which prevented them from recognising the facts in the way in which the Legislature intended that they might recognise them—if they had bargained not to reduce the capital that was to say—they must stand by their bargain. But that was not the fact. One of the terms of the arrangement which the Directors entered into—or, rather, their predecessors—when the preference shares were issued—was that the capital might be reduced. They had to contemplate that losses might arise, and in that event preference shareholders had to take their share of the loss along with the others. It was rather suggested that this was a case where the ordinary shareholders used their voting power to the prejudice of the preference shareholders. He ventured to submit that that was not so at all. He had a report of the meetings at which the whole matter was discussed, with the number of voters and so on, and the number of preference shareholders who agreed to the proposal was almost as large as that of the ordinary shareholders. The numbers for the original resolution were as follows: 34 ordinary and 29 preference shareholders—these were by proxy—and 17 held up their hands whose holding (whether preference or ordinary) did not appear to be quite clear, and only five voted against the resolution. He merely mentioned that as a fact. He did not say that it would alter the powers in the least, but it showed at any rate that it was a question in which a large majority of the preference shareholders themselves were agreed, and that they approved of the plan that was to be adopted, and presumably, therefore, considered it to be to their interest. He agreed, however, that that would not affect the question from a legal point of view. The question really before them was this—Was it intended that those preference shareholders should have, whatever might be the vicissitudes of the Company, a fixed annual payment of £6,000 a year as a preferential charge upon the profits, or was it not? He would now call his lordship's attention to the Articles of Association from his (the speaker's) point of view. The clauses that were important had already been read, but he would like to offer a few observations upon them. Turning to page 6 of the Articles, to which has lordship's attention had already been directed, they found that Article 7 said: "The Directors may with the previous sanction of a special resolution of the Company increase its capital by the issue of new shares to such an aggregate amount with such preferential right to dividend" (that was what was exercised), "and such priority in the distribution of assets, or subject to such postponement of dividends, or in the distribution of assets as should in such special resolution be provided." Now, he would point out that by this Article, if it were for the benefit of the Company, the shareholders in general meeting if they were in a majority sufficient to pass a special resolution on their authority, could at any rate create capital over the heads of the preference shareholders. They could create pre-preference shares to any extent, and in that way could deprive the preference shareholders of what they thought their vested interests—their right to the annuity of £6,000. There was no such thing as a bargain with them that, under all circumstances, and throughout all time, they should have £6,000 a year. If it had been said that there should be paid to them £6,000 a year, under all circumstances, that would have been a different thing. But it was not so. They were in a position perfectly capable of being defined accurately by reference to the bargain entered into. So long as the capital stood as it did at the time when the preference shares were issued, the preference shareholders had an undoubted right to be paid at the rate of a fixed preferential dividend of 10 per cent. per annum on their shares—so long as the capital was unaffected in any way. That would have amounted, as his learned friend had said, to £6,000 a year in a concern represented by a capital of £60,000. But the capital might be altered in different ways. They might alter it to any extent by increasing it, and so they might postpone the payment of the £6,000 a year with perfect propriety. It might become a second, third, or fourth charge, and if the Company became unfortunate, or if they were engaged in a bad business, the £6,000 might disappear. He would not trouble his lordship with Clause 8, but Clause 9 provided that "all capital raised by the creation of new shares should be considered as part of the original capital, and should be subject to the same provisions in all respects." Therefore those preference shares were part of the original capital. There was nothing in the Articles to which his attention, or that of his lordship, had been called which modified that. If he turned to the resolution authorising the raising thereof, he certainly did find that there was one provision, and one only, which affected the preference capital—provision 3 of the special resolution—and which said the preference capital "shall be entitled to a fixed preferential dividend of 10 per cent. per annum, and if in any year the net profits of the Company shall not be sufficient to pay the whole, the balance shall be paid out of the profits of subsequent years." He agreed that that was an important alteration, giving the preference holders a better position as regarded dividend than the other shareholders, but it was the only alteration introduced by the special resolution, and except in that particular their capital was part of the original capital of the Company in all respects, and liable to all the incidents that attached to it as part of the original capital. One of those incidents was that the capital of the Company in certain contingencies sanctioned by Parliament might be reduced; that was one of the incidents that would arise with regard to a Company even if there were no clause in the Articles, and it might be brought in by a special resolution. But in Clause 10 it was expressly provided that "the Company may, by special resolution, from time to time reduce its capital, and alter the amount and denomination of its shares." His lordship would therefore see that taking that along with Clause 9 the Directors were entitled to read it:—"The Company may reduce its capital, including any capital that may be created with a preferential dividend" (that was according to Clause 9) because that incident, among others, applied), "and may alter the amount and denomination of the shares." It could only be done, of course, in accordance with the Act of Parliament, which clearly laid down the provisions which enabled a company to do it, and the cases in which it could be done. One of those cases had arisen in the present instance. There disappeared by a misfortune common to all partners interested in the concern an asset which was worth £95,000 when it was a good going cable, and the preference shareholders wished to introduce into the bargain made with them a term which was not only not there, but which was excluded by the terms of the Articles. The only advantage which they were to have was that 10 per cent. was to be paid on their capital, but in all other respects they were to be in position of the holders of the original capital. They had their votes. They exercised their right of voting solely by virtue of that clause, which put them on the footing of the original capitalists. Therefore the amount of power and authority to be given to them in the Company was defined by the actual bargain—the conditions of which

Digitized by Google

were equally defined, to which each one must have subscribed when he took his shares, providing that "the capital shall be liable to reduction." How was it possible to exclude that from the terms of the bargain? Suppose they had put into the resolution "this is to be without prejudice to any other of the previous Articles," there could then be no doubt about it. But no one reading the Article could fail to see upon what terms the preference shareholders took their shares. The resolution itself did not allow anyone to determine for himself what position he would hold in the Company. He was obliged to go to the Articles, and there he found that his capital was in all respects part of the original capital of the Company, with the single exception that he was not to be paid with the others whatever their dividend might be, but he was to be entitled to a dividend upon his capital of 10 per cent., and he found written in the document which defined his rights and constituted the bargain between him and the Company—he found there written before his eyes the fact that the capital might be reduced. Now he (the learned counsel) would remind his lordship that in Clause 10 the capital did not mean the original capital, but it meant all the capital, for the time being, of the Company. If all the capital for the time being of the Company included preference and ordinary shares, they could not reduce one part. That would indeed be *ultra vires*. They must reduce it in proportion to the interests of the holders. It was a great misfortune to all of them, no doubt; but if their cable was still at work they would not have required the proposed reduction. But, *de facto*, the half of their assets had been swept away. The case that was contemplated by the Act of Parliament now arose. The half of their available assets was gone, and the policy of the Legislature was to bring the accounts of the Company in accordance with the facts—to recognise facts. Half of the capital having disappeared, all that the Company did was to recognise that fact. If it could have been made out that this was an arbitrary use of the power of a company, whereby the ordinary shareholders were taking in their own interest a step which was objected naturally to by the preference shareholders, there might have been more ground for examining into the finances of the Company, and so on, and asking whether it was fair. But, after all, by the terms of the constitution of a company, it was determined that a general meeting—by such a majority as the Legislature required for passing a resolution—should be the judges. He ventured to say that it could not be represented that this was a scheme on the part of the ordinary shareholders, where they were exercising a power which by the literal terms of the bargain was not vested in them—or where they were exercising a power not because a *bonâ fide* case of the kind contemplated by the Legislature had arisen, but for a culpable purpose. On the contrary, a case for the exercise of the power contemplated by the Legislature—namely, that there were not the available assets which represented the nominal capital of the Company—had arisen. Their loss had come upon them as a misfortune. In the action cited by his learned friend, Blisset *v.* Daniel, the case had not arisen. There was a nominal power to do a certain thing, and seeing that in the wideness and extent of that power was an opportunity for carrying out a scheme which they ought not to have carried out, and which the power was never intended to facilitate, they made use of the general power with the unjust intention of bringing about a state of things not contemplated. But here what they did was done when the actual state of things arose. Let them also suppose that in the case of Allhuisen *v.* Borries that it had been settled that on the death of Mr. Allhuisen the partnership might be dissolved if the parties thought fit, it would be idle for the parties to come forward and say when that event arose, "You cannot exercise it, because the exercise of that power will incidentally be injurious to the son." The answer would be clear. That was one of the terms of the bargain. The event had arisen upon which the power should be exercised. It must have been in the contemplation of the parties that the event so provided for would arise, and therefore what was intended by the partnership was brought about by the exercise of the power. When a case arose of the reduction of the capital of a company, the company might exercise its powers. In this case it had arisen, and they said, "Now we must exercise the power given to us by our bargain and by the Act of Parliament. We exercise that power, and it is not for you to say, 'Oh, but that will in an indirect manner have an evil influence upon the preference shareholders.'" That must have been contemplated. Whoever taking preference shares could have failed to see that, if the share capital were reduced—which was one of the things contemplated—his right to dividends on what remained of the capital would be to him less valuable than it was before? There was only one plaintiff here, but he would give that gentleman the benefit of the four others who voted with him. The five preference shareholders—he would assume that they were all preference shareholders, as it was not stated to the contrary—those five out of the thirty-four preference shareholders voted that they did not think that this would be a step for their advantage. That was all. Now, if there was a definite bargain that this would not be done, or, if they could find from any fair construction of the arrangement made that it would not be done, there would be an end to the question. But, on the contrary, there was an express bargain that it might be done, and when the case arose for the reduction of capital the preference shareholders were holders of capital on the same terms as the others. How could it then be said, "You are taking an unfair advantage of that power?" He quite agreed that the Court would look with very great anxiety to see that no injustice was done. But what was the actual constitution of those companies? The shareholders would have different views as to their own interests. If the preference shareholders wished to protect themselves against a possible reduction of capital in a case which might arise, they could have bargained either for a veto upon any such arrangement, or in some other way they might by the bargain have provided some means for protecting themselves against such reductions. But, on the contrary, they submitted to the terms that the Company should always have the power to reduce the capital, and now they came forward to repudiate those terms. He did not think there were cases which could illustrate the matter to advantage. His lordship had seen the way in which the question rested, and how the necessity in the first instance was forced upon the Board of Directors. The Board had not acted in any arbitrary manner. They had brought the whole matter fully before the shareholders' meetings, the reports of which he could go into. No doubt Mr. Bannatyne was perfectly right in saying, "I attended the meetings and voted against the resolutions." Mr. Bannatyne's action was taken expressly for the purpose of asserting what he believed to be his right. But when it was found that Mr. Bannatyne and others had agreed that the power of reduction in a proper case might be made, what right had that gentleman to repudiate that term of the bargain when the case had arisen, or because, he said, "in my opinion that will not be for the advantage of the other preference shareholders?" The other preference shareholders might well take a different opinion. It was quite open for the other preference shareholders to say "We do not at all agree with you." That, in fact, was what they had said by their votes—"we do not think it would be for our advantage not to accept the position as proposed." The advantage of the arrangement proposed would be that they would be entitled to a share in a company which would be a real dividend paying company from the present time. Part of the bargain was that they were to receive, he would not say a large sum per share—£2. 10s.—down, which was 25 per cent., he might say, of the value of their shares, with the prospect of an immediate dividend meantime. He could only say this, that it was by no means clear as a matter of commercial value that a nominal £10 share, which might at some future indefinite period be entitled to a certain interest, was better in value than a share of the nominal value of £5 with £2. 10s. paid down for arrears, and the prospect of immediate dividends. In order to establish the case at all, however, it must be shown that the vested right which the preference shareholders claimed was vested in them—not the right of judging as to their own interests, but the right independent of every one else—the independent members of their own class also, to say the thing could not be done. Not because it hurt their own interests—they might be the judges of that—but because there was something in the contract which prevented it from being done. If he were right in the view he took, so far from there being anything in the contract which would render it improper, when the case properly arose, to reduce the capital, there was a provision in express words that that case might be taken advantage of. At present they had only got so far as to pass the special resolution. That was the necessary preliminary. Their next step was to present a petition to the Court. They were obliged to get an order of the Court to its sanction. Everything would be done in accordance with the provisions of the Act of Parliament, under the direction of the Court of Chancery, and not otherwise, and unless they could find at the very threshold a clear provision that the power of reducing the capital could not be exercised—instead of which they found what they considered a clear provision that it might be—he submitted that the Court had no jurisdiction, and ought not to interfere in the case.

Mr. BEALE said there was very little to add. He, however, wished to deal with this point, that Mr. Marten in opening the case referred his lordship to the principle of the case Blisset *v.* Daniel. Now, if he (Mr. Beale) understood the case, it was one where the Court interfered when a power of this sort was exercised by people merely and solely for their own exclusive benefit. If that were so, the present was not such a case. They were not doing this merely and solely for their own benefit. They were doing it for the benefit of the Company to meet a misfortune that had befallen the Company. They were doing what any reasonable man of business did when he lost the assets of his original capital, reducing the amount of that capital, which the Legislature expressly empowered a company to do under the circumstances. It was suggested by the other side that it was putting the money of the preference shareholders into the pockets of the ordinary shareholders. But he ventured to say it was not doing anything of the sort. It was not the money of the preference shareholders that was touched. The capital had been lost. The preference, as well as the ordinary shareholders, had lost the capital, and the former could not look on the profits of the Company as their money until that capital was replaced. It was a scheme for the benefit of all—possibly a little disagreeable to the minority—but, nevertheless, a thing done in the way in which the Legislature said it should be done. Mr. Bannatyne said, in effect, "Instead of fulfilling the terms of the bargain to which I am entitled, they propose to reduce the capital." He answered that that gentleman was not so entitled. The bargain was that they might reduce the capital in certain circumstances, and that was what they were doing. Then, as his lordship knew, the policy of reducing capital was expressly introduced by the Legislature to meet the ordinary case raised. There was really no hardship in it. A bargain had been made under the original state of the capital of the Company, and, under its present state, what they proposed doing was only what might be expected to be done.

Mr. BUCKLEY said he appeared for Sir James Anderson, the Chairman of the Company, and the other Directors, who were joint defendants in the action. The arguments which had been addressed to his lordship from the other side had, he thought, in substance proceeded upon a hypothesis in favour of the plaintiff. He had not heard any arguments from his learned friend which would amount to a determination of the point in his favour, and what he conceived his lordship would have to determine was this—whether the special resolution which created the preference shares entitled the preference shareholders to receive for all time 10 per cent. upon the total amount which they paid upon their shares, or on such sum as might for the time being be their capital in the Company. Now, they must remember the nature of the subject with which they were dealing. It was the capital of a company incorporated under certain Acts of Parliament which contained in them a power to reduce its

Digitized by Google

capital. It was a false supposition, therefore, to say that the amount of the capital was necessarily a fixed quantity. *Primâ facie* it was not a fixed quantity. It was something which was so much to-day, and which by a process of reduction might become something else to-morrow. Now, the whole of his learned friend's arguments proceeded on the hypothesis that it was a fixed quantity. His learned friend said: "There has been a fixed capital, upon which I am entitled for all time to 10 per cent. because I paid £10 for my shares." He (Mr. Buckley) denied that proposition. When Mr. Bannatyne paid £10 on his share he paid £10 as a subscription to a capital which was liable to be reduced, as might be seen from the terms of the contract. In the first place the resolution was founded upon Article 7 of the Articles of Association, and contained powers to do two things wholly different—one to give a preferential right to the dividends, and if there was not enough in one year to make it up out of the profits of subsequent years; and the other to give a priority in the distribution of the assets It was clear that they had used only the former of those powers. If that was so, so far as the capital subscribed on those shares was concerned, the matter was left to rest on Article 9, which provided that the capital should be considered as part of the original capital, because they did not find anything in the special resolutions which pointed to its being different from the original capital. That being so the capital subscribed upon the preference shares stood precisely on the same footing as the other capital, and was capable, therefore, of being reduced in common with the latter, and whatever the consequences of that reduction might be those consequences must fall equally on both. There was another way of looking at the question. His lordship knew very well that if the majority of the shareholders of the Company chose to pass resolutions winding up the Company, the assets would be distributed among the shareholders. It was not pretended that that would not be so. But in a reduction of capital his lordship would remember that the Act of Parliament provided for the satisfaction of all the debts of the creditors at that date in precisely the same way as if there were a winding up. The matter went to chambers. Every creditor was entitled to come in, and before the Court could make an order sanctioning the reduction of the capital it must be satisfied that every creditor at the date fixed had either been paid or that his claim had been provided for to the satisfaction of the Court. A reduction of capital, therefore, was in many—he would say in most respects—analogous to a winding up *pro tanto*. It was exactly the same as if a company starting with £100,000 wound itself up to the extent of £50,000; but until it could clear away its creditors it could not go on with the reduced capital. That was the nature of the scheme for a reduction of capital. Why should it not be competent to the shareholders to apply that machinery exactly in the same way as if there were a winding up? If there were a winding up in its place the loss of the capital would fall equally on all the shareholders, ordinary as well as preference. He submitted that the true view of the Act of Parliament in writing off capital, as they were entitled to by the Act of 1877, was to work the matter out in the same way as if there were a winding up of the Company. He submitted to the Court that the reduction of capital in this case was not only right, but was the only way in which it could be reduced. His learned friend's argument must go as far as this—that in a company of this kind, where a preferential right to dividend had been created, the Company had precluded itself from ever reducing capital at all; but he challenged his learned friend how it was to be done in any other way. Suppose they reduced the capital by writing off exclusively from the ordinary shares, leaving the preference untouched; in that respect his learned friend would say that would leave the preference shares unaltered. But he (Mr. Buckley) ventured to say it did not; because if six months after that the Company went into liquidation it would do so with preference shares of £10 and ordinary shares of £5, and the assets would have to be administered on that basis. No way could be pointed out in which capital could be reduced except by writing off £5 from every share equally, and he said that such a position was tantamount to saying that the Company could not reduce its capital at all. Article 10 contained an express power to reduce capital. The statutes referring to the Company conferred upon the Company, if it took power to do so, a right to reduce its capital. But his learned friend said, "You cannot reduce it because you have created a preference interest in respect of dividend." Was there any foundation or justification for such an argument as that? He found none at all. It appeared to him that his learned friend was endeavouring to construe the resolution creating preference shares—which was colourless on the point—as if it contained expressions saying that the resolution removed from the powers of the Company Article 10, which contained the powers to reduce the capital, and so impose upon the Company for all future time a veto upon ever reducing its capital. He submitted that the special resolution had no such effect as that contended for, and that the motion ought to be refused.

Mr. MARTEN, in reply, said that the arguments he had listened to had not in any way damaged the case which he had opened to his lordship. The first suggestion made by his learned friend, Mr. Rigby, was with reference to the number of shareholders voting. He did not think that there was any clear evidence what the number of votes was, so as to show any decided majority one way or the other. He submitted that the point on which he was arguing the matter was one quite independent of the numbers voting for or against. Was it not *ultra vires* to pass a special resolution, the effect of which would be to deprive the preference shareholders of a position of that for which they bargained? That was his argument, and if it was well founded it was immaterial what the number of shareholders who voted might be. He did not propose to go into that point. He apprehended there could be no question on this, that if what was being done was contrary to the bargain entered into it was *ultra vires*. Clearly Mr. Rigby agreed that the question really was whether the preference shareholders were entitled to have a fixed preference charge upon the profits. He submitted that there could be no question as to that. The resolution of 1874 expressly stated that those shares were entitled to a fixed preferential dividend of 10 per cent., and that in the event of there not being sufficient to make it up in any one year they were entitled to have it made up out of the profits of subsequent years, with interest in the meantime. That was endorsed on the certificates of shares when they went into the market. He submitted, therefore, that nothing could be clearer than the terms of that resolution. His friend, Mr. Rigby, said in the first place that several things might be done which would have the practical effect of vetoing that obligation—as, for example, that the Company could create pre-preference shares to any extent, and thus put the preference shareholders in a much less favourable position than they occupied by Article 7. His answer, of course, to that was this, that the additional capital could not be raised but in a proper case, and if it were raised, it would be for the advantage of all parties equally. There would be no advantage given to the ordinary shareholders, who would have a pre-preference capital equally with the preference shareholders. They were all familiar with the case in which everybody had to submit to the postponement of his claims for the purpose of raising further capital; but he submitted that Article 7 could not be made use of for that purpose, and write the preference shareholders out of their just claims. His friend had next referred to Article 9, which declared in plain terms that all additional shares created "shall be considered part of the original capital, and shall be subject to the same provisions in all respects as if it were part of the original capital." If the clause had stopped there, there might be a good deal to be said about that view, but it went on to add, "except so far as these Articles or the resolution authorising the raising thereof may otherwise direct." He ventured to say that that preserved intact the virtue of the resolution of 1874, and that no argument could be established by the Articles for making any difference in the contract from that which was in the plain terms of the resolution of 1874. The next argument of Mr. Rigby was this, "That the scheme is intended, not for the purpose of giving any present benefit to the ordinary shareholders at all, but it is a scheme which merely recognised in a formal manner the true facts of the case, and inasmuch as the capital to that extent has, in point of fact, according to the view taken by the Company and the Board of Directors, been really lost, we are now simply carrying into effect that which is a recognition of the actual facts of the case, and accordingly, therefore, the preference shareholders must not complain because the accident is a particular injustice to them." That was the argument put forward as he understood it. Now, the fallacy of that argument was plain. If the Company had proposed a nominal reduction of capital, the preference shareholders should still have the same amount of dividend. In that case it would be 20 per cent. on the reduced capital instead of 10 per cent. on the original capital. But there was no necessity for interfering with the preference shareholders' rights, and there was no necessity why they should resort to any reduction of capital. His lordship had only to look at the special report and circular—which was one of the first documents to which he drew his lordship's attention—and the Articles of Association and special resolution of 1874 to establish his case. That report pointed out particularly what was the nature of that which was proposed to be done? It showed that the result of writing off the nominal capital would be to give a reduced dividend to the preference shareholders, and to give a dividend at once to the ordinary shareholders. It was not, therefore, a fair way of looking at the matter to argue that it was merely a mercantile repudiation of a loss that had occurred, and that it was quite immaterial what the consequences might be to the various classes of shareholders. His argument was this, that if they proposed to take any step with regard to an alteration of the capital, that must be done with a view to the bargain already entered into being kept, and the ordinary shareholders could not at their own will put into their own pockets money which was reserved by special bargain for the preference shareholders. The Company had a plain course indicated to them, and indicated to them in the opinion of the eminent counsel (Sir Horace Davey) whose advice they took, by which after a time the capital would be restored and all the partners would have their rights again. Then it was said that it was part of the original bargain that the capital might be reduced. His answer to that was that it was no part of the original bargain that the shareholders who were preference shareholders were to be deprived of their preferential dividends. The capital might be reduced; but it must be done in accordance with the rights of the parties interested, and it could not possibly be alleged that the Company had a right to reduce the capital in such a way as would interfere with a special bargain they had made, any more than the Company when issuing debentures would have a right to say, "We will appropriate for the ordinary shareholders of the Company a portion of the money which was stipulated for by the debenture holders." The last argument of Mr. Rigby was that it was not clear that the preference shareholders would be injured. He (Mr. Marten) declined to go into an argument of that kind. There was not a tittle of evidence to show that it would not be to the injury of the preference shareholders if that course were adopted. But on the face of it it was absurd to suggest that the Company had a right to say that it had the power it sought to exercise. Mr. Rigby, in concluding, referred to the fact that there must be a petition presented to the Court for confirmation, but it would be inconvenient that the matters should be discussed on a petition, and of course now was the most convenient time, as it was the most expeditious way of disposing of the matter, and it would prevent the necessity of any petition being presented at all. His friend, Mr. Beale, in his argument addressed his lordship on this footing, that what was being done was not for the benefit of the ordinary shareholders but for the benefit of the shareholders at large. He (Mr. Marten) had dealt with that argument sufficiently in replying to the remarks of his learned friend Mr. Rigby. What was being done was specifically injurious to the preference shareholders, and was *ultra vires* in this sense, that the Company could not by any Act interfere with what was a

Digitized by Google

bargain with the preference shareholders. It was said that the preference shareholders had lost the capital as much as the ordinary shareholders. That was not a true view of the case. The preference shareholders were in this position, that they could say, "We came into this concern, and paid our money on these terms." Therefore the Company could not deal with the matter on any such footing as that. With regard to Mr. Buckley's arguments he would speak very shortly. The first contention was that the Company might wind up if they thought fit, which would alter the whole of their rights. Nobody wanted to wind up the Company. He thought that was a sufficient answer to the argument. The Company was a good one, and there was no reason to apprehend such a contingency. Mr. Buckley also said that it was a winding-up of the Company *pro tanto*. The Company was a going concern, and there was no such suggestion. The Company was intending to go on. Mr. Buckley further said that his (Mr. Marten's) argument involved this, that the Company under no circumstances could reduce their capital, because this was the only way in which capital could be reduced. There was no proof whatever that this was the only scheme that could be adopted. He gave a suggestion that might secure to the preference shareholders all their rights. What was proposed to be done would be in manifest violation of the rights of the shareholders, and he submitted that he was entitled to the injunction asked.

The VICE-CHANCELLOR said the present question seemed to have come before the Court for the first time, at all events he had never before seen a case like this. The facts of the case were very simple. A company was formed subject to Articles of Association, which empowered it to increase its capital by the issue of new shares with a preferential dividend, and also to reduce its capital. That had reference to the position of the Company as between themselves and the outside world; but what had that to do with any bargain entered into between the Company and its shareholders? The arguments which had been urged on behalf of the defendants had no application to the case before him. The Company had borrowed money from the preference shareholders on certain terms expressed in the resolutions under which the shares were issued. That was a plain contract entered into by the Company with the holders of those shares—a contract which stated that the holders should be entitled to a "fixed preferential dividend of 10 per cent. per annum." There could be no doubt whatever that under the contract between the Company and the lenders of the money, the latter on paying their £10 per share became entitled to interest on their money at 10 per cent. It was true the Companies Act, 1877, gave power to a company to reduce its capital. There might be many cases in which it was desirable that the capital should be reduced; but at the same time the Act said that care must be taken to see that the creditors were not injured by the reduction. The shareholders of a company might settle between themselves what was to be done with regard to their own shares; but what inkling was there to be found in the Act of any power on the part of a company to depart at their will from any contract they had entered into? He had not heard it suggested that a company had such power. One argument addressed to him was that this Company could, without any consent on the part of their preference shareholders, wind themselves up, when the whole thing would go by the board, and that if they wanted more money they could give a preference over the present preference shares. The power of raising new capital was to be exercised for the benefit of the existing preference shareholders. That power was to be exercised not for the purpose of adding to their loss but to protect them from further loss. The real question was whether a company, having contracted to pay a dividend at a fixed rate, could by any contrivance, whether honest or fraudulent, say "We entirely neutralise the provisions we have made; and, more than that, these profits out of which we are to make up the 10 per cent. we shall pay to the ordinary shareholders." That would be the result of what was intended to be done by this Company. There was not a suspicion of dishonesty on the part of the Directors of the Company; he himself had no such notion. But there might be a case of other Directors whose motives were not so pure as those of the Directors of this Company; and if he authorised such a transaction as this he should be opening the door to the contrivances which the purlieus of the Stock Exchange were somewhat cognisant of, and be enabling persons to form fictitious joint stock companies. They might hold out a prospect to the preference shareholders, and as soon as they got the money by means of those preference shares they might resort to some expedient to cancel or reduce the amount of the capital, and so let in the ordinary shareholders, and let them take the same share as the preference shareholders would have been entitled to if they had been paid, for all time, as long as the thing would last, good years and bad years. It would be alarming to suppose that he could allow such a state of things. He could not go into motives, and he did not. He imputed no improper motives in this case, but in another case he would not be at liberty to look into the motives of the parties, if he found the thing done formally, as it was here. The consequence of allowing a company to do such a thing as this would be to raise the value of the ordinary shares from, perhaps, a farthing apiece to the same value as the preference shares. It would be a recipe for ousting the preference shareholders for the benefit of the ordinary shareholders. The resolution authorising the issue of the preference was literally within the terms of the Articles of Association; the amount of the new capital was mentioned there, the shares were mentioned there, and the contract was evidenced there. Some other mode than that proposed might be devised for effecting the reduction of capital, but, in his opinion, this 10 per cent. dividend was secured by the resolution and the certificates of the shares themselves mentioned in the contract. If he were to assent to the arguments of the defendants, it would be a wholesale authority to deprive persons of their rights fixed by contract. In his opinion, therefore, the plaintiff was entitled to the injunction asked for.

Mr. MARTEN: Then the order will be an injunction according to the terms of the notice of motion?

The VICE-CHANCELLOR: Yes.

Mr. MARTEN: The notice of motion asks for the costs of the motion. They will follow the result. We will say an injunction according to the terms of the notice of motion until trial or further order.

The VICE-CHANCELLOR: I make no order as to costs.

In reference to the above case, we are informed that an appeal has been granted, and will come on for hearing in a few days.

Callow v. Young.

Yesterday (Thursday), in the Chancery Division of the High Court of Justice, the case of Callow *v.* Young was heard before Mr. Justice Stirling.

The plaintiff, Mr. Douglas James Callow, who carries on business under the style of F. Young and Co., at 11, Clerkenwell-green, as a telegraph, telephone, and bell case manufacturer, sought to restrain the defendant, Mr. Frederick Young, from carrying on or being directly or indirectly concerned in the business of a telegraph, telephone, and bell case manufacturer under the name or style of F. Young and Co., or to carry on or assist in carrying on, or to receive the benefit of any such business within 100 miles of the Royal Exchange, in the City of London.

Mr. Warmington, Q.C., M.P., and Mr. J. F. Oswald (instructed by Mr. Herbert F. Oddy, of 58, Lombard-street), were counsel for the plaintiff. The defendant had entered an appearance, but was not represented by counsel.

Mr. WARMINGTON, in opening the case, said that prior to the 10th of November, 1883, the defendant carried on business in co-partnership with a Mr. Heaton, at 11, Clerkenwell-green, under the style of J. Young and Co., as telegraph, telephone, and bell case manufacturers. On that date the defendant (Young) assigned his interest to a Mr. James, who, with Mr. Heaton, continued to carry on business under the style of F. Young and Co. Upon the defendant Young retiring from that business he entered into an undertaking not to carry on a similar business, either in name or style, within 100 miles of the Royal Exchange. On the 11th of September, 1884, the present plaintiff acquired the interest of Messrs. Heaton and James, and he still continued to carry it on under the style of F. Young and Co., at 11, Clerkenwell-green. Amongst the original customers of the firm was the Consolidated Telephone Construction and Maintenance Company (Limited), of Farringdon-road, from whom important orders had been received for telephone cabinet work. The plaintiff now complained that shortly after he had acquired the business of Messrs. Heaton and James, the defendant took the lease of certain premises at 21, Lloyd's-row, Clerkenwell, and he there conducted a business precisely and in all respects similar to that which he had previously carried on, and which he had undertaken to Messrs. Heaton and James not to do. The plaintiff, as the assignee of their interest, of course complained, and sought the protection of the Court by asking that a perpetual injunction should be given restraining the defendant according to the terms of his covenant. The defendant did not carry on the business at Lloyd's-row in his own name, but put forward a man named Charles Carrington as proprietor. But Carrington was only a workman who had formerly been in the employ of the defendant, and who was paid £3 per week in the new business for allowing his name to be put forward as the proprietor. The defendant by this means, and also through the intervention of a Mr. George Alanson Mason, secured orders from the Consolidated Telephone Construction and Maintenance Company (Limited), who had been customers of the old business. This was, of course, detrimental to Mr. Callow, the plaintiff, and a source of considerable loss. It was believed by the plaintiff that this Mr. Mason was now engaged in carrying on a precisely similar business with the defendant as that which the defendant had been discovered to be carrying on with Carrington. The defendant, in certain affidavits which had been filed on his behalf, had said that he had only assisted Carrington as a friend, and that he had no personal interest in the business which was being carried on at Lloyd's-row; and also that Carrington had sold the business in April last to the American Telephone Company for £385. He (the learned counsel) was in a position to be able to call Carrington, who would say that that statement by the defendant was untrue, and that every shilling of the purchase money of the business in Lloyd's-row went into the defendant's pocket. Under all these circumstances he submitted that the plaintiff was entitled to restrain the defendant from doing anything of the kind again, and also to have an inquiry of the damages which he had sustained in consequence of the defendant's conduct in commencing another business in contravention of the covenant which he had entered into with Messrs. Heaton and James.

Mr. Charles Carrington said he had formerly been employed by the defendant at 11, Clerkenwell-green, and when that business was sold to Messrs. Heaton and James, the defendant again employed him at Lloyd's-row. An arrangement was entered into by which the business was to be conducted under his name, and he was to receive £3 per week. He had sworn an affidavit in which he said that the business was really his; but that was because he was induced to do so by the defendant. When the business was sold to the American Telephone Company for £385 the defendant wrote out a receipt and witness signed it without reading it. Witness never received a single shilling of the proceeds. The witness was severely questioned by the learned judge as to his swearing the affidavit and signing the receipt in the manner in which he detailed, but the statements were strictly adhered to.

Mrs. Carrington, wife of the last witness, corroborated as to the arrangement which was made between the defendant and her husband.

A witness named Parker said that he was employed at the business at

Digitized by Google

Lloyd's row. The defendant Young acted as master of the business, and Carrington as foreman.

Mr. WARMINGTON said he had a mass of evidence, all pointing in the same direction. There were nearly fifty witnesses in Court; but he did not know whether the learned judge would require to hear them all.

The learned JUDGE said he thought that upon the evidence before him the plaintiff was entitled to a perpetual injunction.

Mr. WARMINGTON: And an inquiry of damages as well, my lord?

The learned JUDGE: Will you want that as well?

Mr. WARMINGTON: Yes, my lord. This is only the opening scene of these transactions.

A perpetual injunction was then granted, restraining the defendant his workmen, servants, or agents, from carrying on, or being interested in, the business of a telephone, telegraph, or bell case manufacturer, or any similar business, or the manufacture or sale of articles usually made or sold by makers or dealers in such business within 100 miles of the Royal Exchange, in the City of London. An inquiry of the damages sustained by the plaintiff by the defendant's previous breaches was also ordered to be instituted.

COMPANIES' MEETINGS.

Brazilian Submarine Telegraph Company (Limited).

The twenty-sixth ordinary general meeting of the shareholders in this Company was held yesterday at Winchester House, 50, Old Broad-street, under the presidency of the Right Hon. Viscount Monck.

The SECRETARY (Mr. Richard Collett) read the advertisement convening the meeting, and the minutes of the twenty-fifth ordinary general meeting, which were confirmed by the present meeting and signed by the Chairman as carried. The report of the Directors was taken as read.

The CHAIRMAN proposed the following resolution:—"That the report and accounts of the Directors to the 30th of June, 1886, now submitted, be approved and adopted, and that a dividend be now declared of 3s. per share, making, with the interim dividend already paid, a total dividend of 6 per cent., free of income tax, for the year ended the 30th June, 1886." He reminded them that the last time he addressed them he was compelled to say that the depression of trade which had prevailed for so many years, and which for a long time seemed to have spared the Company, had affected them in the way of receipts. The difference between the receipts for the quarter ended on the 30th of June this year and the 30th of June, 1885, amounted to a decrease of between £5,000 and £6,000; and he was bound to say that if it had not been for the improvement in the exchange as between this country and Brazil their loss would have been considerably larger. However, he was glad to say that they seemed to have touched bottom, because there had been a considerable increase in their receipts in the present half year, as far as they had gone, though they had reduced their tariff from 9s. to 7s. At the same time, they must not shut their eyes to the fact that though in many departments of trade they might notice an improvement, yet they could not assert positively that the depression which had so long prevailed had ceased to exist. They might, however, trust that they were turning the corner, and that their business, as well as other departments of trade, would be affected by the result. He told them at the last meeting that they were carrying on negotiations with a view to improving their position in Brazil. He asked them at that time not to call upon him to state explicitly what the nature of those negotiations was, or how far they had gone. The shareholders kindly acceded to his request, and he was sorry to say that he must still make a draft on their confidence and forbearance. It would not be for the interests of the Company that he should state at present the position of the negotiations, which, however, they hoped to bring to a successful issue. With reference to the accounts he did not think there was anything that called for observation. The general expenses were £198 less than those of the corresponding period of last year—a fact showing that, as far as possible, the Directors were consulting economy in the management of the Company's affairs. This reduction was also contemporaneous with a considerable expenditure on the renewal of houses and plant of different kinds at some of the stations.

The VICE-CHAIRMAN (Sir James Anderson) seconded the motion.

Mr. W. GRIFFITH asked what profit the Company were likely to make from their investment in the African Direct Telegraph Company. The balance-sheet, though it spoke creditably for the efforts made by the Directors, was not one which, in his opinion, gave the shareholders much encouragement for the future; and he found from official sources that, notwithstanding the great efforts of the Brazilian Government to foster private enterprise, they had had a woeful falling off in trade, and deficits for the last ten years. Though there did not seem much hope at present, it was possible that they might have something beneficial from their large investment in the Company mentioned.

The CHAIRMAN, in reply, stated that the African Direct Company's cables had only just been opened, and it would be very imprudent therefore for him to pronounce either for or against a very great traffic on that cable. Moreover, he was informed that that was just the time of the year when European people were away for their holidays, and when trade was more or less suspended. They hoped, however, that the cable might be made profitable, and he had no doubt that it would after a while.

The motion was then carried unanimously.

On the motion of the CHAIRMAN, seconded by the Hon. W. ST. JOHN BRODRICK, M.P., Dr. Taylor, who, the Chairman stated, represented the Company in Brazil, was re-elected to his seat at the Board; as was also Mr. Frederick Youle, on the motion of the CHAIRMAN, seconded by Mr. HENRY DANIEL GOOCH.

Mr. ANDERSON next proposed and Mr. C. S. HAWKES seconded the re-election for the ensuing year of the auditors, Mr. Henry Dever and Mr. John Gane.

The resolution was carried unanimously.

On the motion of Mr. HAWKES, seconded by Mr. GEORGE ANDREWS, a vote of thanks was passed to the Chairman and Directors.

The CHAIRMAN, in reply, said that the Directors were exceedingly obliged to the shareholders for the kind way in which they had treated them that day, and the confidence which they had always shown to them.

The proceedings then terminated.

Western Union Telegraph Company.

At the annual meeting of the Western Union Telegraph Company President Green submitted his report for the year ended June 30th, which shows the following results, contrasted with two previous years:—

	1883-4.	1884-5.	1885 6.
Revenue for the year	$19,632,940	$17,706,834	$16,298,659
EXPENSES—			
Operating and general expenses	$9,278,761	$8,544,554	$8,510,658
Rentals of leased lines	1,842,090	1,822,543	1.892,347
Maintenance and reconstruction	1,350,448	1,146,871	1,273,125
Taxes	301,077	301,723	499,592
Equipment of offices and wires	249,528	190,210	203,061
Total expenses	$13,022,504	$12,005,910	$12,378,783
Profits	$6,610,436	$5,700,925	$3,919,856
DISBURSEMENTS—			
For dividends	$5,599,179	$4,999,325	$3,399,573
For interest on bonds	472,350	495,072	494 461
For sinking funds	39,991	39,992	39,991
Total disbursements	$6,111,520	$5,534,389	$3,934,025
Balance of profits	$498,916	$166,536	- $14,169
Surplus July 1 (beginning of year)	$3,658,553	$4,157,469	$4,324,004
Balance of profits for year	498,916	166,535	- 14,169
Total nominal surplus June 30 (end of year)	$4,157,469	$4,324,004	$4,309,835

The following table exhibits the mileage of lines operated, number of offices, number of messages sent, receipts and profits, for the past four years:—

Year.	Miles of Poles & Cables.	Miles of Wire.	Offices. No.	Messages. No.	Receipts. $	Profits. $
1882-3	144,294	432,726	12,917	41,181,177	19,454,902	7,660,350
1883-4	145,037	450,571	13,761	42,076,226	19,632,939	6,610,435
1884-5	147,500	462,283	14,184	42,096,583	17,706,833	5,700,924
1885-6	151,832	489,607	15,142	43,289,807	16,298,638	3,919,855

The changes made in the directory were Austin Corbin, Henry B. Hyde, and John G. Moore, in the places of Harrison Durkee, Hugh J. Jewett, and Frank Work.

The Pilsen-Joel and General Electric Light Company (Limited).

An extraordinary general meeting of the shareholders of this Company was held on Tuesday at the City Terminus Hotel, Cannon-street, E.C., Sir Rawson W. Rawson, K.C.M.G., C.B., in the chair.

Mr. W. H. TRENTHAM (the secretary) read the notice convening the meeting, which stated that the meeting was called for the purpose of submitting a resolution having for its effect the reduction of the capital of the Company.

The CHAIRMAN said: Gentlemen, I hope it will not be necessary to detain you long to-day. Most of you will understand the object of our meeting, and to me it is a satisfaction at last to be able to present myself, and to offer to you an expectation of this property yielding a return to its shareholders. Hitherto my position here has not been either an acceptable one to myself or a very welcome one to you; but we fell upon hard lines at the commencement of our career. We have, however, persevered patiently, and, we hope, with a single view to the interest of our contributors; and we believe now that we see our way towards yielding a return to our shareholders — a modest one it must ever be whilst electric lighting, and lighting by arc lamps especially, is so little sought after by the public. But we have held ourselves firm during the last three years of difficulty and trial. We have maintained and established the excellence of our arc light, and whatever we have attempted of late has been carried out successfully, and, we hope to show, at a profit. And now the time has come when we may adopt the step which was referred to in our report of last year, but which we did not feel ourselves justified in then carrying out, whilst our prospects were still uncertain. "The point may present itself to shareholders that a further amount should be written off the Company's capital as lost, but although this subject has engaged the Directors' attention they have not considered any advantage would accrue from taking the step at present." Until we saw clearly the prospect of making a dividend upon our capital there was no advantage in reducing the nominal value of our concern, and incur the legal expense necessary to authorise us to reduce our capital. We do now see our way, and therefore we come to you to authorise that reduction of our capital, which by law must be effected before we can make a dividend. You are aware that in the last report the balance brought down against our capital was £22,878. Now, until that £22,878 has been recovered out of profits, we should not have been justified in making a dividend unless we reduce our nominal capital. It will not reduce the value of our property, because if we can increase our profits we shall be able to yield a larger dividend upon a smaller capital. It comes to be really as broad as it is long. We have gone through a time of storm; we

Digitized by Google

have had our sails torn and our rigging damaged—with all the other companies—we have had a time of difficulty; but we now hope to get out of it, and we believe that by throwing our dead weight overboard and by trimming our ship we shall float into smooth water, and we look forward to a favourable breeze, which will enable us to make some return to our shareholders. We propose to wipe off that £22,878 of the balance. You will see that it is actually proposed to reduce the capital by £28,000; that is a deduction from the nominal value of our patents, which, of course, has been reduced to a certain extent by the lapse of time, and more particularly our patent for incandescent lamps, which never possessed a very high value, and which at the present time may be taken at a very low rate. This will make a reduction of our capital to the extent of writing off what is unrepresented by available assets, for if they were brought into the market at the present time they would certainly not yield even the sum at which we at present state them, and we believe that the steps we are now proposing will place our concern on a sound basis, and that we shall be able to call you together, possibly in a very short time, as soon as the Court has sanctioned this proceeding, with a favourable report for the last year. I therefore beg to move the resolution that has been read:—"If an order of the Court be obtained for confirming this resolution, the capital of the Company be reduced by cancelling the sum of one pound per share on the twenty-eight thousand shares of the Company of three pounds each, with two pounds five shillings called up thereon, and the sum of one pound fifteen shillings per share on the one hundred fully paid up shares of four pounds each, as being capital which has been lost or is unrepresented by available assets, and that the Memorandum of Association of the Company be modified so as to carry into effect this resolution."

Major HORACE W. SCRIVEN seconded the resolution.

Mr. KING: I think before you ask us to support that resolution you ought to supply us with a balance-sheet and revenue account of last year's working. You are asking us to write off £28,000, and we wrote off £28,000 last year. Why should we write off £28,000 in the dark? Surely you can supply a profit and loss account. Last year you stated that:—"The Directors feel satisfied that in the new premises the profit rentals from installations, royalties from licenses, and other receipts, may be confidently expected to more than cover all the general charges of the Company, including rent of factory, staff, directors' and auditors' fees, &c., and they look to the increasing development of electric lighting as a means of improving the value of the capital invested in the Company." That report is dated November 7, 1885; we are now in November, 1886, and the shareholders will naturally look to you for some information as to whether those sanguine estimates have been realised, and if so, why should they go on writing off £28,000 from their capital?

The CHAIRMAN: But we did not write off £28,000 last year. The statement produced to that meeting left a balance against us of £22,800.

Major SCRIVEN: We are not proposing to write off any further loss; it is the loss inserted in last year's balance-sheet. We were £22,000 to the bad last year; but since then we have more than paid all expenses.

Mr. KING: Then, consider my observations unsaid.

Major SCRIVEN: Our scheme was in lieu of winding up a year ago. We were all agreed that to go on making calls on the shareholders and wasting the money would be a mistake; but we recognise the possibility of living in a quiet way in the hope that our patents may be of value some day. If we had wound up, our patents would have sold for nothing; but by going on as we have we hope, as the Chairman has said, to be able to make you a small dividend. We believe that what was a failure has been turned into a success, and we now only propose to write off the loss that was incurred up to last year. We propose to write off £28,000 instead of £22,000, so that our shares may stand at even figures.

Mr. G. L. WHATELY: The other writing off of £1 a share was when the vendors' shares were cut off. It is now proposed to cut off a further £1.

Major SCRIVEN: You will understand that at the last meeting the sum had already been lost. If we do not write off the losses any little money we may make must be written off against them before we can pay a dividend.

Mr. KING: Do I understand you to say that we have made a profit last year?

Major SCRIVEN: We have more than covered our expenses. We have done quite as well as we expected.

Mr. FYFE: You may also say that the money said to be lost last year was merely through the manner of taking the stock.

Major SCRIVEN: A great deal of loss was incurred in selling the stock.

Mr. FYFE: In reducing the capital now you say there is a prospect of paying a dividend soon.

Major SCRIVEN: I am afraid it will be a very small one.

Mr. FYFE: Possibly the smaller the better for the good health of the Company. If we pay away the capital we have now, and have to make another call of 15s., it would not be agreeable to the shareholders.

Major SCRIVEN: I should say that would be a step which would justify great complaint on the part of the shareholders, and possibly would result in the removal of this Board.

Mr. FYFE: Therefore you must be very careful what you do.

Major SCRIVEN: Perhaps you had better wait until you have our proposal before you.

Mr. FYFE: There was no reason why the balance-sheet should not be placed before us. It has been made up for some time, and it would enable the shareholders to judge whether it is wise and prudent to make this reduction. I think this should be left to the Directors. This reduction has nothing to do with the balance-sheet which has yet to be presented.

Major SCRIVEN: Well, you are able to judge, because you are in possession of the facts.

Mr. WHATELY: If you issue a balance-sheet, exhibiting a profit—that is a profit declared—you must write it off before you reduce the capital; but as it is you can reduce the capital at once.

Mr. FYFE: I think even that would be better for the Company.

Mr. WHATELY: It is after all a pure question of discretion. Any shareholder can capitalise his small dividend if he chooses.

Mr. FYFE: At the last meeting I objected to the gloomy view put before the shareholders, and I then said that you could not have lost £22,000 in working.

Major SCRIVEN: It was not actually in working. It was a loss in selling off machinery that we did not require.

Mr. FYFE: Even then I say you did not lose so much.

Major SCRIVEN: It is not there.

Mr. FYFE: It is if you take the stock properly.

Major SCRIVEN: Of course, you can take the stock on any principle you like.

Mr. FYFE: Either my stock-taking of the previous year was utterly dishonest or there has been a tremendous waste since.

Major SCRIVEN: It seems to me you are discussing last year's balance-sheet, which was fully discussed and threshed out a year ago.

A SHAREHOLDER: When this reduction is made, will the shares be treated as fully paid up?

The CHAIRMAN: No; it does not alter the condition of the shares at all, except by a reduction of the nominal capital. It still leaves a liability of 15s.; but our object is to avoid the necessity of anything of the kind. We do not intend to make another call.

Mr. FYFE: Could we not write off 5s. from the present capital, and 15s. from the capital, and make them fully paid shares?

Mr. WHATELY: You could not do that without giving notice to every creditor, and it would take you a twelvemonth to get it through. To get rid of an uncalled amount on shares is a very elaborate process.

Mr. FYFE: But you can pay your creditors.

Mr. WHATELY: You still have to go through the Court in the same way. You have to satisfy the Court. You can do that afterwards. If the shareholders express their view there is no reason, I think, why the Board should dissent from it.

After some further discussion of a desultory character between Mr. FYFE and Major SCRIVEN,

The CHAIRMAN interposed: I think our members will trust their Directors for not depreciating the value of their property as Mr. Fyfe has supposed. We do not want to make ourselves paupers. On the contrary, in the revaluation of the stock and plant we have taken the lowest terms. There is no loss in the matter necessarily. If we can sell at a better price than the stock stands at in our books, so much the better for our proprietors; but it would not be wholesome for the Company that the stock should stand in our books at a price which we do not expect to realise. We could not pay a dividend after writing off only five shillings a share. We must write off ascertained losses before we declare a dividend.

Mr. FYFE: Would the shareholders not rather get rid of the liability on their shares, and defer the payment of a dividend?

Major SCRIVEN: You can do nothing at this meeting but vote yes or no to the proposition that is put before you.

The resolution was then put and carried *nem. dis.*

A SHAREHOLDER: I really think that our shares now ought to appear as fully paid up.

Major SCRIVEN: There is no reason why it should not be done. The reason why it was not done before was that we should have the capital to call if better times came for electricity; but we should not make any calls without consulting you. If there is a better Electric Lighting Act passed, and there is a prospect that by calling up a little money we should much improve our position, we should, as matters stand, be able to do it.

The meeting then closed.
